Contents 2
Deckhouse Platform documentation 90
System requirements 90
- Deployment options 90
- Resource requirements 91
- Node requirements 94
- Network requirements 94
- Requirements for running virtual machines 95
- Access to the infrastructure 95
- Additional resources 95

Installation 95
- Installation methods 96
- Installation options 96
- Installation requirements 96
- Preparing the Configuration 96
  - Installation configuration file 96
  - Post-bootstrap script 103
- Installing 104
  - Pre-installation checks 105
  - The local deckhouse system user 109
  - Aborting the installation 109
- Installing virtualization 110
  - Placement of virtualization components across nodes 110
  - Cluster with taints on all nodes 111
- Air-gapped environment, working via proxy and using external registries 111
  - Installing from an external (third-party) registry 112
  - Nexus configuration notes 113
  - Harbor configuration notes 119
  - Manual loading of Deckhouse Platform images and vulnerability DB into a private registry 120
  - Creating a cluster and running Deckhouse Platform without using release channels 124
  - Using a proxy server 124
  - Automatic proxy variable loading for users in CLI 125
- Additional resources 126

How to configure? 126
- Deckhouse configuration 126
  - Modifying cluster configuration 127
    - Modifying protected parameters 128
      - Modifying protected parameters using dhctl 128
      - Manually changing protected parameters 129
  - Viewing current configuration 129
- Configuring the module 130
  - Enabling and disabling the module 130
- Module bundles 131
  - Things to keep in mind when working with the Minimal module set 132
  - Accessing documentation for the current version 132
- Managing placement of Deckhouse components 132
  - Advanced scheduling 132
  - Module features that depend on its type 133
- Additional resources 133

DP components registry 134
- Additional resources 134

Managing the registry in Deckhouse Platform-managed clusters 134
- Implementations of container image pull path management 134
- Current implementation 135
  - Modes of operation 135
  - Installer behavior when no container image registry is configured 136
  - Garbage collection 136
    - Running garbage collection manually 137
  - Additional container image registries 138
  - Requirements for using the current implementation 138

Examples of configuring the current implementation 138
Configuring pull path management for Deckhouse Platform component images 138
Enabling the in-cluster cache 139
Switching the cluster into an air-gapped state 140
Adding an additional container image registry 141
Pulling from a private container image registry without declaring it 141
Turning off pull path management 142
V1 implementation 142
Restrictions on Deckhouse Platform component registry settings 143
Restrictions during cluster installation 143
Operating conditions restrictions 143
Restrictions on mode switching 143
Examples of switching between the v1 implementation’s modes 143
Switching to Unmanaged mode 143
Migrating from the v1 implementation to the current one 145
Determining the migration method and steps 145
Checking which implementation the cluster uses 146
Migrating from Unmanaged mode 146
Migrating from Direct mode 146
Migrating from Proxy mode 147
Migrating an air-gapped cluster from Local mode 148
Migration to registry management format using the registry module 149
For containerd v2 149
For containerd v1 150
Migration to the deprecated registry management format (without the registry module) 154
Checking the registry mode switch status in the v1 implementation 156
Additional resources 158
Switching a Managed Kubernetes cluster to use third-party registry 158
Additional resources 160
Authentication 160
Additional resources 160
Integration with external authentication providers 161
General integration workflow 161
Limiting the identities of a provider 162
Checking provider connectivity 163
OIDC (OpenID Connect) integration 164
Keycloak 164
Blitz Identity Provider 165
Okta 166
SAML 2.0 integration 166
LDAP integration 167
GitHub integration 168
GitLab integration 169
Atlassian Crowd integration 169
Bitbucket Cloud Integration 170
Additional resources 170
Local authentication 171
Creating a static user 171
Deleting a user 172
Local user operations 172
Administrative operations 172
Self-service operations 173
Creating UserOperation manually 173
Viewing account state 174
Adding a user to a group 174
Configuring password policy 175
Configuring two-factor authentication (2FA) 176
Additional resources 176
Accessing the Kubernetes API via load balancer 176
How API access protection works in Kubernetes 177
Access using Basic Authentication (LDAP) 178
Kerberos (SPNEGO) SSO for LDAP 178

Additional resources 179
Resource configuration 180
Example configuration 180
Additional resources 181
Authorization 181
Combined use of ClusterAuthorizationRule, AuthorizationRule, and RBAC 182
Who gets access and when 182
User authentication 182
Service account authentication 182
Additional resources 185
Basic authorization model 185
High-level roles used in the basic model 186
Default access list for each high-level role 187
AuthorizationRule example 192
ClusterAuthorizationRule example 192
How rules are applied 193
Extending permissions for high-level roles 193
Additional resources 194
Granular authorization model 194
Role scopes 195
Access levels 195
Namespace roles 196
Automatic access to cluster-wide catalog resources 196
Project roles 197
System and subsystem roles 197
Access of system and subsystem roles to the namespaces of the modules 198
Who can assign roles 198
Global resource dictionaries 200
Automatic binding 200
Role model subsystems 200
How the roles are built: aggregation and capabilities 202
Creating a new subsystem role 203
Extending a custom role 204
Extending existing subsystem roles 205
Extending subsystem roles by adding a new namespace 206
Extending existing namespace roles 206
Creating a custom namespace or project role 207
Admin level restrictions and superadmin rights 208
Built-in protection mechanisms of the role model 209
Display names of roles 209
Deprecated role names 210
Custom roles of the previous scheme 211
Getting an equivalent of the basic model’s ClusterAdmin and SuperAdmin roles 211
Additional resources 212
Cluster admin access model 213
Kubeconfig files on master nodes 213
RBAC-based admin access 213
Recommended admin access 213
Root kubeconfig symlink 213
Security hardening 214
Break-glass access 214
Additional resources 214
Granting permissions to users and service accounts 214
Granting permissions using AuthorizationRule and ClusterAuthorizationRule (basic role model) 215
Granting permissions to a user within a single namespace 215
Granting permissions to a user in all namespaces 215
Granting permissions using ClusterRoleBinding and RoleBinding (granular role model) 216
Assigning cluster administrator permissions (granular role model) 216
Assigning networking administrator permissions (granular role model) 217
Granting administrator permissions to a user within a namespace (granular role model) 218
Additional resources 219

Checking user permissions 220
Quick check of a single permission 220
Checking whether a user has access 220
Getting a full permission report 221
Additional resources 222
Access for CI/CD 222
ServiceAccount 223
Prerequisites 223
Create ServiceAccount and a long-lived token 223
Grant permissions 223
Get API URL and CA certificate 224
Create kubeconfig 225
Short-lived tokens (TokenRequest) 225
Usage patterns in CI 225
Basic Auth 226
Prerequisites 226
Enable 226
Get API endpoint 226
Verification 226
Configure kubeconfig 226
Use in GitLab CI 227
Token Exchange 227
Prerequisites 227
Create DexClient 227
Create TokenExchangeProvider 228
Get Dex and API URLs 229
Grant RBAC 229
Token exchange request 230
GitLab CI 230
GitHub Actions 231
Migration from DexProvider 231
Diagnostics 232
Additional resources 233
Resource listing with access-based filtering 233
Using via Deckhouse CLI 233
Resource filtering scopes 233
Examples 233
Example of an interface query for where the user may perform actions 234
Using from your own code (HTTP API) 235
How it works 236
Aggregated APIs 237
Security model 238
Special case: namespaces 238
Special case: projects 238
Monitoring 238
Components involved 239
Additional resources 239
Integration with IaaS 240
Public cloud providers 240
Connection and authorization in Yandex Cloud 241
Preparing the environment 241
Creating a service account 241
Assigning IAM roles 242
Generating an authorization key 242
Credentials Secret 242
Checking and increasing quotas 243
Reserving a public IP 243
Additional resources 243
Layouts and configuration in Yandex Cloud 243
Layouts 243
Standard 243
WithoutNAT 245

WithNATInstance 247
Configuration 249
Configuration example 249
Network parameters and security 251
Internal node addressing 251
Assigning external IP addresses and outgoing traffic 251
DNS and DHCP settings for internal networks 252
Using pre-existing subnets 253
Additional external networks 253
Configuring security groups in Yandex Cloud 254
Configuring access via bastion host 255
Replacing the OS image 256
Additional resources 256
Storage and load balancing in Yandex Cloud 256
Storage (CSI and StorageClass) 256
Excluding unnecessary StorageClasses 257
Creating additional StorageClasses and block size 257
Setting the default StorageClass 258
Resizing a PVC 258
Load balancing 261
External LoadBalancer 261
Internal LoadBalancer 261
Service annotations 261
Using a separate target group for a NodeGroup 262
Target group health checks 263
Applying changes 263
Changing networkType does not recreate CloudEphemeral nodes 264
Integrating manually created VMs 264
Additional resources 264
Integration with Yandex Cloud services 264
Integration with Yandex Lockbox 265
Integration with Yandex Managed Service for Prometheus 267
Additional resources 268
Connection and authorization in VK Cloud 268
Layouts and configuration in VK Cloud 270
List of required OpenStack services 270
Layouts 270
Standard 270
StandardWithNoRouter 272
Simple 274
SimpleWithInternalNetwork 276
Configuration 278
Configuration examples 279
Example 1 279
Example 2 279
LoadBalancer configuration 280
IngressNginxController with a pre-created load balancer 280
IngressNginxController with a pre-allocated floating IP 280
Uploading an image to VK Cloud 281
Replacing the OS image 282
Verifying security group support by the cloud provider 282
Cinder CSI resilience during re-authentication in OpenStack 282
Configuring online volume resize 283
Using rootDiskSize 283
Disks in VK Cloud 283
rootDiskSize parameter 283
Recommendations for master nodes and bastion with network-attached disks 283
Recommendations for ephemeral nodes with local disks 284
Checking the disk size in a flavor 284
Overriding the cloud provider’s default disk type 284
Connection and authorization in Selectel Cloud 284
Layouts and configuration in Selectel Cloud 284

Recommendations 393
Additional resources 393
Virtualization systems 393
Integration with built-in virtualization 393
Load balancers 393
Load balancer network policy 394
Additional resources 394
Connection and authorization in built-in virtualization 394

- Creating a user 395
- Assigning a role 395
- Generating a kubeconfig 395
- Credentials Secret 396

Layouts and configuration in built-in virtualization 396
- Standard 396
- Configuration 398
- Replacing the OS image 400
- Additional resources 401

Connection and authorization in VMware Cloud Director 401
- Resource preparation 401
  - User permissions 401
  - Adding a network 404
  - DHCP setup 407
  - Adding a vApp 409
  - Adding a network to a vApp 410
  - Incoming traffic 412
  - Configuring DNAT/SNAT rules on the Edge Gateway 412
  - Let’s Encrypt certificate issuance 413
  - Firewall setup 413
- Virtual machine template 415
  - Preparing the template from an OVA file 416
  - Configuring the template in VCD 420
  - Replacing the OS image 425
- Storage usage 426
- Using the LoadBalancer 426
- Additional resources 426

Layouts and configuration in VMware Cloud Director 426
- List of required VMware Cloud Director services 426
- Layouts 426
  - Standard 426
  - WithNAT 427
- Configuration 430
  - Example configuration of VCDInstanceClass 431
  - Storage 431
    - CSI 431
- Additional resources 431

Connection and authorization in VMware vSphere 432
- Requirements 432
  - VM image requirements 432
  - Preparing the virtual machine image 432
  - Replacing the OS image 433
- vSphere configuration 433
  - Configuration in vSphere Client 433
    - Creating tags and tag categories in vSphere Client 433
    - Configuring Datastore in vSphere Client 436
    - Creating and assigning a role in vSphere Client 437
  - Configuration with govc 438
    - Installing govc 438
    - Creating tags and tag categories with govc 438
    - Datastore configuration with govc 439
    - Creating and assigning a role with govc 439
- Additional resources 440

Layouts and configuration in VMware vSphere 440
- Standard 440
- List of required privileges 442
- Additional resources 445

Storage and load balancing in VMware vSphere 445
- Storage 445
  - Resizing a volume (PVCs) 445
- Load balancing 445
- CSI 446

- Important information on PVC size expansion 446
- Datastore configuration 446
- Additional resources 446
- Integration with VMware vSphere services 446
- vSphere resource management 447
  - Removing CloudPermanent nodes in vSphere 447
    - Reducing the number of nodes 447
    - Completely removing a node group 447
- Additional resources 448
- Connection and authorization in zVirt 448
- Requirements 448
- User permissions 449
- Preparing a cloud image 449
- Preparing a virtual machine template 450
- Replacing the OS image 452
- Credentials Secret 452

  - Virtual machine disks 457
- Load balancing 457
- Additional resources 458
- Integration with zVirt services 458
- Key features 458
- Additional resources 458
- Hybrid clusters 458
- NodeGroup types 458
- Ways to add nodes 459
- General network requirements 459
- Additional resources 459
- Hybrid cluster with Yandex Cloud 459
- Prerequisites 459
- Adding automatically created nodes 460
- Adding manually created nodes through a bootstrap script 463
- Additional resources 465
- Hybrid cluster with VCD 465
- Prerequisites for VCD 465
- Adding automatically created nodes 465
- Adding manually created nodes through a bootstrap script 466
- Additional resources 468
- Hybrid cluster with vSphere 468
- Prerequisites for vSphere 468
- Adding automatically created nodes 468
- Adding manually created nodes through a bootstrap script 470
- Additional resources 472
- Hybrid cluster with built-in virtualization 473
- Prerequisites 473
- Adding automatically created nodes 473
- Adding manually created nodes using a bootstrap script 477
- Additional resources 478
- High reliability and availability 479
- Additional resources 479
- Recommendations for configuring cluster nodes and preventing overload 479
- Master nodes 479

- Frontend nodes 479
- Monitoring nodes 480
- System nodes 480
- Preventing Kubernetes API overload (FlowSchema) 480
- Delaying node reboot or shutdown while critical pods are running 480
  - Enabling a node shutdown delay 480
  - Searching pods that prevent shutdown and performing the node troubleshooting 481
- Additional resources 481

Managing HA mode 481
- Enabling HA mode globally 482
  - Using ModuleConfig/global custom resource 482
  - Using Deckhouse web UI 482
- Configuring HA mode with two master nodes and an arbiter node 482
  - Configuring in a cloud cluster 482
  - Configuring in a static cluster 484
- Enabling HA mode for individual components 484
- Additional resources 485

Chaos engineering 485
- Additional resources 486

Virtual machine fault tolerance and balancing 486
- VM rebalancing 486
- Diagnosing a slow VM 487

Platform scaling and node management 488

General management and configuration of the control plane 489
- Main features 489
- Enabling, disabling, and configuring the module 489
  - Enabling / disabling 489
  - Configuration 490
  - Checking DP status and queues 490
- Certificate management 491
  - PKI management 491
  - Additional SANs and auto-update 491
  - Kubelet certificate rotation 491
  - Manual renewal of control plane certificates 492
- Speeding up pod restarts after losing connection to a node 492
- Forcibly disabling IPv6 on cluster nodes 493
- etcd periodic defragmentation configuration 493
- Additional resources 494

Control plane recovery and debugging 494
- Recovery from failures 494
- Restoring etcd cluster functionality 494
- Restoring a master node when kubelet fails to load control plane components 494
  - containerd 495
- etcd restore 495
  - Viewing etcd cluster members 495
    - Option 1 495
    - Option 2 495
  - Restoring the etcd cluster in case of complete unavailability 495
  - Recovering etcd after panic: unexpected removal of unknown remote peer error 496
  - Actions to take when etcd database exceeds quota-backend-bytes limit 496
- etcd defragmentation 497
  - How to defragment an etcd node in a single-master cluster 498
  - How to defragment etcd in a cluster with multiple master nodes 499
- High availability 501
- Additional resources 501

Scaling and changing master nodes 501
- Scaling and single/multi-master transition 501
  - Control plane operation modes 502
  - Automatic scaling of master nodes 502
  - Common scaling scenarios 502

Removing the master role from a node without deleting the node itself 503
Changing the OS image of master nodes in a multi-master cluster 503
In a cloud cluster 504
In a static cluster 505
Changing the OS image in a single-master cluster 507
In a cloud cluster 507
In a static cluster 507
Adding master nodes to a static or hybrid cluster 507
Adding master nodes in a cloud cluster 508
Reducing the number of master nodes in a cloud cluster 510
Accessing the DP controller in a multi-master cluster 511

Network policies 649
- Network policy implementation in DP 649
- What is available in each engine 649
- Network infrastructure requirements 650
- Sections 650
- Additional resources 650

Kubernetes NetworkPolicy 650
- Isolation model 650
- Selectors and fields 651
  - AND vs OR in selectors 652
  - Selecting a namespace by name 652
  - Port ranges 652
- Default policies for a namespace 652
- Edge cases 653
  - hostNetwork pods 653
  - Pod lifecycle 653
  - Existing connections 653
  - L4 only 653
- Enforcement without Cilium: the network-policy-engine module 653
- API limitations 654
- Additional resources 654

CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy 654
- How rules are evaluated 654
- What CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy add 654
- Resource structure 655
  - Egress to a Kubernetes service 655
- Entities 656
- L4 rules: ICMP and SNI 656
  - ICMP and ICMPv6 656
  - TLS Server Name Indication (SNI) 657
- L7 rules 657
  - Kafka 658
  - DNS Policy and IP Discovery 658
- FQDN rules 659
- Deny rules 659
- Default policies via CiliumNetworkPolicy 660
- Audit mode (policyAuditMode) 660
- Additional resources 661

Host firewall on nodes 661
- How a host firewall differs from regular policies 661
- Safe rollout 661
- Mandatory rules 662

Example: API server access for the control plane 662
Example: SSH from administrative networks 662
Example: baseline for worker nodes 663
Additional resources 663
Common policy examples 663
Deny all external ingress to a namespace, allow internal traffic 664
Allow ingress from a specific namespace 664
Allow egress to DNS and one CIDR only 664
Allow specific pods to reach the API server 665
Allow only GET requests to an API at L7 665
Allow egress to specific DNS names (FQDN) 666
Deny access to the cloud metadata service 667
Additional resources 667
Diagnostics and observability 668
Inspecting an applied policy 668
Observability via Hubble 668
Continuous flow logs collection 669
Diagnosing FQDN rules 669
Common mistakes 669
DNS broken after default-deny egress 669
AND vs OR mixed up 669
Policy does not apply to hostNetwork pods 670
FQDN rule does not allow traffic 670
Connection drops after a policy change 670
“Policy not applied” checklist 670

Frequently Asked Questions 2203

- Common 2203
  - How can I apply an update for a specific module immediately? 2204
  - How can I apply an update DP immediately, bypassing update windows, canary releases, and manual update mode? 2204
  - What to do if, with VPN enabled, the container with the installer cannot access the network? 2204

How do I change the release channel for a module? 2205
How do I configure an external module to update to patch versions only? 2206
What should I do if the module image did not download and the module did not reinstall? 2207
Cluster and Infrastructure 2208
What to do if you encounter problems updating Kubernetes components on cluster nodes, synchronizing nodes, or applying NodeGroup Configuration? 2208
How to migrate node groups to Cluster API (CAPI)? 2209
What to do if problems adding a node to the cluster via Cluster API Provider Static are present? 2210
How do I replace the OS image in a cloud cluster? 2210
Requirements for the new image 2212
Changing the image in the configuration 2213
Applying the changes 2215
How to change the instance type for nodes with the CloudPermanent type? 2216
How to migrate a cloud provider to ModuleConfig-based configuration? 2218
How to migrate 2218
How to delete the legacy secret 2219
What to do if it takes a long time to switch to custom nodes in lower-priority groups? 2220
If you encounter issues with node ordering in a cluster with a single node group 2221
Example of the node ordering process with default settings 2221
What to do if the resources generated by an object are not created after adding the object? 2222
Deckhouse 2223
How can I check DP versions available in different release channels? 2223
How to check the job queue in Deckhouse? 2223
How to check the status of all Deckhouse task queues? 2223
How to view the status of the main task queue? 2224
What should I do if DP is not receiving updates from the configured channel? 2224
Example DNS settings that may cause issues resolving the DP image registry IP address 2224
Does Deckhouse support realtime (rt) and low-latency Linux kernels? 2225
How can I know when a new DP version is available for the cluster? 2225
How can I receive information about upcoming updates in advance? 2225
How can I tell that the update was successful? 2225
If something goes wrong 2226
How can I tell that an update is in progress? 2226
What to do if there are problems updating DP? 2226
Deckhouse Platform update fails, one or more Deckhouse pods are in an unworkable state 2226
DP update is stuck in the Release is suspended status 2227
IAM 2227
What to do if there are problems applying DexProvider settings? 2227
Kubernetes and Scheduling 2228
What to do when the API server is overloaded? 2228
How to check the Kubernetes version in use? 2228
Network 2229
Is the ingress-nginx module supported? Will it affect passing a PCI DSS audit? 2229
Virtualization 2229
How to use Ansible to provision virtual machines? 2229
How to automatically generate inventory for Ansible? 2230
How to use cloud-init to configure virtual machines? 2230
Updating and installing packages 2230
Creating a user 2231
Creating a file with required permissions 2231
Configuring disk and filesystem 2231
Configuring network interfaces for additional networks 2232
How to increase the DVCR size? 2233
How to change the DVCR StorageClass when a PVC already exists? 2234
How to install an operating system in a virtual machine from an ISO image? 2235
How to create a golden image for Linux? 2237
How to restore the cluster if images from registry.deckhouse.io cannot be pulled after a license change? 2239
How to redirect traffic to a virtual machine? 2240
Why is only one connection method available for a virtual machine? 2241
Why does VNC not work when the serial console is available? 2241

Why does the serial console not work when VNC is available? 2241
How to provide a Windows answer file (Sysprep)? 2242

FAQ 2367
How do I configure alternative security policy management solutions? 2367
How do I configure policy selectors? 2367

When to use labelSelector 2368
Can matchNames and labelSelector be used together? 2368
Typical scenarios 2368
How do I extend Pod Security Standards policies? 2370
How to allow some Pod Security Standards policies without disabling whole list? 2371
What if there are multiple policies (operational or security) that are applied to the same object? 2373
Why is an Assign or AssignMetadata mutation rejected or silently ignored? 2374
How to apply a mutation only when a resource is created? 2375
Verification of image signatures 2375
How to block deleting a node without a label 2375
How to deny kubectl exec and kubectl attach to specific Pods? 2376
Built-in policy for finalizers 2377
Custom policy example 2377
How do I restrict GPU resource usage in namespaces? 2378
What to do if the validating webhook is unavailable? 2379
The cert-manager module 2379
Features of the cert-manager module (with the changes made) 2380
Restricting ClusterIssuers for projects 2380
Monitoring 2380
Module roles 2380
Third-party components 2380
Configuration 2380
Parameters 2382
Custom Resources 2389
Usage 2389
An example of provisioning a certificate 2389
Issuing a DNS wildcard certificate using Cloudflare 2389
Issuing a DNS wildcard certificate using Route53 2390
Issuing a DNS wildcard certificate using Google 2391
Issuing a DNS wildcard certificate using Yandex Cloud DNS 2392
Issuing a self-signed certificate 2393
FAQ 2393
What types of certificates are supported? 2393
How to add an additional ClusterIssuer? 2393
When is an additional ClusterIssuer required? 2393
How to add an additional ClusterIssuer using Let’s Encrypt and DNS-01 verification method? 2394
How to add an additional Issuer and ClusterIssuer using HashiCorp Vault to issue certificates? 2394
How to add ClusterIssuer using its own or intermediate CA to to issue certificates? 2395
How does cert-manager work behind a proxy server? 2396
How to secure cert-manager credentials? 2397
Does the tls-acme annotation work? 2398
How do I check the certificate status? 2399
How do I get a list of certificates? 2400
The “CAA record does not match issuer” error 2400
What to do if the HTTP-01 self-check never completes? 2400
The chrony module 2401
How it works 2401
Boot-time synchronization on master nodes 2401
Limitations 2402
Third-party components 2402

Managing nodes: FAQ 3194
How do I add master nodes to a cloud cluster? 3194
How do I reduce the number of master nodes in a cloud cluster? 3194
Static nodes 3194

How do I add a static node to a cluster (Cluster API Provider Static)? 3194
How do I add a batch of static nodes to a cluster manually? 3195
How do I clean up a static node manually? 3196
For all nodes except the control-plane 3197
For control-plane nodes 3197
Can I delete a StaticInstance? 3197
How do I change the IP address of a StaticInstance? 3198
How do I migrate a manually configured static node under CAPS control? 3198
Why are the SSH key and the sudo password of SSHCredentials shown as <omitted>? 3198
How do I change the NodeGroup of a static node? 3198
How to clean up a node for adding to the cluster? 3199
How do I know if something went wrong? 3199
How do I know what is running on a node while it is being created? 3199
How do I update kernel on nodes? 3200
Debian-based distros 3200
CentOS-based distros 3200
NodeGroup parameters and their result 3201
How do I redeploy ephemeral machines in the cloud with a new configuration? 3202
How do I allocate nodes to specific loads? 3202
How do I give pods dedicated CPUs and NUMA alignment? 3202
Rules of the Restricted and SingleNumaNode policies 3204
Changing the settings 3204
Limitations 3204
How to allocate nodes to system components? 3205
Frontend 3205
System components 3205
How do I speed up node provisioning on the cloud when scaling applications horizontally? 3205
How do I disable machine-controller-manager/CAPI in the case of potentially cluster-damaging changes? 3205
How do I restore the master node if kubelet cannot load the control plane components? 3206
containerd 3206
How to change CRI for NodeGroup? 3206
Why might the CRI change not apply? 3207
How to change CRI for the whole cluster? 3207
How to add node configuration step? 3208
How to automatically put custom labels on the node? 3208
How to deploy custom containerd configuration? 3209
How to add configuration for an additional registry? 3210
Old Method 3211
How to add additional registry auth (deprecated method)? 3211
How to configure a certificate for an additional registry (deprecated method)? 3212
How to add TLS skip verify (deprecated method)? 3213
How to set up a mirror for public image registries (deprecated method)? 3214
New Method 3215
How to add additional registry auth (actual method)? 3216
How to configure a certificate for an additional registry (actual method)? 3217
How to add TLS skip verify (actual method)? 3217
How to set up a mirror for public image registries (actual method)? 3218
How to use NodeGroup’s priority feature 3219
How to interpret Node Group states? 3220
How do I make werf ignore the Ready conditions in a node group? 3222
What is an Instance resource? 3222
When is a node reboot required? 3222
How to enable a delay before a node shutdown or restart while critical pods are running on it? 3222
Searching pods that prevent shutdown and performing the node troubleshooting 3223
How do I set up fencing for a node group? 3223
How do I check the fencing state of the nodes? 3224
What happens when the fencing agent restarts? 3225
What are the limits of softdog? 3225
Deckhouse Engine nodes 3225
How does fencing work on master nodes? 3225

- Fencing in a cluster with one master node 3225
- Which network ports does fencing need? 3226
- What does the D8FencingSystemNetworkNotFound alert mean? 3226
- How does fencing protect the network key? 3226
- How do I rotate the fencing network key? 3226
- How the fencing mechanism handles different node types? 3227
  - When the controller sets the taint 3228
  - Phases of a fencing incident 3229
  - Fencing alerts 3229
  - Known limitations of the evacuation 3230
- What to do with the out-of-service taint before you turn fencing off in all node groups? 3231
- How do I work with GPU nodes? 3231

Deckhouse Platform documentation

Download PDF

Welcome to the Deckhouse Platform documentation homepage. Deckhouse Platform is an AI-driven platform for building hybrid distributed infrastructure.

Here you can find information about installing, configuring, and using the platform, as well as descriptions of its features, components, and modules.

If you are new to Deckhouse Platform, we recommend starting with the “Getting Started” section, which provides step-by-step instructions for deploying the platform on any infrastructure.

To quickly find the information you need:

- Use search if you are looking for a specific Deckhouse Platform feature, parameter, or resource.
- Go to the list of modules if you are looking for information about a specific module.
- Use the sidebar to navigate through the documentation sections.

The content of the Deckhouse Platform documentation may vary depending on the version. Select the required version from the drop-down list at the top of the page. The list contains currently supported documentation versions.

If you need help:

- Ask a question in the “Deckhouse | EN-community” Telegram channel.
- If you use a commercial edition of Deckhouse Platform, contact technical support at `support@deckhouse.io`.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

System requirements

This page describes the requirements for cluster nodes and the environment that must be met before installing Deckhouse Platform.

Before the installation, check the following:

- The deployment option is chosen: how many nodes the cluster has, how roles are distributed between them, and whether the cluster tolerates a node failure.
- Nodes have the CPU, memory and disks from the tables for the chosen deployment option and workload type: running containers, running virtualization or combined workloads.
- Nodes have fast disks (400+ IOPS), and the disk layout follows the disk layout and size recommendations.
- Nodes meet the node requirements: CPU architecture, operating system, kernel version and installed software.
- For an installation into an existing Kubernetes cluster, its version is in the list of supported Kubernetes versions, and the node OS is in the list of supported OS.
- The network between nodes meets the network requirements: nodes have permanent IP addresses, the required ports are open, latency between master nodes is within limits, and a domain for the platform web interfaces is prepared.
- If the cluster will run virtual machines, nodes and the infrastructure meet the requirements for running virtual machines.
- There is access to the infrastructure: to the container image registry, to nodes over SSH or to the cloud provider API, and the installer host is ready to run the installation.

Deployment options

The deployment option defines how many nodes the cluster has, how roles are distributed between them, and whether the cluster tolerates a node failure.

A cluster can have nodes of the following types:

- **Master nodes** — nodes that run the control plane components and manage the cluster.
- **Worker nodes** — nodes for the user workload: containerized applications and virtual machines.
- **System nodes** — nodes for Deckhouse Platform modules.
- **Frontend nodes** — nodes that balance incoming traffic. Ingress controllers run on them.
- **Monitoring nodes** — nodes for Prometheus, Grafana and other monitoring components.

For details on configuring nodes of each type, see Things to consider when configuring in the “Going to production” guide.

Examples of deployment options:

- **Single-node cluster** (Single Node / Edge). One node performs all roles: it runs the control plane, Deckhouse Platform modules and the user workload. This option suits getting acquainted with the platform, test environments and edge scenarios.

  > ⚠ A single-node cluster is not fault-tolerant. Do not use it in production environments.

- **Single-master cluster**. One master node manages the cluster, and the user workload runs on one or more worker nodes. Some Deckhouse Platform components also run on worker nodes. This option suits small projects with a low load. The cluster is not fault-tolerant: if the master node fails, the entire cluster is affected.
- **High-availability (HA) cluster with three master nodes**. The control plane is distributed across three master nodes and keeps working if one of them fails: the two remaining nodes keep the quorum. The user workload can run on master nodes or on dedicated worker nodes. This is the recommended option for production environments. To provide high availability with limited resources, you can use an arbiter node instead of one of the master nodes.
- **Cluster with role separation**. The control plane runs on three dedicated master nodes, Deckhouse Platform modules run on system nodes, and Ingress controllers run on frontend nodes. The user workload runs only on worker nodes and is isolated from system components. In loaded clusters with a large volume of metrics, monitoring components are moved to dedicated monitoring nodes; without them, they run on system nodes. This option suits large and loaded clusters.

The node resource requirements for these options are listed in the Resource requirements section.

Resource requirements

Resource requirements depend on the deployment option and on the solution you choose for the infrastructure tasks (running containers, virtual machines, or both containers and virtual machines).

> **i** The requirements below are given per node and cover only the load of system components. Allocate resources for the user workload in addition to them.

When choosing resources, consider the following:

- The values are calculated for an installation with the `Default` module bundle.
- The values in the “Disk, GB” column include 100 GB for system PVCs (of the `prometheus`, `upmeter` modules and others) on the node’s local disk. If system PVCs are stored in an external storage, this space is not needed on the node.
- The values in the “Disk, GB” column for master nodes do not include the store of the in-cluster cache of the `registry` module. If the cache is enabled (`storage.cache`), each master node additionally needs space for `storage.size` plus the reserve the store leaves free for the node. Preferably, give the store a separate disk of that size mounted at the store directory: on a disk shared with etcd, etcd slows down while the cache is being filled (see “Disk layout and size” and the `registry` module documentation).
- On every worker node, reserve at least 1 CPU and 2 GB of memory for system services (`kubelet`) and system pods.
- For all nodes, use fast disks with performance of at least 400 IOPS.
- An arbiter node in an HA cluster with two master nodes needs at least 2 CPU, 4 GB of memory and 8 GB of disk for etcd. For details, see the Configuring HA mode with two master nodes and an arbiter node section.

For details on resource planning, see the guides:

- Picking resources for a bare metal cluster;

- Disk layout and size;
- Going to production.

Select an option depending on the goals of the Deckhouse Platform deployment:

- For containers
- For virtualization
- For combined workloads

The table lists the Deckhouse Platform resource requirements for running containers, depending on the deployment option:

Cluster configuration	Node type	Number of nodes	vCPU	RAM, GB	Disk, GB
All-in-one cluster where a single node performs both master and worker roles	Master node	1	12	24	350
Cluster with one master node and one or more worker nodes	Master node	1	8	16	150
	Worker node	1+	8	16	250
High-availability cluster with three master nodes	Master node	3	6	12	150
Cluster with role separation: dedicated master, worker, system, frontend and monitoring nodes	Master node	3	6	12	60
	Worker node	1+	2	4	60
	System node	2+	2	4	100
	System node (applied if there are no dedicated monitoring nodes)	2+	6	12	300
	Frontend node	2+	2	4	60
	Monitoring node	2+	4	8	200

The table lists the Deckhouse Platform resource requirements for running virtual machines, depending on the deployment option:

Cluster configuration	Node type	Number of nodes	vCPU	RAM, GB	Disk, GB
All-in-one cluster where a single node performs both master and worker roles	Master node	1	16	32	450
Cluster with one master node and one or more nodes intended for running virtual machines	Master node	1	8	16	150
	Virtual machine node	1+	12	24	350

Cluster configuration	Node type	Number of nodes	vCPU	RAM, GB	Disk, GB
High-availability cluster with three master nodes	Master node	3	8	16	200
Cluster with role separation: dedicated master, virtual-machine, system, frontend and monitoring nodes	Master node	3	6	12	60
	Virtual machine node	1+	4	8	120
	System node	2+	4	8	100
	System node (applied if there are no dedicated monitoring nodes)	2+	8	16	300
	Frontend node	2+	2	4	60
	Monitoring node	2+	4	8	200

Also consider the requirements for running virtual machines.

The table lists the Deckhouse Platform resource requirements for combined workloads (running containers and virtual machines), depending on the deployment option:

Cluster configuration	Node type	Number of nodes	vCPU	RAM, GB	Disk, GB
All-in-one cluster where a single node performs both master and worker roles	Master node	1	16	32	450
Cluster with one master node and one or more nodes intended for running containers or virtual machines	Master node	1	8	16	150
	Worker or virtual machine node	1+	12	24	350
High-availability cluster with three master nodes	Master node	3	8	16	200
Cluster with role separation: dedicated master, worker, virtual-machine, system, frontend and monitoring nodes	Master node	3	6	12	60
	Worker node	1+	2	4	60
	Virtual machine node	1+	4	8	100
	System node	2+	4	8	100
	System node (applied if there are no dedicated monitoring nodes)	2+	8	16	300
	Frontend node	2+	2	4	60

Cluster configuration	Node type	Number of nodes	vCPU	RAM, GB	Disk, GB
	Monitoring node	2+	4	8	200

Also consider the requirements for running virtual machines.

Before the installation, the installer checks that the server (VM) for the first master node has the minimum resources. These values are lower than those in the tables: they are enough for the installation to start, but not for running the cluster under load.

Minimum resources checked by the installer...

The server (VM) for the first master node must have:

- At least 4 CPU cores (at least 2 CPU cores with the `Minimal` module bundle).
- At least 8 GB of RAM (at least 4 GB with the `Minimal` module bundle).
- At least 50 GB of disk space with 400+ IOPS performance.

The other installer checks are described in the Pre-installation checks section.

Node requirements

The servers (VMs) for cluster nodes must meet the following requirements.

Hardware:

- **CPU architecture** — `x86_64` on all nodes.
- **Identical nodes** — all nodes of the same type have the same configuration: the same make and model with the same CPU, memory and storage.
- **Network interfaces** — each node has at least one network interface for the routed network.

Operating system and software:

- An OS from the list of supported ones or a compatible one is installed.
- Linux kernel version 5.8 or newer.
- One of the package managers is installed: `apt`, `apt-get`, `yum`, or `rpm`. For RED OS, `yum` and `which` are installed (they may be missing by default).
- Access to standard OS package repositories for installing dependencies.
- Python and the `sudo` command are available: the installer needs them.
- The hostname is unique within the cluster and meets the Kubernetes requirements: no more than 63 characters, lowercase letters only, hyphens and periods are allowed but not at the beginning or end of the name.
- The node resolves its own hostname, and `localhost` resolves to `127.0.0.1`.
- The system time is correct.
- The node has no container runtime of its own (for example, containerd or Docker) and no Kubernetes components.
- The local `deckhouse` user and group are either absent or have UID and GID `64535`, and the user has no `sudo` privileges. For details, see the The local deckhouse system user section.
- **When using `ContainerdV2`** as the default container runtime on cluster nodes:
  - Support for `CgroupsV2`.
  - Systemd version `244` or newer.
  - Support for the `erofs` kernel module.
  - The Linux kernel version is not in the 6.12.0–6.12.28 or 6.14.0–6.14.6 ranges (these versions are affected by the CVE-2025-37999 vulnerability in EROFS).

The installer checks these requirements before the installation starts. The full list of checks is given in the Pre-installation checks section.

If security policies or security scanners apply to the nodes, take into account the sysctl parameters that the platform sets on nodes and the directories used by the platform.

Network requirements

The following requirements apply to the network between cluster nodes:

- Nodes can reach each other over the network. There are no MTU requirements.
- Each node has a permanent IP address. If a DHCP server assigns the addresses, configure it to assign a fixed address to each node. Changing the IP address of a node is undesirable.
- Master nodes can access external time sources via NTP. The other nodes synchronize time with master nodes, but can also use other time servers (the `ntpServers` parameter).
- If the infrastructure restricts network interaction, the ports from the tables in the Network interaction of the platform components section are open between nodes.

- The sum of the round-trip time (RTT) and jitter between the servers for master nodes and arbiter nodes does not exceed 100 ms, or 50 ms when planning the cluster. For details, see the Requirements for network latency between master nodes section.
- A domain for the platform web interfaces is prepared; it is set in the DNS name template: a wildcard record pointing to the Ingress controller, or an A or CNAME record for every name from the list of reserved DNS names.

Requirements for running virtual machines

⚠ Nodes that run virtual machines have to be physical servers (bare metal). Installation on virtual machines is allowed for demonstration purposes only, requires nested virtualization to be enabled, and isn't covered by technical support.

Nodes and infrastructure for running VMs have to meet additional requirements. Take them into account when planning the cluster, because some settings can't be changed after the installation:

- A CPU supporting Intel-VT (VMX) or AMD-V (SVM) instructions, with hardware virtualization enabled in the BIOS/UEFI settings.
- The same Linux kernel version on all cluster nodes.
- Astra Linux nodes require Astra Linux version 1.8.3 or later: earlier versions contain a bug that interferes with virtualization.
- One or several supported storages in the cluster. Also set the default StorageClass.
- The subnets that VMs will get IP addresses from (set in the `virtualMachineCIDRs` parameter) must not overlap the pod (`podSubnetCIDR`) and service (`serviceSubnetCIDR`) address spaces.

A cluster with virtualization is designed to run up to `1000` nodes and up to `50000` virtual machines.

Access to the infrastructure

The installation requires the following access:

- Access to the Deckhouse Platform container image registry: the public one (`registry.deckhouse.io` or `registry.deckhouse.ru`) or its mirror.
- For an installation on bare metal (including a hybrid cluster) or in an unsupported cloud — access to nodes over SSH with a key.
- For an installation of a hybrid cluster — network connectivity between the sites according to the general network requirements for hybrid clusters.
- For an installation in a supported cloud — quotas for creating resources and the cloud infrastructure access parameters. They depend on the provider and are described in the Infrastructure integration section.
- For an installation into an existing Kubernetes cluster — access to the Kubernetes API of the cluster from the installer host with administrator rights (kubeconfig). Installation directly from a master node is not supported.
- On the host that runs the installer — a container runtime for running the installer container, access to the container image registry, and network access to the master node server on port `22/TCP`.

The requirements for the bastion host and the image registry in an air-gapped environment are listed in the Installing Deckhouse Platform in an air-gapped environment guide.

- Getting started
- Disk layout and size
- Going to production
- Installing Deckhouse Platform in a private environment
- Supported Kubernetes and OS versions
- Network interaction of the platform components

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Installation

> **i** Step-by-step installation instructions are available in the Getting started section.

This page provides an overview of installing Deckhouse Platform.

Installation methods

You can install Deckhouse Platform using a CLI installer, which is available as a container image and based on the dhctl utility.

Installation options

You can install Deckhouse Platform in the following ways::

- **In a supported cloud.** The installer automatically creates and configures all required resources (including virtual machines, network objects, etc.), deploys a Kubernetes cluster, and installs Deckhouse Platform. A full list of supported cloud providers is available in the Integration with IaaS section.
- **On bare-metal servers (including hybrid clusters) or in unsupported clouds.** The installer configures the servers or virtual machines specified in the configuration, deploys a Kubernetes cluster, and installs Deckhouse Platform. Step-by-step instructions for bare metal are available in Getting started → Deckhouse Platform for bare metal.
- **In an existing Kubernetes cluster.** The installer deploys Deckhouse Platform and integrates it with the current infrastructure. Step-by-step instructions for an existing cluster are available in Getting started → Deckhouse Platform in existing cluster.

Installation requirements

Before starting the installation, review the Deckhouse Platform deployment scenarios and installation requirements in the “System Requirements” section.

Preparing the Configuration

Before installation, you need to prepare the installation configuration file and, if needed, a post-bootstrap script.

Installation configuration file

The installation configuration file is a set of YAML documents that contains Deckhouse Platform settings and manifests for cluster objects and resources to be created after installation. The configuration file is used by the CLI installer and is passed via the `--config` parameter (see below).

Required and optional objects/resources that may be needed in the installation configuration file:

1. InitConfiguration (**required**): Initial configuration parameters necessary to start Deckhouse Platform.

   > **i** Starting with Deckhouse Platform 1.75, use the ModuleConfig `deckhouse` to configure access to the Deckhouse Platform container registry. Configuring access with InitConfiguration (via `imagesRepo`, `registryDockerCfg`, `registryScheme`, and `registryCA` parameters) is considered a legacy method.

2. ClusterConfiguration: General cluster parameters, such as Kubernetes (control plane components) version, network settings, CRI parameters, etc. **Required**, except when Deckhouse Platform is installed into an already existing Kubernetes cluster.
3. StaticClusterConfiguration: Parameters for a cluster deployed on bare-metal servers (including hybrid clusters) or in unsupported clouds. **Required**, except when Deckhouse Platform is installed into an already existing Kubernetes cluster.

   To add worker node groups (the NodeGroup object), you may also need StaticInstance and SSHCredentials.
4. `<PROVIDER>ClusterConfiguration`: Parameters for integration with a cloud provider. **Required** when integrating Deckhouse Platform with a supported cloud infrastructure.

> **i** The DVPClusterConfiguration, YandexClusterConfiguration, and ZvirtClusterConfiguration resources are deprecated. The parameters for integration with built-in virtualization, Yandex Cloud, and zVirt are set in the ModuleConfig of the `cloud-provider-dvp`, `cloud-provider-yandex`, and `cloud-provider-zvirt` modules and in the related resources. These resources are described in Layouts and configuration in built-in virtualization, Layouts and configuration in Yandex Cloud, and Layouts and configuration in zVirt.

Examples of resources configuring integration with a cloud provider:

- AWSClusterConfiguration: Amazon Web Services
- AzureClusterConfiguration: Microsoft Azure
- ModuleConfig `cloud-provider-dvp`: Deckhouse Virtualization Platform (together with the `d8-credentials` Secret and DVPInstanceClass / NodeGroup resources)
- GCPClusterConfiguration: Google Cloud Platform
- HuaweiCloudClusterConfiguration: Huawei Cloud
- OpenStackClusterConfiguration: OpenStack, OVHcloud, Selectel, VK Cloud
- VsphereClusterConfiguration: VMware vSphere
- VCDClusterConfiguration: VMware Cloud Director
- ModuleConfig `cloud-provider-yandex`: Yandex Cloud (together with the `d8-credentials` Secret and YandexInstanceClass / NodeGroup resources)
- ModuleConfig `cloud-provider-zvirt`: zVirt (together with the `d8-credentials` Secret and ZvirtInstanceClass / NodeGroup resources)

To add cloud nodes, you also need `<PROVIDER>InstanceClass` objects (for example YandexInstanceClass for Yandex Cloud) that describe VM configuration in the node group (the NodeGroup object).

5. Deckhouse Platform module configurations.

   Each module is configured (and can be enabled or disabled) with its own ModuleConfig (for example, ModuleConfig `user-authn` for the `user-authn` module). Parameters that are allowed in the ModuleConfig object are described in the respective module documentation under “Configuration” (for example, configuration of the `user-authn` module).

   A list of all Deckhouse Platform modules is available in the Modules section.

   Some modules may be enabled and preconfigured automatically depending on the selected installation option and cluster configuration (for example, modules that provide control plane and networking functionality).

   Modules often configured during installation:

   - `global`: Global Deckhouse Platform settings for parameters used by default by all modules and components (DNS name template, StorageClass, module component placement settings, etc.).
   - `deckhouse`: Container registry access settings, the desired release channel, and other parameters.
   - `user-authn`: Unified authentication.
   - `cni-cilium`: Cluster networking (for example, used when installing Deckhouse Platform on bare metal or in an air-gapped environment);
   - `virtualization`: Running virtual machines in the cluster, enabled during the installation or later.

   If the cluster is created with nodes dedicated to specific workload types (for example, system or monitoring nodes), it is recommended to explicitly set the `nodeSelector` parameter in module configurations that use persistent storage volumes (for example, in the `nodeSelector` parameter of the `prometheus` ModuleConfig for the `prometheus` module).

6. IngressNginxController: Parameters of the HTTP/HTTPS load balancer (Ingress controller).
7. NodeGroup: Node group parameters. Required to add worker nodes.
8. Objects for authentication and authorization such as ClusterAuthorizationRule, AuthorizationRule, User, Group, and DexProvider.

   See authentication and authorization documentation for details.

An example of the installation config...

- Configuration applicable since Deckhouse Platform 1.75
- Legacy configuration

In this example, access to the Deckhouse Platform container registry is configured using ModuleConfig

`deckhouse`.

Post-bootstrap script

The installer allows you to run a custom script on one of the master nodes after installation (post-bootstrap script). This script can be used for:

- Additional cluster configuration
- Collecting diagnostic information
- Integrating with external systems or other tasks

The path to the post-bootstrap script can be specified using the `--post-bootstrap-script-path` parameter when running the CLI installer.

Example: a script that retrieves the IP address of the load balancer...

This sample script retrieves the IP address of the load balancer after Deckhouse Platform is installed:

```
#!/usr/bin/env bash

set -e
set -o pipefail

INGRESS_NAME="nginx"

echo_err() { echo "$@" 1>&2; }

# Declare the variable.
lb_ip=""

# Get the load balancer IP address.
for i in {0..100}
do
  if lb_ip="$(kubectl -n d8-ingress-nginx get svc "${INGRESS_NAME}-load-balancer" -o
jsonpath='{.status.loadBalancer.ingress[0].ip}')"; then
    if [ -n "$lb_ip" ]; then
      break
    fi
  fi

  lb_ip=""

  sleep 5
done

if [ -n "$lb_ip" ]; then
  echo_err "The load balancer external IP: $lb_ip"
else
  echo_err "Could not get the external IP of the load balancer"
  exit 1
fi

outContent="{\"frontend_ips\":[\"$lb_ip\"]}"

if [ -z "$OUTPUT" ]; then
  echo_err "The OUTPUT env is empty. The result was not saved to the output file."
else
  echo "$outContent" > "$OUTPUT"
fi
```

Installing

> **i** When installing a commercial edition of Deckhouse Platform from the official container registry `registry.deckhouse.io`, you must first log in with your license key:
>
> ```
> docker login -u license-token registry.deckhouse.io
> ```

The command to run the installer container from the public Deckhouse container registry:

```
docker run --pull=always -it [<MOUNT_OPTIONS>]
registry.deckhouse.io/deckhouse/<DECKHOUSE_REVISION>/install:<RELEASE_CHANNEL> bash
```

Where:

1. `<DECKHOUSE_REVISION>`: Deckhouse Platform edition. For example, `ee` for Enterprise Edition, `ce` for Community Edition, etc.
2. `<MOUNT_OPTIONS>`: Parameters for mounting files into the installer container, such as:
   - SSH access keys

    - Configuration file
    - Resource file, etc.
3. `<RELEASE CHANNEL>`: Release channel in kebab-case format:
    - `alpha`: Alpha channel
    - `beta`: Beta channel
    - `early-access`: Early Access channel
    - `stable`: Stable channel
    - `rock-solid`: Rock Solid channel

Here is an example of a command to run the Deckhouse Platform Community Edition/Open installer container from the Stable release channel:

```
docker run -it --pull=always \
  -v "$PWD/config.yaml:/config.yaml" \
  -v "$PWD/dhctl-tmp:/tmp/dhctl" \
  -v "$HOME/.ssh/:/tmp/.ssh/" registry.deckhouse.io/deckhouse/ce/install:stable bash
```

Deckhouse Platform installation is performed within the installer container using the `dhctl` command:

- To start the installation of Deckhouse Platform with the deployment of a new cluster (for all cases except installing into an existing cluster), use the command `dhctl bootstrap`.
- To install Deckhouse Platform into an already existing cluster, use the command `dhctl bootstrap-phase install-deckhouse`.

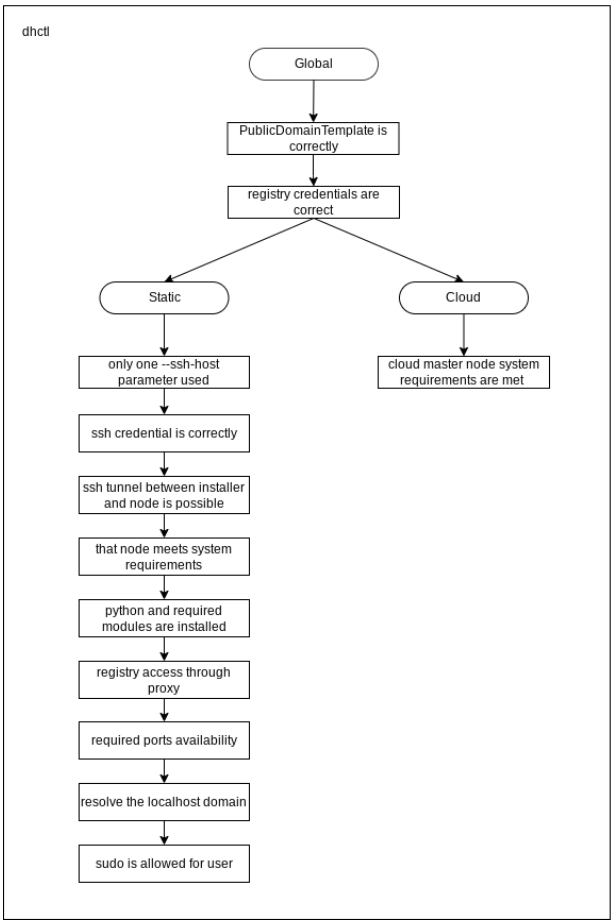
> **i** To learn more about the available parameters, run `dhctl bootstrap -h`.

Example of running a Deckhouse Platform installation with cloud cluster deployment:

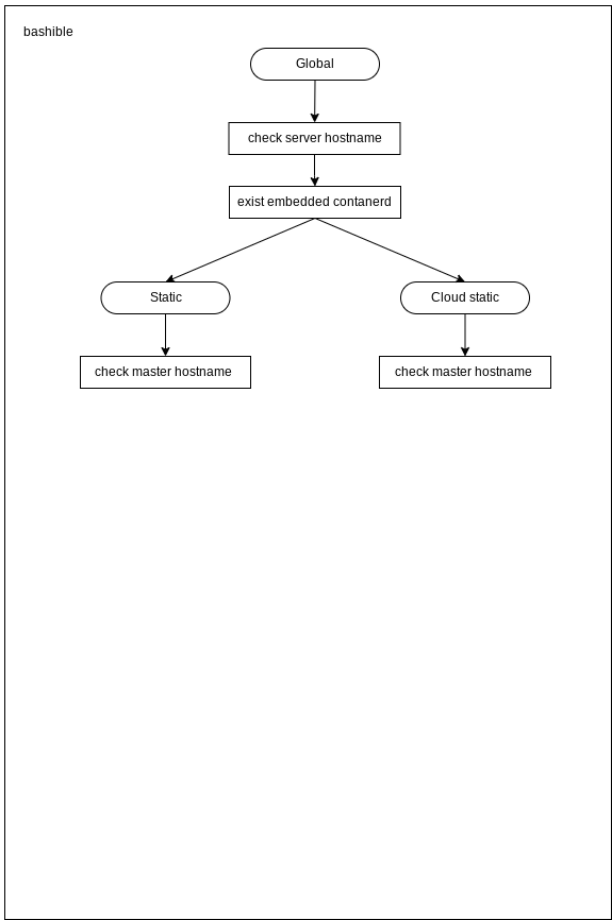
```
dhctl bootstrap \
  --ssh-user=<SSH_USER> --ssh-agent-private-keys=/tmp/.ssh/<SSH_PRIVATE_KEY_FILE> \
  --config=/config.yml
```

Where:

- `/config.yml`: Installation configuration file.
- `<SSH USER>`: Username for SSH connection to the server.
- `--ssh-agent-private-keys`: Private SSH key file for SSH connection.
- `<SSH_PRIVATE_KEY_FILE>`: Name of private key. For example, for a key with RSA encryption it can be `id_rsa`, and for a key with ED25519 encryption it can be `id_ed25519`.



If the server accepts only keys signed by an SSH certificate authority, put the certificate next to the private key as `<SSH_PRIVATE_KEY_FILE>-cert.pub`, for example `id_ed25519-cert.pub`. dhctl uses it automatically.



Pre-installation checks

> **i** Starting with version 1.74, Deckhouse Platform modules are installed as images in the EROFS format that are mounted read-only, which protects them from being modified after installation. This mechanism is enabled automatically if the `erofs` filesystem is registered in the kernel on the node running the Deckhouse Platform controller (a master node by default). Deckhouse Platform loads this kernel module only on nodes with containerd v2, so if master nodes use containerd v1, the operating system has to load `erofs` on its own. Otherwise, Deckhouse Platform will install modules the regular way, without protecting their integrity and without a dedicated alert. For details, refer to “Integrity protection of Deckhouse Platform modules”.

Diagram of checks performed by the installer before installation...

Preflight checks

List of checks performed by the installer before starting Deckhouse Platform installation:

1. General checks:
   - The values of the parameters `publicDomainTemplate` and `clusterDomain` (or the deprecated `ClusterConfiguration.clusterDomain`) do not match.
   - The authentication data for the container registry specified in the installation configuration is correct.
   - The host name meets the following requirements:
     - The length does not exceed 63 characters.
     - It consists only of lowercase letters.
     - It does not contain special characters (hyphens `-` and periods `.` are allowed, but they cannot be at the beginning or end of the name).
   - The server (VM) has a supported container runtime (`containerd`) installed.
   - The host name is unique within the cluster.
   - The server's system time is correct.
   - The address spaces for Pods (`podSubnetCIDR`) and services (`serviceSubnetCIDR`) do not intersect.
2. Checks for static and hybrid cluster installation:
   - Only one `--ssh-host` parameter is specified. For static cluster configuration, only one IP address can be provided for configuring the first master node.
   - SSH connection is possible using the specified authentication data.
   - SSH tunneling to the master node server (or VM) is possible.
   - The server (VM) selected for the master node installation has the minimum resources listed in the Resource requirements section. The same section lists the node resources for each deployment option.
   - Python (Python 3 or Python 2) must be available on the server (VM) intended for the master node. The standard Python modules used by the installer must also be available:
     - For HTTP request handling: `urllib.request` (Python 3) or `urllib2` (Python 2)
     - For HTTP error handling: `urllib.error` (Python 3) or `urllib2` (Python 2)
     - For working with configuration files: `configparser` (Python 3) or `ConfigParser` (Python 2)
     - For HTTP server: `http.server` (Python 3) or `SimpleHTTPServer` (Python 2)
     - For TCP server: `http.server` (Python 3) or `SocketServer` (Python 2)
   - The container registry is accessible through a proxy (if proxy settings are specified in the installation configuration).
   - On the server (VM) intended for the master node and on the host from which the installer is launched, port `22/TCP` (network access from a personal computer) must be accessible, as it

    is required for the installation process. For details, see the Network interaction of the platform components section.
    - DNS must resolve `localhost` to IP address `127.0.0.1`.
    - The user has `sudo` privileges on the server (VM).
    - Required ports for the installation must be open:
      - Port `22/TCP` between the host running the installer and the server.
      - No port conflicts with those used by the installation process.
    - The server (VM) has the correct time.
    - The server (VM) has no conflicts with the local `deckhouse` system user and group: the user and group are either absent, or the user has UID and primary GID `64535`, the group has GID `64535`, the user has no `sudo` privileges, and UID/GID `64535` are not assigned to other accounts. For details, see The local `deckhouse` system user.
    - The address spaces for Pods (`podSubnetCIDR`), services (`serviceSubnetCIDR`), and internal network (`internalNetworkCIDRs`) do not intersect.
3. Checks for cloud cluster installation:
    - The configuration of the virtual machine for the master node has the minimum resources listed in the Resource requirements section.
    - The cloud provider API is accessible from the cluster nodes.
    - The configuration for Yandex Cloud with NAT Instance is verified.

List of preflight skip flags...

To skip a specific check, use the `--preflight-skip-check` flag and pass the preflight check name as its argument. The flag can be specified multiple times.

`dhctl preflight list` prints every check, what it applies to and what it asserts.

- `--preflight-skip-all-checks`: Skip all preflight checks.

Configuration checks (the `PreInfraPreflights` phase):

- `--preflight-skip-check=registry-credentials`: Skip the check for registry access credentials.
- `--preflight-skip-check=registry-reachable`: Skip the check that the registry answers from the installer host.
- `--preflight-skip-check=deckhouse-image-available`: Skip the check that the Deckhouse image of this version is in the registry.
- `--preflight-skip-check=registry-required-images`: Skip the check that the registry holds the images the release is made of, and not just the tag that names it.
- `--preflight-skip-check=dhctl-edition`: Skip the check that the installer edition matches the Deckhouse image edition.
- `--preflight-skip-check=dhctl-version`: Skip the check that the installer version matches the Deckhouse image version.
- `--preflight-skip-check=bastion-availability`: Skip the bastion host availability check.
- `--preflight-skip-check=cloud-disk-name-length`: Skip the check that the cluster prefix does not make generated disk names too long.
- `--preflight-skip-check=cloud-master-system-requirements`: Skip the check that the master node instance class meets the minimum requirements.
- `--preflight-skip-check=instance-class-provider`: Skip the check that InstanceClass resources match the cloud provider.
- `--preflight-skip-check=cloud-node-network-cidr-intersection`: Skip the check that the cluster subnets do not overlap the cloud network the nodes are created on.
- `--preflight-skip-check=cloud-ssh-key-matches-public-key`: Skip the check that a private key dhctl holds matches the `sshPublicKey` the cloud will install.
- `--preflight-skip-check=dynamix-storage-policy`: Skip the check that Basis Dynamix is version 4.6 or newer and that every storage policy named in DynamixClusterConfiguration is `ENABLED` and available to the account.
- `--preflight-skip-check=static-instances-ip-duplication`: Skip the check for duplicate StaticInstance addresses.
- `--preflight-skip-check=immutable-installer-images`: Skip the check that the installer image carries the requested Kubernetes control plane.
- `--preflight-skip-check=immutable-kubeconfig-kept`: Skip the check that the admin kubeconfig is written outside the directory dhctl cleans up.
- `--preflight-skip-check=immutable-kubeconfig-out`: Skip the check that the admin kubeconfig has a destination.
- `--preflight-skip-check=immutable-machines-availability`: Skip the check that the machines named with `--master-host` answer.
- `--preflight-skip-check=immutable-post-bootstrap-script`: Skip the check that no post-bootstrap script is requested.
- `--preflight-skip-check=immutable-signature-mode`: Skip the check that the control-plane signature mode is off.
- `--preflight-skip-check=immutable-supported-provider`: Skip the check that the platform is supported for an immutable master.

Node checks (the `PostInfraPreflights` phase):

- `--preflight-skip-check=static-single-ssh-host`: Skip the check for the number of specified SSH hosts.
- `--preflight-skip-check=ssh-connectivity`: Skip the check that the node answers on its SSH port.
- `--preflight-skip-check=ssh-credential`: Skip the check that the SSH user can log in to the node.
- `--preflight-skip-check=static-ssh-tunnel`: Skip the SSH forwarding check.
- `--preflight-skip-check=static-instances-ssh-access`: Skip the check for SSH access to StaticInstances.
- `--preflight-skip-check=sudo-installed`: Skip the check that `sudo` is installed on the node.
- `--preflight-skip-check=sudo-allowed`: Skip the check for `sudo` privileges.
- `--preflight-skip-check=deckhouse-user`: Skip checks of the `deckhouse` user and group, including their UID/GID, conflicts with UID/GID `64535`, and whether the `deckhouse` user has `sudo` privileges.
- `--preflight-skip-check=node-system-requirements`: Skip the check for meeting system requirements.
- `--preflight-skip-check=python-modules`: Skip the check for Python installation.
- `--preflight-skip-check=ports-availability`: Skip the check for the availability of required ports.
- `--preflight-skip-check=resolve-localhost`: Skip the `localhost` resolution check.
- `--preflight-skip-check=time-drift`: Skip the time drift check.
- `--preflight-skip-check=node-hostname`: Skip the check that the node hostname is one Kubernetes accepts as a node name.
- `--preflight-skip-check=node-os-supported`: Skip the check that the node runs an operating system Deckhouse can configure.
- `--preflight-skip-check=node-xfs-ftype`: Skip the check for an XFS filesystem formatted without `d type`.
- `--preflight-skip-check=node-resolve-hostname`: Skip the check that the node resolves its own hostname.
- `--preflight-skip-check=node-leftovers`: Skip the check that the node carries no container runtime or Kubernetes of its own.
- `--preflight-skip-check=node-cri-requirements`: Skip the check that the node meets what `ContainerdV2` needs (kernel, systemd, cgroup v2, `erofs`).
- `--preflight-skip-check=node-kernel-modules`: Skip the check that the kernel modules Deckhouse loads can be loaded on the node.
- `--preflight-skip-check=node-selinux-tools`: Skip the check that a node with SELinux enforcing has the tools to install the Deckhouse policy.
- `--preflight-skip-check=node-disk-space`: Skip the check that the node has the disk Deckhouse needs.
- `--preflight-skip-check=static-free-disk-space`: Skip the check that the node has enough free disk for the bootstrap.
- `--preflight-skip-check=node-internal-network`: Skip the check that the node has an address inside `internalNetworkCIDRs`.
- `--preflight-skip-check=host-network-cidr-intersection`: Skip the check for intersection between the cluster CIDRs and the host networks.
- `--preflight-skip-check=registry-access-through-proxy`: Skip the check for accessing the registry through a proxy server.
- `--preflight-skip-check=cloud-api-accessibility`: Skip the Cloud API accessibility check.
- `--preflight-skip-check=cloud-api-from-installer`: Skip the check that the installer itself reaches the cloud provider API.
- `--preflight-skip-check=network-single-source`: Skip the check that the cluster network parameters are declared in only one of `ClusterConfiguration` or the `control-plane-manager` ModuleConfig.
- `--preflight-skip-check=cloud-kube-data-device`: Skip the check that the disk the provider attached for Kubernetes data is on the master.
- `--preflight-skip-check=registry-access-from-master`: Skip the check that the master node itself can reach the registry.
- `--preflight-skip-check=immutable-api-reachable`: Skip the check that the API port of an immutable first master answers.

The cluster subnets and `publicDomainTemplate` are not preflight checks: they read only the configuration, so they are validated when it is loaded — by `dhctl config`, by converge and by bootstrap alike. No flag can skip them.

The names `cidr-intersection`, `static-cidr-intersection` and `public-domain-template` are accepted for compatibility but do not affect check execution.

When a check name is specified with `--preflight-skip-check`, both checks corresponding to that name are skipped: `registry-credentials` skips `registry-reachable`, `dhctl-edition` skips `deckhouse-image-available`, `sudo-allowed` skips `sudo-installed`, and `ssh-credential` skips `ssh-connectivity`.

Checks that concern the machine itself are named `node-*`, while checks that concern access to it are named `ssh-*`. Both run on a cloud master as well as on a static node. Checks with the `static-` prefix apply only to a static cluster. Renamed check names are accepted by `--preflight-skip-check`.

The node checks — `sudo-installed`, `sudo-allowed`, `python-modules`, `resolve-localhost`, `time-drift`, `node-hostname`, `node-disk-space`, `node-leftovers`, `node-cri-requirements`, `node-internal-network`, `node-system-requirements` and `host-network-cidr-intersection` — also run on a cloud master as well as on a static node. Their names are the same on both paths.

Two more flags control check execution:

- `--preflight-fail-fast`: Stop at the first failed check instead of running the remaining checks in the phase.
- `--preflight-no-cache`: Run all checks again without using results saved from the previous run.

Example of using a preflight skip flag:

```
dhctl bootstrap \
--ssh-user=<SSH_USER> --ssh-agent-private-keys=/tmp/.ssh/<SSH_PRIVATE_KEY_FILE> \
--config=/config.yml \
--preflight-skip-all-checks
```

> **i** Replace `<SSH_PRIVATE_KEY_FILE>` here with the name of your private key. For example, for a key with RSA encryption it can be `id_rsa`, and for a key with ED25519 encryption it can be `id_ed25519`.

The local `deckhouse` system user

Deckhouse Platform components use UID/GID `64535` to run unprivileged processes and access their files on the node. The local `deckhouse` user and group reserve these identifiers for Deckhouse Platform and let the OS display the `deckhouse` name instead of numeric UID/GID values in tools such as `ps`, `top`, and `ls`. Processes owned by `deckhouse` in `ps` or `top` output are expected: they belong to Deckhouse Platform components, not to user sessions.

If the account does not exist, bashible creates it with the `/sbin/nologin` shell, without a password or `sudo` privileges. `/etc/passwd` lists the system default home directory for the user (usually `/home/deckhouse`). Bashible creates this directory separately as the base directory for the home directories of users defined by `NodeUser` resources; the `deckhouse` system account itself is not intended for login or storing user files. The account must not be provided through AD or LDAP.

The `deckhouse` name and UID/GID `64535` are reserved for Deckhouse Platform and are not configurable. Do not delete or rename the user or group, change their UID/GID, or grant the user `sudo` privileges. The preflight check accepts an absent user and group, or an existing pair where the user has UID and primary GID `64535`, the group has GID `64535`, and the user has no `sudo` privileges. Installation fails if the name is used with different IDs or UID/GID `64535` are assigned to other accounts.

The `--preflight-skip-check=deckhouse-user` flag disables the check but does not resolve the conflict. If the `deckhouse` user or group exists with different IDs, bashible does not modify it and logs a warning. If UID/GID `64535` are assigned to another account, bashible cannot create the `deckhouse` user or group. Nor does bashible revoke `sudo` privileges from an existing user.

If the conflict was left by a previous Deckhouse Platform installation on a static node, perform manual cleanup of the static node. This is a destructive operation: the cleanup script removes the services, configuration, and local Kubernetes, containerd, and etcd data created by Deckhouse Platform, as well as Deckhouse Platform accounts, and then reboots the server. Run the cleanup only on a node prepared for redeployment. In all other cases, resolve the conflict manually or recreate the node.

Aborting the installation

If the installation was interrupted or issues occurred during the installation process in a supported cloud, there might be leftover resources created during the installation. To remove them, run the following command within the installer container:

```
dhctl bootstrap-phase abort
```

> **⚠** The configuration file provided through the `--config` parameter when running the installer must be the same that was used during the initial installation.

Installing virtualization

Virtualization is enabled by the `virtualization` ModuleConfig resource and deploys its components to the `d8-virtualization` namespace. You can either include the resource in the installation configuration file or apply it in a ready cluster.

> ⚠ Enabling virtualization restarts kubelet, containerd, and the network module agents on every node that is expected to run virtual machines. This is required to set up connectivity between containerd and the DVCR image storage.

A minimal configuration defines the image storage size and the subnets that virtual machines get addresses from:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: virtualization
spec:
  enabled: true
  version: 1
  settings:
    dvcr:
      storage:
        type: PersistentVolumeClaim
        persistentVolumeClaim:
          size: 50G
    virtualMachineCIDRs:
      - 10.66.10.0/24
```

The other parameters are covered in the module settings reference.

To check if virtualization is ready, run the following command:

```
d8 k get modules virtualization
```

Example output:

```
NAME             WEIGHT   SOURCE      PHASE   ENABLED   READY
virtualization   900      deckhouse   Ready   True      True
```

The module phase should be `Ready`.

Placement of virtualization components across nodes

How components are distributed across nodes depends on the cluster configuration. A cluster may have only master nodes running both control plane components and workloads; master and worker nodes; master, system, and worker nodes; or other combinations. Worker nodes here are the nodes without restrictions (taints) that would prevent regular workloads from running.

Deckhouse Platform distributes the components by priority, and if the cluster has a suitable node type, the component lands on it. What each component is responsible for is described in Virtualization subsystem.

Component name	Node group	Comment
`virt-operator-*`	system/master	
`virt-api-*`	master	
`virt-controller-*`	system/worker	
`virt-handler-*`	Nodes with KVM	
`virtualization-api-*`	master	

Component name	Node group	Comment
`virtualization-controller-*`	master	
`dvcr-*`	system	Storage has to be available on the node. With no system nodes, the component lands on a worker node.
`virtualization-audit-*`	master	Available in commercial Deckhouse Platform editions.
`virtualization-dra-*`	Dedicated nodes	Available in commercial Deckhouse Platform editions.
`vm-route-forge-*`	All cluster nodes	

The `virt-handler-*` component runs only on the nodes where Deckhouse Platform detected KVM support and set the `virtualization.deckhouse.io/kvm-enabled` label, and the `virtualization-dra-*` component runs only on nodes labeled with `virtualization.deckhouse.io/usbip`.

The components that create and upload virtual machine images and disks run only while that work is in progress:

Component name	Node group	Comment
`d8v-vi-importer-*`, `d8v-cvi-importer-*`	system/worker	Uploads an image from an external source or another resource to the image storage.
`d8v-vi-uploader-*`, `d8v-cvi-uploader-*`	system/worker	Accepts the file that you upload from the CLI or the web interface.
`d8v-vd-pvc-importer-*`, `d8v-vi-pvc-importer-*`	system/worker	Moves an image from the image storage to a disk volume.
`d8v-pvc-pvc-source-importer-*`	system/worker	Serves the data of the source volume over the network when a disk is cloned.
`d8v-pvc-pvc-target-importer-*`	system/worker	Receives the data on the target volume when a disk is cloned.
`d8v-vi-bounder-*`	system/worker	Keeps the volume on the required node while an image is created on it.

Cluster with taints on all nodes

Sometimes taints are configured on every cluster node, which is how an administrator explicitly controls where workloads land. In such a configuration, keep the following in mind:

1. When creating a VirtualDisk, pay attention to the `volumeBindingMode` of the StorageClass. With `Immediate`, the PersistentVolume is created right after the disk is created, before the virtual machine is scheduled. Make sure the storage can create volumes on the nodes allowed for virtual machines by the placement parameters, including `nodeSelector`, `tolerations`, and the settings in the `spec` of the virtual machine or the VirtualMachineClass. Otherwise, the disk may end up on a node where the virtual machine can’t start. With `WaitForFirstConsumer`, the volume is created on the node the virtual machine is scheduled to, and the problem doesn’t occur.
2. VirtualImage and ClusterVirtualImage rely on the temporary components from the table above. They have a toleration for the `dedicated.deckhouse.io=system` taint.
3. The cluster has to have a `system` NodeGroup, or the administrator adds the `dedicated.deckhouse.io=system` taint to selected nodes without creating a NodeGroup. Without such nodes, these components won’t be scheduled, and images won’t reach the `Ready` phase.

Air-gapped environment, working via proxy and using external registries

> **i** For more details on installing and updating Deckhouse Platform in an air-gapped environment, see the “Installing Deckhouse Platform in an air-gapped environment” and “Updating Deckhouse Platform in an air-gapped environment” guides.

Installing from an external (third-party) registry

Deckhouse Platform can be installed from an external container registry or via a proxy registry inside an air-gapped environment.

> **⚠** Deckhouse Platform supports Basic and Bearer token authentication schemes for container registries (Basic is tried first; if it fails, Bearer is used).
>
> If a reverse proxy is placed in front of the registry, it must correctly forward the Registry API v2 header `Docker-Distribution-API-Version: registry/2.0`. Otherwise the Basic check may fail, and the subsequent Bearer attempt may fail with the error `couldn't find bearer realm parameter`.
>
> The following container registries were verified and are guaranteed to work: Nexus, Harbor, Artifactory, CNCF Distribution, Quay.
>
> When working with external registries, do not use an administrator account to access them from Deckhouse Platform. Create a dedicated read-only account limited to the required repository in the registry. Refer to an example of creating such an account.

There are several options for configuring access to external container registries during cluster installation:

- Starting from Deckhouse Platform version 1.75 — using the `deckhouse` ModuleConfig.
- Prior to Deckhouse Platform version 1.75 — using InitConfiguration (considered a legacy method, refer to the example below).

To configure access using the `deckhouse` ModuleConfig, specify the external registry access parameters in the `settings.registry` section.

Specify the parameters for accessing a third-party registry in the `settings.registry` section of the ModuleConfig `deckhouse`.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Direct
      direct:
        imagesRepo: test-registry.io/some/path
        scheme: HTTPS
        username: <username>
        password: <password>
        ca: <CA>
```

Configuration of an external registry using InitConfiguration **(legacy method)**

Set the following parameters in `InitConfiguration`:

- `imagesRepo: <PROXY_REGISTRY>/<DECKHOUSE_REPO_PATH>/ee`: Path to the Deckhouse Platform EE image in an external registry. Example: `imagesRepo: registry.deckhouse.io/deckhouse/ee`.
- `registryDockerCfg: <BASE64>`: Base64-encoded access credentials to the external registry.

If anonymous access is allowed to Deckhouse Platform images in the external registry, the

`registryDockerCfg` should look as follows:

```
{"auths": { "<PROXY_REGISTRY>": {}}}
```

The provided value must be Base64-encoded.

If authentication is required to access Deckhouse Platform images in the external registry, the `registryDockerCfg` should look as follows:

```
{"auths": { "<PROXY_REGISTRY>": {"username":"<PROXY_USERNAME>","password":"
<PROXY_PASSWORD>","auth":"<AUTH_BASE64>"}}}
```

Where:

- `<PROXY_USERNAME>`: Username for authenticating to `<PROXY_REGISTRY>`
- `<PROXY_PASSWORD>`: Password for authenticating to `<PROXY_REGISTRY>`
- `<PROXY_REGISTRY>`: Address of the external registry in the `<HOSTNAME>[:PORT]` format
- `<AUTH_BASE64>`: A Base64-encoded string of `<PROXY_USERNAME>:<PROXY_PASSWORD>`

The final value for `registryDockerCfg` must also be Base64-encoded.

You can use the following script to generate the `registryDockerCfg`:

```
declare MYUSER='<PROXY_USERNAME>'
declare MYPASSWORD='<PROXY_PASSWORD>'
declare MYREGISTRY='<PROXY_REGISTRY>'

MYAUTH=$(echo -n "$MYUSER:$MYPASSWORD" | base64 -w0)
MYRESULTSTRING=$(echo -n "{\"auths\":{\"$MYREGISTRY\":
{\"username\":\"$MYUSER\",\"password\":\"$MYPASSWORD\",\"auth\":\"$MYAUTH\"}}}" |
base64 -w0)

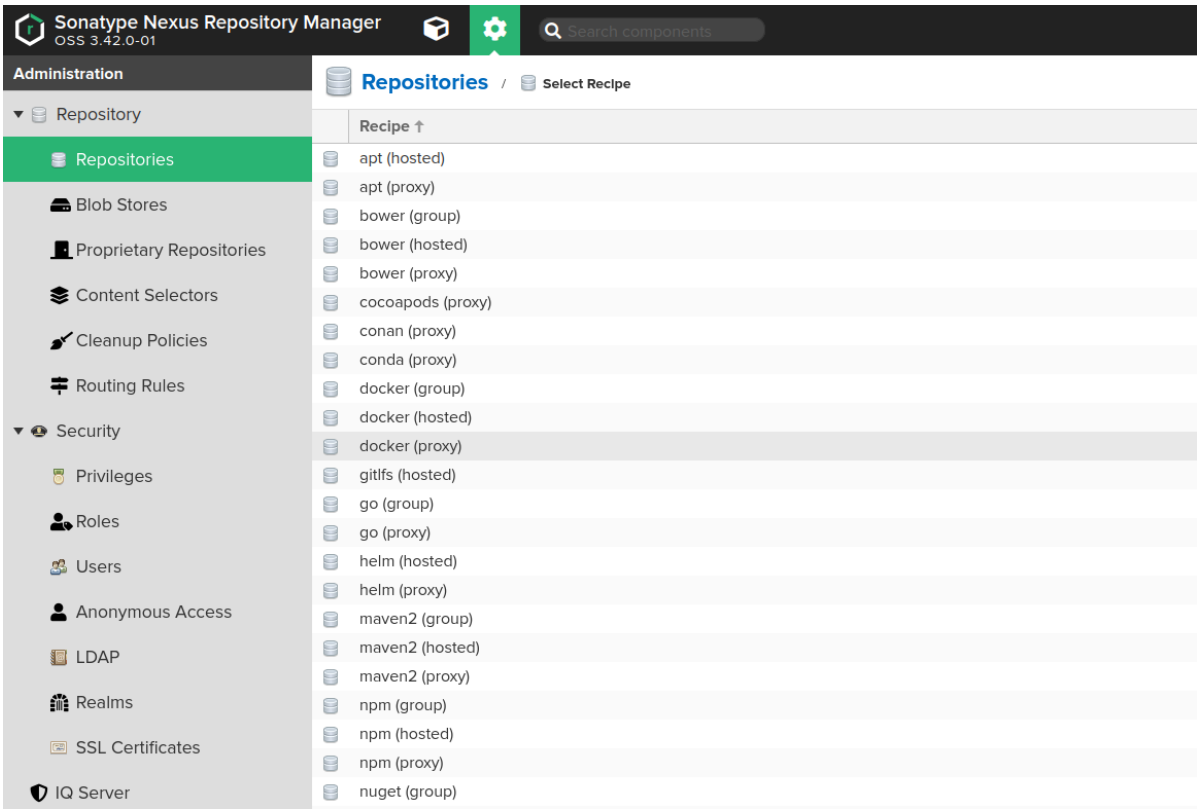
echo "$MYRESULTSTRING"
```

To support non-standard configurations of external registries, InitConfiguration provides two additional parameters:

- `registryCA`: Root certificate to validate the registry's certificate (used if the registry uses self-signed certificates).
- `registryScheme`: Protocol used to access the registry (`HTTP` or `HTTPS`). The default is `HTTPS`.

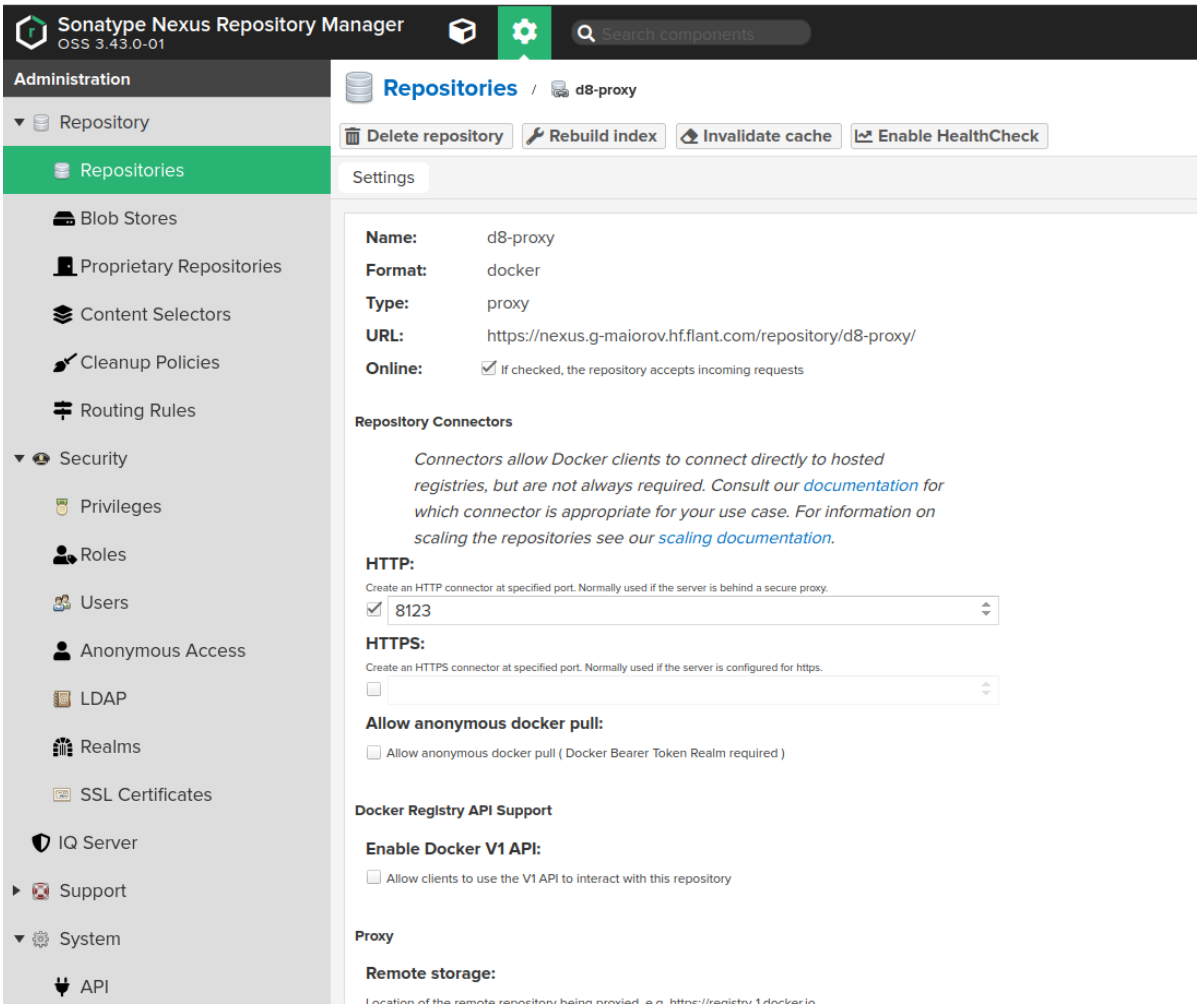
Nexus configuration notes

⚠ When interacting with a `docker`-type repository in Nexus (for example, using `docker pull` or `docker push` commands), you must specify the address in the following format: `<NEXUS_URL>:<REPOSITORY_PORT>/<PATH>`.

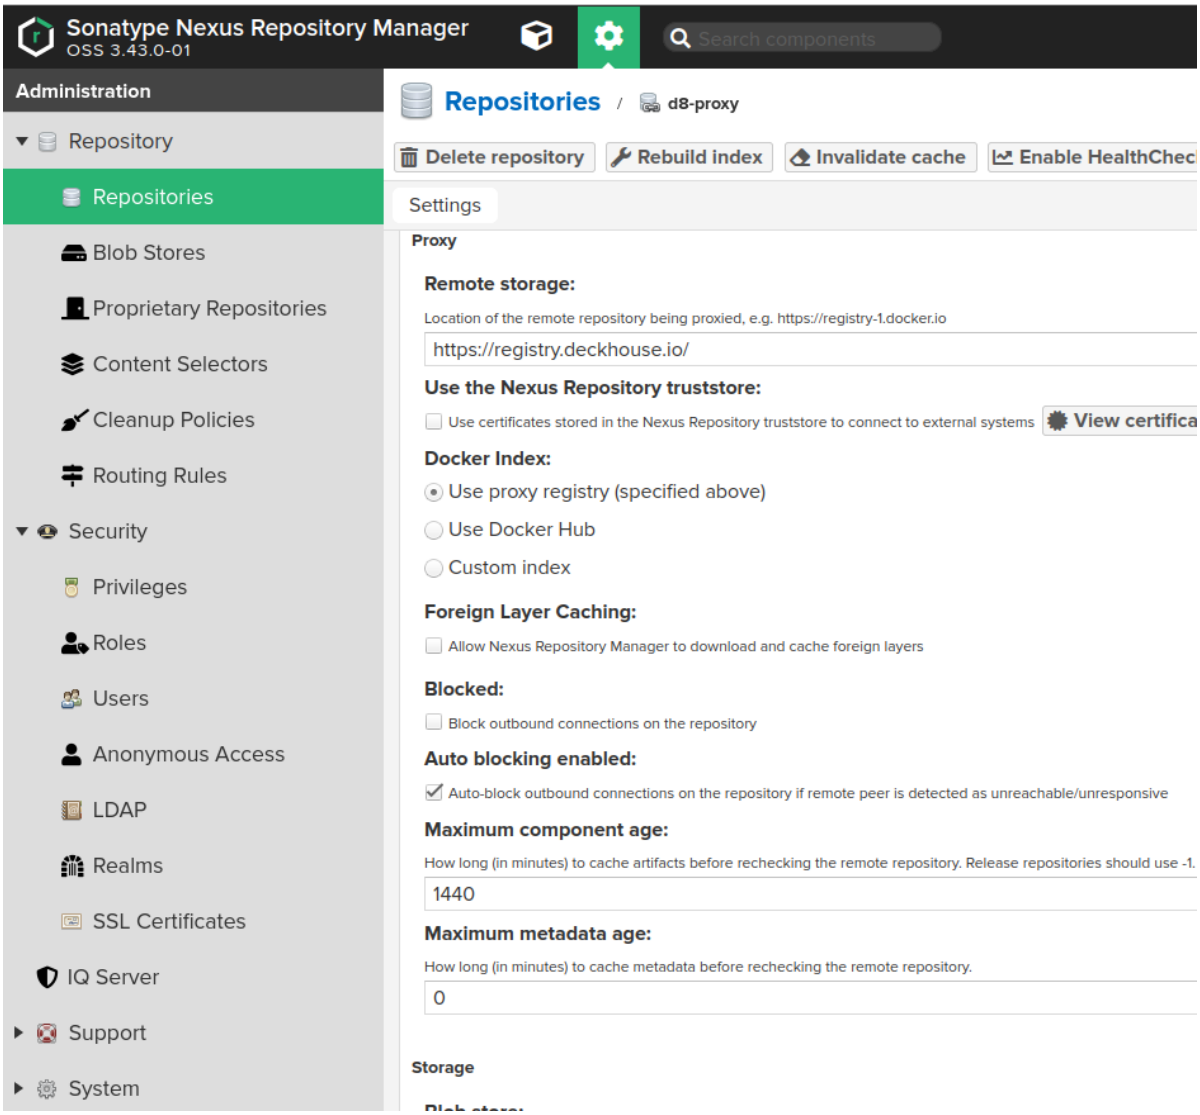


Using the `URL` value from the Nexus repository settings is **not allowed**.

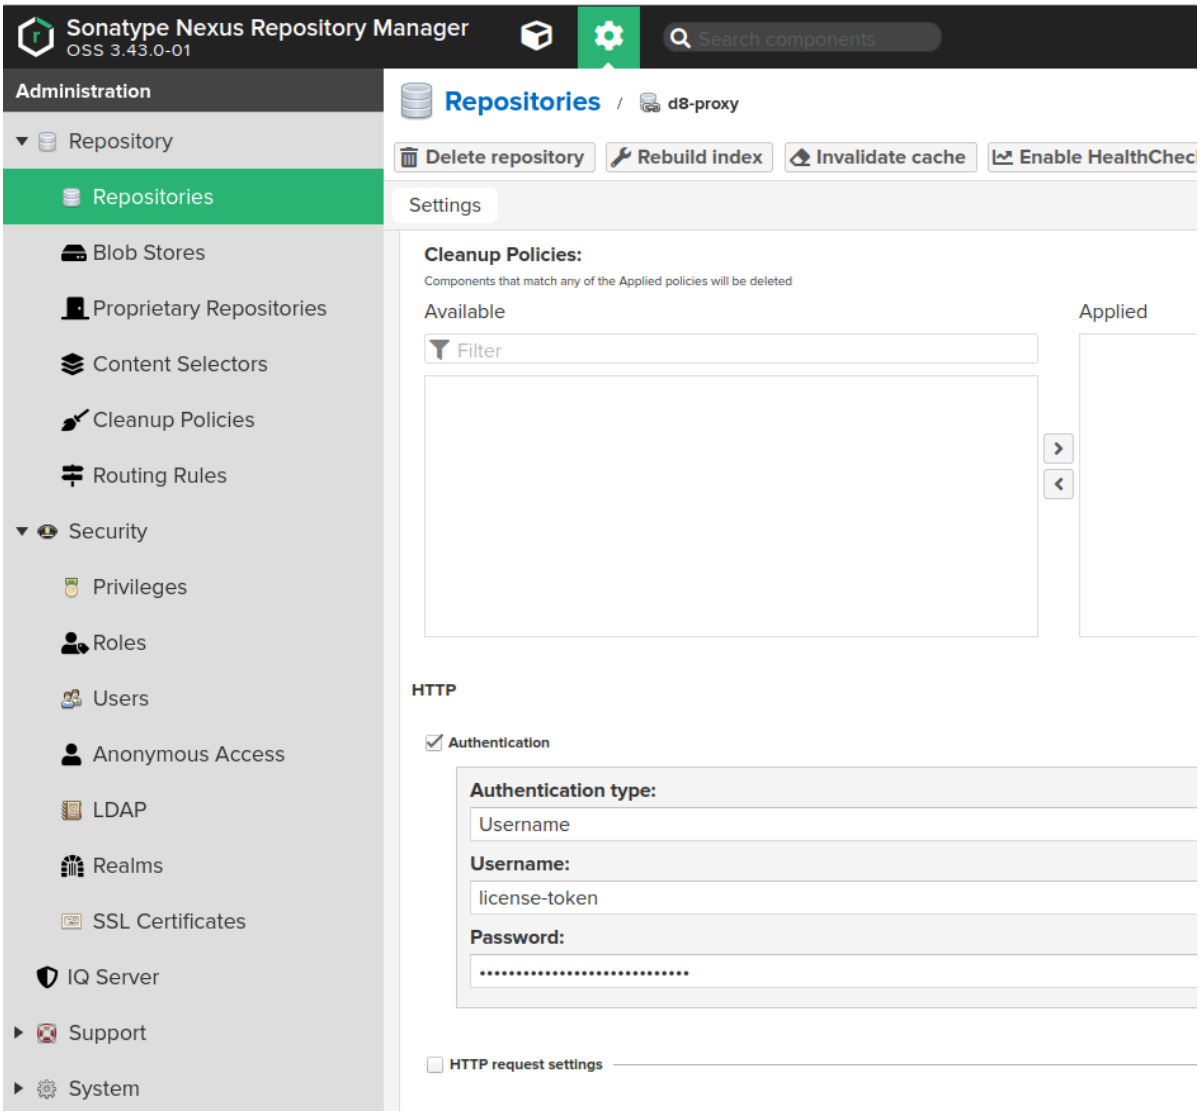
When using the Nexus repository manager, the following requirements must be met:



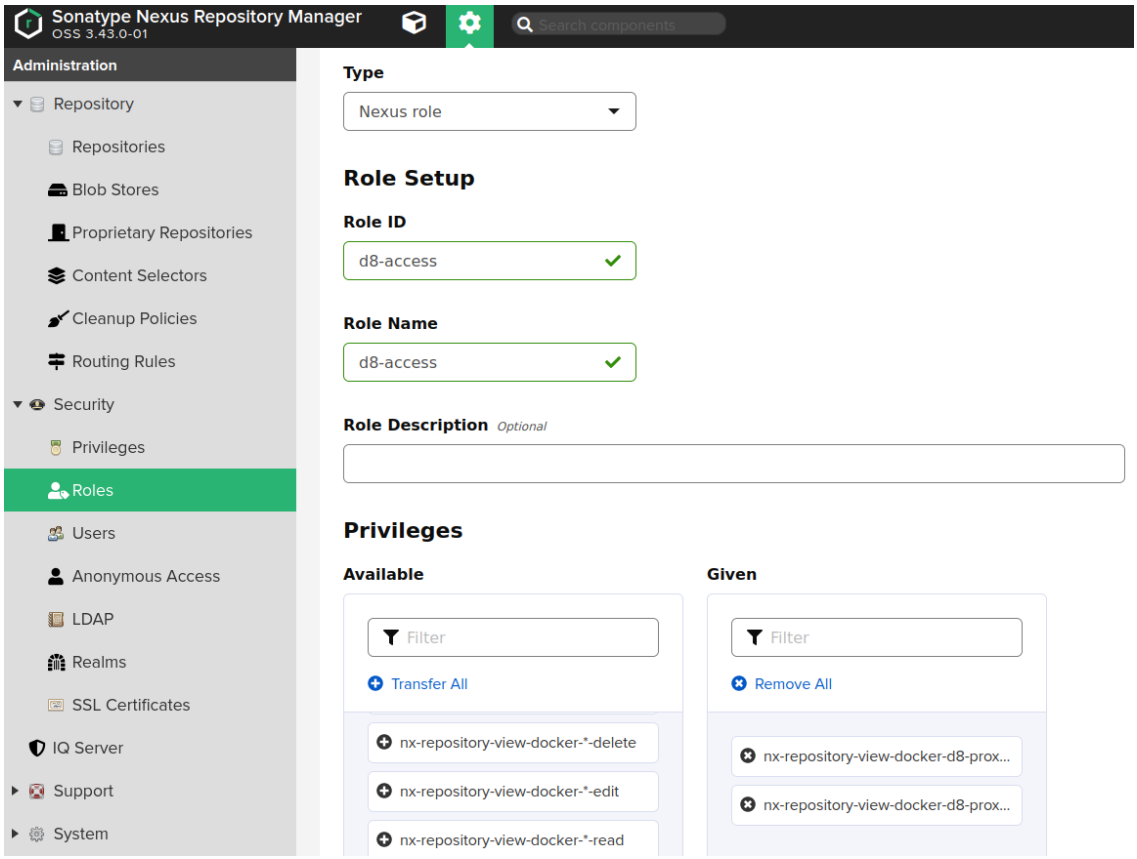
- A proxy Docker repository must be created ("Administration" → "Repository" → "Repositories"):
  - The `Maximum metadata age` parameter is set to `0`.
- Access control must be configured:
  - Create a role named **Nexus** ("Administration" → "Security" → "Roles") with the following privileges:
    - `nx-repository-view-docker-<repository>-browse`
    - `nx-repository-view-docker-<repository>-read`
  - Create a user ("Administration" → "Security" → "Users") and assign them the **Nexus** role.



To configure Nexus, follow these steps:



1. Create a proxy Docker repository ("Administration" → "Repository" → "Repositories") that points to the public Deckhouse container registry.



2. Fill out the repository creation form with the following values:
   - `Name`: the desired repository name, e.g., `d8-proxy`.
   - `Repository Connectors / HTTP` or `HTTPS`: a dedicated port for the new repository, e.g., `8123` or another.
   - `Remote storage`: must be set to `https://registry.deckhouse.io/`.
   - `Auto blocking enabled` and `Not found cache enabled`: can be disabled for debugging; otherwise, enable them.
   - `Maximum Metadata Age`: must be set to `0`.
   - If using a commercial edition of Deckhouse Platform, enable the `Authentication` checkbox and fill in the following:
     - `Authentication Type`: `Username`.
     - `Username`: `license-token`.
     - `Password`: Your Deckhouse Platform license key.

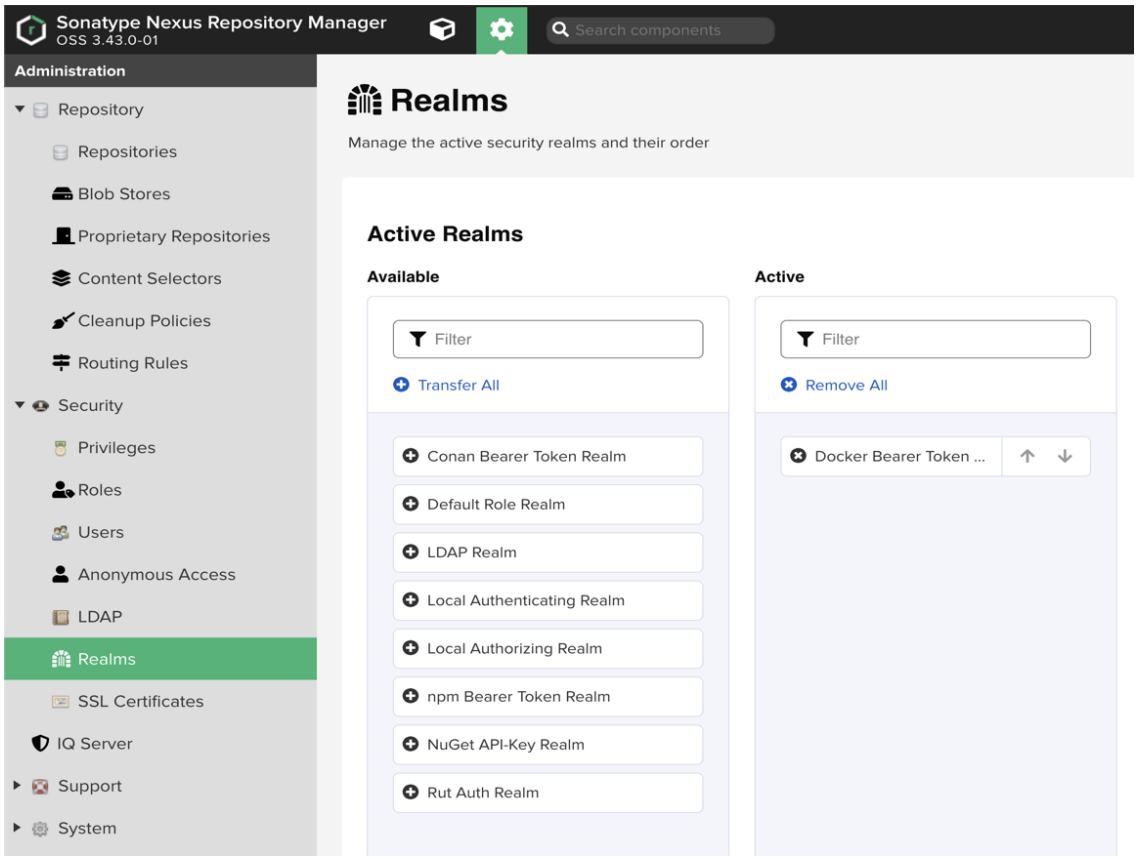
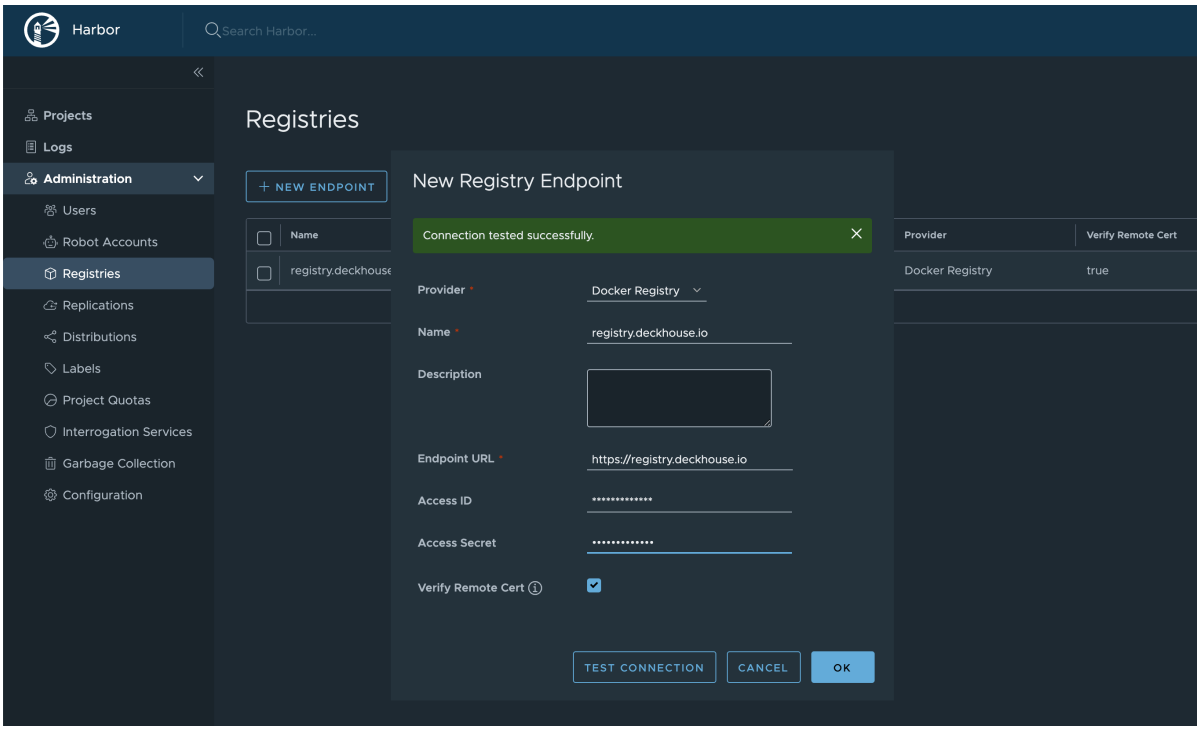
Block outbound connections on the repository
Auto blocking enabled:
Auto-block outbound connections on the repository if remote peer is detected as unreachable/unresponsive
Maximum component age:
How long (in minutes) to cache artifacts before rechecking the remote repository. Release repositories should use -1.
1440
Maximum metadata age:
How long (in minutes) to cache metadata before rechecking the remote repository.
0
Storage



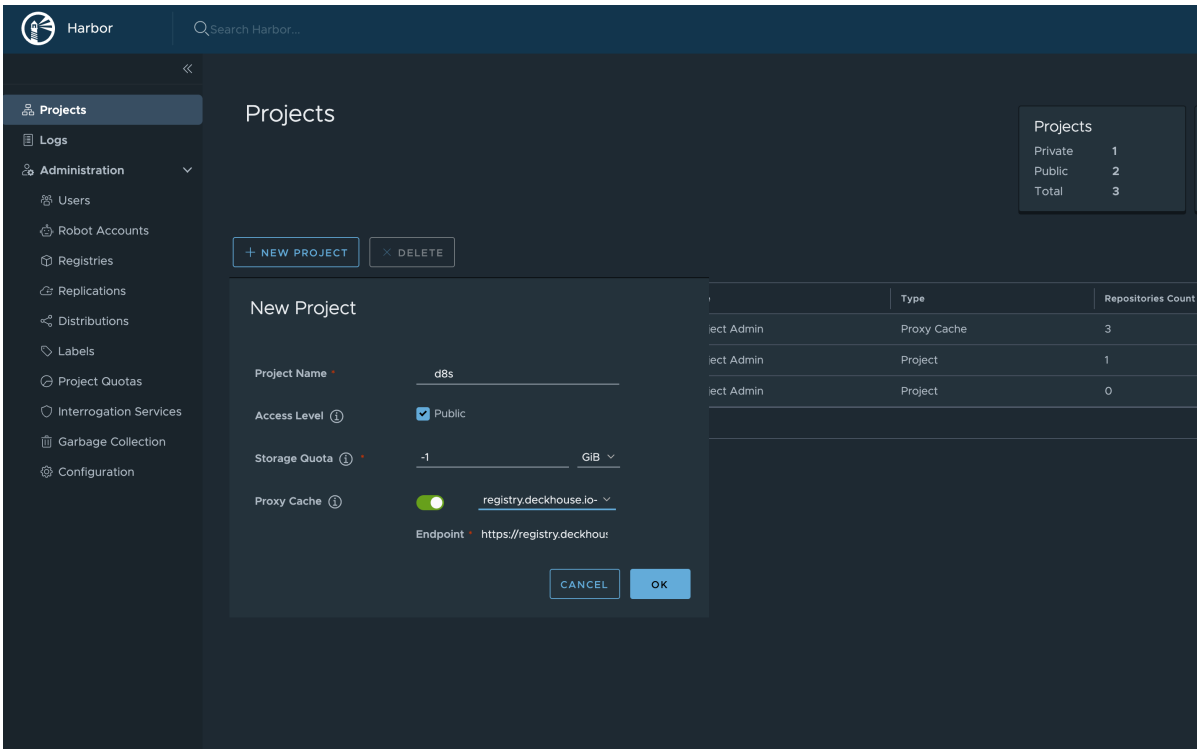
3. Configure Nexus access control to allow Deckhouse Platform to access the created repository:
   - Create a **Nexus** role (“Administration” → “Security” → “Roles”) with the following privileges: `nx-repository-view-docker-<repository>-browse` and `nx-repository-view-docker-<repository>-read`.

- Create a user (“Administration” → “Security” → “Users”) and assign them the role created above.

- Enable **Docker Bearer Token Realm** (“Administration” → “Security” → “Realms”):
  - The **Docker Bearer Token Realm** must be in the **Active** list (on the right), not in **Available** (on the left).
  - If it is not in **Active**:
    1. Find it in the **Available** list.
    2. Move it to **Active** using the arrow button.
    3. Click **Save**.
    4. **Restart Nexus** (it is required for the changes to take effect).



As a result, Deckhouse Platform images will be available at a URL as follows: `https://<NEXUS_HOST>:<REPOSITORY_PORT>/deckhouse/ee:<d8s-version>`.



Harbor configuration notes

Use the Harbor Proxy Cache feature.

1. Configure the registry access:
   - In the side menu, navigate to “Administration” → “Registries” and click “New Endpoint” to add a new endpoint for the registry.
   - In the “Provider” dropdown list, select “Docker Registry”.
   - In the “Name” field, enter an endpoint name of your choice.
   - In the “Endpoint URL” field, enter `https://registry.deckhouse.io`.
   - In the “Access ID” field, enter `license-token`.
   - In the “Access Secret” field, enter your Deckhouse Platform license key.
   - Set any remaining parameters as necessary.
   - Click “OK” to confirm creation of a new endpoint for the registry.

2. Create a new project:
   - In the side menu, navigate to “Projects” and click “New Project” to add a project.
   - In the “Project Name” field, enter a project name of your choice (for example, `d8s`). This name will be a part of the URL.
   - In the “Access Level” field, select “Public”.
   - Enable “Proxy Cache” and in the dropdown list, select the registry created earlier.
   - Set any remaining parameters as necessary.
   - Click “OK” to confirm creation of a new project.

Once Harbor is configured, Deckhouse Platform images will be available at a URL as follows: `https://your-harbor.com/d8s/deckhouse/ee:{d8s-version}`.

Manual loading of Deckhouse Platform images and vulnerability DB into a private registry

> **i** You can check the current status of versions in the release channels at releases.deckhouse.io.

- Download and install the Deckhouse CLI utility.
- Download Deckhouse Platform images to a dedicated directory using the `d8 mirror pull` command.

  By default, `d8 mirror pull` downloads only the current versions of Deckhouse Platform, vulnerability scanner databases (if included in the Deckhouse Platform edition), and officially delivered modules. For example, for Deckhouse Platform 1.59, only version 1.59.12 will be downloaded, as it is sufficient for upgrading the platform from 1.58 to 1.59.

  Run the following command (specify the edition code and license key) to download the current version images:

  ```
  d8 mirror pull \
    --source='registry.deckhouse.io/deckhouse/<EDITION>' \
    --license='<LICENSE_KEY>' /home/user/d8-bundle
  ```

  Where:

  - `--source`: Address of the Deckhouse container registry.
  - `<EDITION>`: Deckhouse Platform edition code (for example, `ee`, `se`, `se-plus`). By default, the `--source` parameter refers to the Enterprise Edition (`ee`) and can be omitted.
  - `--license`: Parameter for specifying the Deckhouse Platform license key for authentication in the official container registry.
  - `<LICENSE_KEY>`: Deckhouse Platform license key.
  - `/home/user/d8-bundle`: Directory where the image packages will be placed. It will be created if it does not exist.

  > **i** If the image download is interrupted, rerunning the command will resume the download, provided no more than one day has passed since the interruption.

  Example command to download all Deckhouse Platform EE versions starting from version 1.59 (specify your license key):

  ```
  d8 mirror pull \
  --license='<LICENSE_KEY>' \
  --since-version=1.59 /home/user/d8-bundle
  ```

  Example command to download the current Deckhouse Platform SE versions (specify your license key):

  ```
  d8 mirror pull \
  --license='<LICENSE_KEY>' \
  --source='registry.deckhouse.io/deckhouse/se' \
  /home/user/d8-bundle
  ```

  Example command to download Deckhouse Platform images from an external registry:

  ```
  d8 mirror pull \
  --source='corp.company.com:5000/sys/deckhouse' \
  --source-login='<USER>' --source-password='<PASSWORD>' /home/user/d8-bundle
  ```

  Example command to download the vulnerability scanner database package:

  ```
  d8 mirror pull \
  --license='<LICENSE_KEY>' \
  --no-platform --no-modules /home/user/d8-bundle
  ```

  Example command to download all available additional module packages:

  ```
  d8 mirror pull \
  --license='<LICENSE_KEY>' \
  --no-platform --no-security-db /home/user/d8-bundle
  ```

Example command to download module packages `stronghold` and `secrets-store-integration`:

```
d8 mirror pull \
--license='<LICENSE_KEY>' \
--no-platform --no-security-db \
--include-module stronghold \
--include-module secrets-store-integration \
/home/user/d8-bundle
```

Example command to download `stronghold` module with semver `^` constraint (allows updates that don't change the leftmost non-zero digit) from version 1.2.0:

```
d8 mirror pull \
--license='<LICENSE_KEY>' \
--no-platform --no-security-db \
--include-module stronghold@1.2.0 \
/home/user/d8-bundle
```

Example command to download `secrets-store-integration` module with semver `~` constraint (allows updates that don't change the last specified digit's place) from version 1.1.0:

```
d8 mirror pull \
--license='<LICENSE_KEY>' \
--no-platform --no-security-db \
--include-module secrets-store-integration@~1.1.0 \
/home/user/d8-bundle
```

Quote the `--include-module` flag value when it contains `>=` or `<=`. Unquoted, the shell treats it as an input/output redirection.

Example command to download the `console` module with semver `>=` constraint (any version from the specified one and above) from version 1.43.2:

```
d8 mirror pull \
--license='<LICENSE_KEY>' \
--no-platform --no-security-db \
--include-module "console@>=1.43.2" \
/home/user/d8-bundle
```

Example command to download exact version of `stronghold` module 1.2.5 and publish to all release channels:

```
d8 mirror pull \
--license='<LICENSE_KEY>' \
--no-platform --no-security-db \
--include-module stronghold@=v1.2.5 \
/home/user/d8-bundle
```

Other command parameters available for use:

- `--no-pull-resume`: Force the download to start from the beginning.
- `--force`: Overwrite existing packages if they conflict with the current pull operation.
- `--ignore-suspend`: Ignore suspended release channels and continue mirroring. Use with caution.
- `--no-platform`: Skip downloading the Deckhouse Platform image package (`platform.tar`).
- `--no-modules`: Skip downloading module packages (`module-*.tar`).
- `--no-security-db`: Skip downloading the vulnerability scanner database package (`security.tar`).
- `--no-packages`: Skip downloading Deckhouse packages.
- `--no-installer`: Skip downloading Deckhouse installer images.
- `--only-extra-images`: Pull only extra module images without pulling main module images.
- `--skip-vex-images`: Skip downloading VEX images.
- `--include-platform = CONSTRAINT`: Download Deckhouse Platform releases by a semver constraint. Cannot be used together with `--since-version` and `--deckhouse-tag`. Always quote the constraint value: `>` and `<` are shell redirections. Examples: `--include-platform ">=1.64 <=1.68"`, `--include-platform "~1.65.0"`, `--include-platform "^1.65.0"`, `--include-`

`platform "1.65.0"`, `--include-platform "=v1.65.3"`, or `--include-platform "=v1.65.3+stable"`.

- `--include-module` / `-i = name[@Major.Minor]`: Download only a specific set of modules using a whitelist (and, if needed, their minimum versions). Use multiple times to add more modules to the whitelist. These flags are ignored if used with `--no-modules`.

  The following syntax options are supported for specifying module versions. When using `>=` or `<=`, quote the whole flag value:

  - `module-name@1.3.0`: Pulls versions with semver ^ constraint (^1.3.0), including v1.3.0, v1.3.3, v1.4.1.
  - `module-name@~1.3.0`: Pulls versions with semver ~ constraint (>=1.3.0 <1.4.0), including only v1.3.0, v1.3.3.
  - `"module-name@>=1.3.0"`: Pulls versions with semver `>=` constraint, including the explicitly specified version and newer versions matching the constraint.
  - `"module-name@>=1.3.0 <=1.4.0"`: Pulls versions in the range, honoring both the lower and upper boundaries.
  - `module-name@=v1.3.0`: Pulls exact tag match v1.3.0, publishing to all release channels.
  - `module-name@=v1.3.0+stable`: Pulls exact tag match v1.3.0, publishing to the stable release channel.
  - `module-name@=bobV1`: Pulls exact tag match `bobV1`, publishing to all release channels.
- `--exclude-module` / `-e = name`: Skip downloading a specific set of modules using a blacklist. Use multiple times to add more modules to the blacklist. Ignored if `--no-modules` or `--include-module` is used;
- `--include-package = name[@version]`: Download only a specific set of packages using a whitelist. Versions and semver constraints use the same syntax as `--include-module`, including quoting rules.
- `--exclude-package = name[@version]`: Skip downloading a specific set of packages using a blacklist. Ignored if `--include-package` is used.
- `--modules-path-suffix`: Change the suffix of the path to the module repository in the main Deckhouse Platform registry. The default suffix is `/modules` (for example, the full path to the module repo will be `registry.deckhouse.io/deckhouse/EDITION/modules`).
- `--since-version=X.Y`: Download all Deckhouse Platform versions starting from the specified minor version. This option is ignored if the specified version is higher than the version on the Rock Solid release channel. Cannot be used with `--deckhouse-tag`.
- `--deckhouse-tag`: Download only the specific Deckhouse Platform version (regardless of release channels). Cannot be used with `--since-version`.
- `--installer-tag=TAG`: Download a specific Deckhouse installer tag. Defaults to `latest` if omitted.
- `--proxy-registry`: Pull from a proxy/cache registry that does not support the registry catalog API. Requires `--include-platform` unless the platform is skipped with `--no-platform`, and at least one `--include-module` unless modules are skipped with `--no-modules`. Cannot be used together with `--deckhouse-tag` or `--since-version`.
- `--dry-run`: Print what would be pulled without downloading images.
- `--verbose-summary`: Print a detailed summary for every module and package with resolved versions.
- `--gost-digest`: Calculate the checksum of the final Deckhouse Platform image bundle using the GOST R 34.11-2012 (Streebog) algorithm. The checksum will be displayed and written to a `.tar.gostsum` file in the folder containing the image tarball.
- `--source-login` and `--source-password`: Authentication data to access the external registry.
- `--tls-skip-verify`: Disable TLS certificate validation.
- `--insecure`: Interact with registries over HTTP.
- `--images-bundle-chunk-size=N`: The maximum file size (in GB) to split the image archive into. As a result, instead of one image archive, a set of CHUNK files will be created (for example, `d8.tar.NNNN.chunk`). To upload images from such a set, use the file name without the `.NNNN.chunk` suffix (for example, `d8.tar` for files `d8.tar.NNNN.chunk`).
- `--tmp-dir`: Path to a directory for temporary files used during image download and upload. All processing is done in this directory. It must have enough free disk space to hold the entire image bundle. Defaults to the `.tmp` subdirectory in the image bundle directory.

Additional configuration parameters for the `d8 mirror` command family are available as environment variables:

- `HTTP_PROXY` / `HTTPS_PROXY`: Proxy server URL for HTTP(S) requests not listed in the `$NO_PROXY` variable.
- `NO_PROXY`: Comma-separated list of hosts to exclude from proxying. Each entry can be an IP (`1.2.3.4`), CIDR (`1.2.3.4/8`), domain, or wildcard (`*`). IPs and domains may include a port (`1.2.3.4:80`). A domain matches itself and all subdomains. A domain starting with a `.` matches only subdomains. For example, `foo.com` matches `foo.com` and `bar.foo.com`; `.y.com` matches `x.y.com` but not `y.com`. The `*` disables proxying.
- `SSL_CERT_FILE`: Path to an SSL certificate. If set, system certificates are not used.
- `SSL_CERT_DIR`: Colon-separated list of directories to search for SSL certificate files. If set, system

certificates are not used. More info...
- `MIRROR_BYPASS_ACCESS_CHECKS`: Set this variable to `1` to disable credential validation for the registry.
- On the host with access to the container registry where Deckhouse Platform images should be uploaded, copy the downloaded Deckhouse Platform image bundle and install the Deckhouse CLI.
- Upload Deckhouse Platform images to the registry using the `d8 mirror push` command.

  The `d8 mirror push` command uploads images from all packages located in the specified directory. If you only want to push specific packages, you can either run the command separately for each TAR image bundle by specifying the direct path to it, or temporarily remove the `.tar` extension from unwanted files or move them out of the directory.

  Example command to upload image packages from the `/mnt/MEDIA/d8-images` directory (provide authentication data if required):

  ```
  d8 mirror push /mnt/MEDIA/d8-images 'corp.company.com:5000/sys/deckhouse' \
    --registry-login='<USER>' --registry-password='<PASSWORD>'
  ```

  Before uploading the images, make sure that the target path in the container registry exists (in the example, `/sys/deckhouse`) and that the account used has write permissions.

  If you're using Harbor, you won't be able to upload images to the root of a project. Use a dedicated repository within the project to store Deckhouse Platform images.
- After uploading the images to the registry, you can proceed with installing Deckhouse Platform. Use the getting-started guide.

  When running the installer, use the address of your own image registry (where the images were uploaded earlier) instead of the official public Deckhouse Platform container registry. For the example above, the installer image address will be `corp.company.com:5000/sys/deckhouse/install:stable` instead of `registry.deckhouse.io/deckhouse/ee/install:stable`.

  In the `registry` section of ModuleConfig `deckhouse`, use your registry address and authorization data (starting with Deckhouse Platform 1.75). The legacy method is to use InitConfiguration (parameters `imagesRepo`, `registryDockerCfg`).

Creating a cluster and running Deckhouse Platform without using release channels

⚠ This method should only be used if your private (isolated) registry does not contain images with release channel metadata.

If you need to install Deckhouse Platform with automatic updates disabled:

1. Use the installer image tag corresponding to the desired version. For example, to install release `v1.44.3`, use the image `your.private.registry.com/deckhouse/install:v1.44.3`.
2. Specify the appropriate version number in the `deckhouse.devBranch` parameter of InitConfiguration.

   ⚠ **Do not specify** the `deckhouse.releaseChannel` parameter in InitConfiguration.

If you want to disable automatic updates in an already running Deckhouse Platform installation (including patch updates), remove the `releaseChannel` parameter from the `deckhouse` module configuration.

Using a proxy server

Example steps for configuring a proxy server using Squid...

1. Prepare a server (or virtual machine). The server must be reachable from the required cluster nodes and must have internet access.
2. Install Squid (the following examples are for Ubuntu):

```
apt-get install squid
```

3. Create the Squid configuration file:

```
cat <<EOF > /etc/squid/squid.conf
auth_param basic program /usr/lib/squid3/basic_ncsa_auth /etc/squid/passwords
auth_param basic realm proxy
acl authenticated proxy_auth REQUIRED
http_access allow authenticated
# Specify the required port. Port 3128 is used by default.
http_port 3128
```

4. Create a username and password for proxy server authentication:

   Example for user `test` with password `test` (make sure to change it):

```
echo "test:$(openssl passwd -crypt test)" >> /etc/squid/passwords
```

5. Start Squid and enable it to start on server boot:

```
systemctl restart squid
systemctl enable squid
```

To configure Deckhouse Platform to work with a proxy server, use the `proxy` parameter of the ClusterConfiguration resource.

Example:

```
apiVersion: deckhouse.io/v1
kind: ClusterConfiguration
clusterType: Cloud
cloud:
  provider: OpenStack
  prefix: main
cri: "Containerd"
proxy:
  httpProxy: "http://user:password@proxy.company.my:3128"
  httpsProxy: "https://user:password@proxy.company.my:8443"
---
# control-plane-manager module settings.
# https://deckhouse.io/modules/control-plane-manager/configuration.html
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  enabled: true
  settings:
    kubernetesVersion: "Default"
    network:
      podSubnetCIDR: 10.111.0.0/16
      serviceSubnetCIDR: 10.222.0.0/16
      clusterDomain: "cluster.local"
```

Automatic proxy variable loading for users in CLI

Starting from version 1.67, the `/etc/profile.d/d8-system-proxy.sh` file is no longer configured in Deckhouse Platform to set proxy variables for users.
To automatically load proxy variables for users in CLI, use the NodeGroupConfiguration resource:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: profile-proxy.sh
spec:
  bundles:
    - '*'
  nodeGroups:
    - '*'
  weight: 99
  content: |
    {{- if .proxy }}
      {{- if .proxy.httpProxy }}
    export HTTP_PROXY={{ .proxy.httpProxy | quote }}
    export http_proxy=${HTTP_PROXY}
      {{- end }}
      {{- if .proxy.httpsProxy }}
    export HTTPS_PROXY={{ .proxy.httpsProxy | quote }}
    export https_proxy=${HTTPS_PROXY}
      {{- end }}
      {{- if .proxy.noProxy }}
    export NO_PROXY={{ .proxy.noProxy | join "," | quote }}
    export no_proxy=${NO_PROXY}
      {{- end }}
    bb-sync-file /etc/profile.d/profile-proxy.sh - << EOF
    export HTTP_PROXY=${HTTP_PROXY}
    export http_proxy=${HTTP_PROXY}
    export HTTPS_PROXY=${HTTPS_PROXY}
    export https_proxy=${HTTPS_PROXY}
    export NO_PROXY=${NO_PROXY}
    export no_proxy=${NO_PROXY}
    EOF
    {{- else }}
    rm -rf /etc/profile.d/profile-proxy.sh
    {{- end }}
```

Additional resources

- Getting started
- Supported Kubernetes and OS versions
- Integration with IaaS providers
- Installing Deckhouse Platform in a private environment
- Going to Production
- Global custom resources
- Global parameters

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

How to configure?

Deckhouse configuration

You can configure Deckhouse using:

- **Global settings**. Global settings are stored in the `ModuleConfig/global` custom resource. Global settings can be be thought of as a special `global` module that cannot be disabled.
- **Module settings**. Module settings are stored in the `ModuleConfig` custom resource; its name is

the same as that of the module (in kebab-case).
- **Custom resources.** Some modules are configured using the additional custom resources.

An example of a set of custom resources for configuring Deckhouse:

```
# Global settings.
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: global
spec:
  version: 1
  settings:
    modules:
      publicDomainTemplate: "%s.kube.company.my"
---
# The monitoring-ping module settings.
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: monitoring-ping
spec:
  version: 1
  settings:
    externalTargets:
    - host: 8.8.8.8
---
# Disable the dashboard module.
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: dashboard
spec:
  enabled: false
```

You can view the list of `ModuleConfig` custom resources and the states of the corresponding modules (enabled/disabled) as well as their statuses using the following command:

```
d8 k get moduleconfigs
```

Example output...

```
$ d8 k get moduleconfigs
NAME             ENABLED   VERSION   AGE     MESSAGE
deckhouse        true      1         12h
documentation    true      1         12h
global                     1         12h
prometheus       true      2         12h
upmeter          false     2         12h
```

To change the global Deckhouse configuration or module configuration, create or edit the corresponding `ModuleConfig` custom resource.

For example, this command allows you to configure the `upmeter` module:

```
d8 k edit moduleconfig/upmeter
```

Changes are applied automatically once the resource configuration is saved.

Modifying cluster configuration

⚠ To apply changes related to node configuration, you must run the `dhctl converge` command using the DP installer.
This command synchronizes the actual node state with the specified configuration.

General cluster parameters are defined in the ClusterConfiguration structure.

To modify these parameters, run the following command:

```
d8 system edit cluster-configuration
```

After saving the changes, DP will automatically reconcile the cluster state with the new configuration. Depending on the cluster size, this process may take some time.

Modifying protected parameters

Some cluster parameters are critical for cluster operation and cannot be changed in a running cluster by default. These parameters include:

- `podSubnetCIDR`: The Pod network address space.
- `podSubnetNodeCIDRPrefix`: The Pod network prefix size per node.
- `serviceSubnetCIDR`: the Service network address space.

Attempts to change these parameters will be blocked by the admission webhook with an error message.

✖ **Changing these parameters in a running cluster can lead to:**

- Complete loss of access to the Kubernetes API.
- Invalidation of TLS certificates.
- Necessity to restart all cluster nodes and control plane components.
- Data inconsistency if the process is interrupted.

It is recommended to recreate the cluster instead of changing these parameters.

If you absolutely must change these parameters (e.g., for testing or in exceptional circumstances), you can bypass the protection mechanism.

⚠ Even with the protection mechanism bypassed, there is **no guarantee** that the cluster will continue to function correctly after changing these parameters. Be prepared for the possibility of complete cluster failure and have a backup plan.

Modifying protected parameters using dhctl

Use the `dhctl` tool from the DP installer container with the `--yes-i-am-sane-and-i-understand-what-i-am-doing` flag.

It will automatically:

- Add the `deckhouse.io/allow-unsafe` annotation to the `d8-cluster-configuration` Secret;
- Open an editor to modify the configuration;
- Remove the annotation after you save the changes.

To change protected settings using `dhctl`, follow these steps:

1. Get the current DP version and edition from your cluster. To do this, run the DP installer container of the appropriate edition and version **on your local machine**:

   ```
   DH_VERSION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/version}')
   DH_EDITION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/edition}' | tr '[:upper:]'
   '[:lower:]')
   ```

2. Run the DP installer container (adjust the registry address if needed):

```
docker run --pull=always -it [<MOUNT_OPTIONS>] \
  registry.deckhouse.io/deckhouse/${DH_EDITION}/install:${DH_VERSION} bash
```

Where `<MOUNT_OPTIONS>` — mounting parameters for files in the installer container, such as:

- SSH access keys;
- Configuration file;
- Resources file, etc.

3. Inside the container, run the following command to edit the cluster configuration:

```
dhctl config edit cluster-configuration \
  --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> \
  --ssh-user=<USERNAME> \
  --ssh-host=<MASTER-NODE-HOST> \
  --yes-i-am-sane-and-i-understand-what-i-am-doing
```

Where:

- `<SSH_KEY_FILENAME>`: Your SSH private key filename;
- `<USERNAME>`: SSH user with sudo privileges on the target master node of the cluster;
- `<MASTER-NODE-HOST>` — master node IP address or hostname.

4. Edit the configuration in the opened editor, save, and exit the editor.

Manually changing protected parameters

Manually edit the configuration:

1. Add the `deckhouse.io/allow-unsafe` annotation to the `d8-cluster-configuration` Secret:

```
d8 k -n kube-system annotate secret d8-cluster-configuration deckhouse.io/allow-unsafe="true"
```

2. Get the current configuration, decode it, and save to a file:

```
d8 k -n kube-system get secret d8-cluster-configuration \
  -o jsonpath='{.data.cluster-configuration\.yaml}' | base64 -d > cluster-config.yaml
```

3. Edit the `cluster-config.yaml` file with your preferred editor:

```
vi cluster-config.yaml
```

4. Encode the edited configuration and update the Secret:

```
d8 k -n kube-system patch secret d8-cluster-configuration \
  --patch="{\"data\":{\"cluster-configuration.yaml\":\"$(base64 -w0 < cluster-
config.yaml)\"}}"
```

5. Remove the annotation after applying the changes:

```
d8 k -n kube-system annotate secret d8-cluster-configuration deckhouse.io/allow-unsafe-
```

6. Delete the temporary file:

```
rm cluster-config.yaml
```

⚠ If you forget to remove the `deckhouse.io/allow-unsafe` annotation, this protection mechanism will remain disabled, leaving your cluster vulnerable to accidental configuration changes.

Viewing current configuration

DP is managed through global settings, module configurations, and various custom resources.

1. To view global settings, run:

   ```
   d8 k get mc global -o yaml
   ```

2. To view the status of all modules (available in Deckhouse version 1.47+):

   ```
   d8 k get modules
   ```

3. To view the configuration of the `user-authn` module:

   ```
   d8 k get moduleconfigs user-authn -o yaml
   ```

Configuring the module

The module is configured using the ModuleConfig custom resource , whose name is the same as the module name (in kebab-case). The ModuleConfig custom resource has the following fields:

- `metadata.name` — the name of the module in kebab-case (e.g, `prometheus`, `node-manager`).
- `spec.version` — version of the module settings schema. It is an integer greater than zero. This field is mandatory if `spec.settings` is not empty. You can find the latest version number in the module's documentation under *Settings*.
  - Deckhouse is backward-compatible with older versions of the module's settings schema. If an outdated version of the schema is used, a warning stating that you need to update the module's schema will be displayed when editing or viewing the custom resource.
- `spec.settings` — module settings. This field is optional if the `spec.enabled` field is used. For a description of the available settings, see *Settings* in the module's documentation.
- `spec.enabled` — this optional field allows you to explicitly enable or disable the module. The module may be enabled by default based on the bundle in use if this parameter is not set.

> **i** Deckhouse doesn't modify ModuleConfig resources. As part of the Infrastructure as Code (IaC) approach, you can store ModuleConfigs in a version control system and use Helm, `d8 k`, and other familiar tools for deploy.

An example of a custom resource for configuring the `kube-dns` module:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: kube-dns
spec:
  version: 1
  settings:
    stubZones:
    - upstreamNameservers:
      - 192.168.121.55
      - 10.2.7.80
      zone: directory.company.my
    upstreamNameservers:
    - 10.2.100.55
    - 10.2.200.55
```

Some modules can also be configured using custom resources. Use the search bar at the top of the page or select a module in the left menu to see a detailed description of its settings and the custom resources used.

Enabling and disabling the module

> **i** Depending on the bundle used, some modules may be enabled by default.

To enable/disable the module, set `spec.enabled` field of the ModuleConfig custom resource to `true` or

`false`. Note that this may require you to first create a ModuleConfig resource for the module.

Here is an example of disabling the `user-authn` module (the module will be turned off even if it is enabled as part of a module bundle):

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: user-authn
spec:
  enabled: false
```

To check the status of the module, run the `d8 k get moduleconfig <MODULE_NAME>` command:

Example:

```
$ d8 k get moduleconfig user-authn
NAME         ENABLED   VERSION   AGE   MESSAGE
user-authn   false     1         12h
```

Module bundles

Depending on the bundle used, modules may be enabled or disabled by default.

⚠ The table below describes module bundles only for built-in modules of Deckhouse Platform. Modules from sources are not included in this table.

Bundle name	List of modules, enabled by default
Default	• node-local-dns • admission-policy-engine • cert-manager • chrony • control-plane-manager • dashboard • deckhouse • documentation • deckhouse-tools • descheduler • extended-monitoring • kube-dns • kube-proxy • monitoring-custom • monitoring-deckhouse • monitoring-kubernetes-control-plane • monitoring-kubernetes • monitoring-ping • multitenancy-manager • namespace-configurator • registry-packages-proxy • node-manager • operator-prometheus • prometheus • prometheus-metrics-adapter • secret-copier • terraform-manager • user-authn • user-authz • vertical-pod-autoscaler • registry

Bundle name	List of modules, enabled by default
Managed	• admission-policy-engine • cert-manager • dashboard • deckhouse • documentation • deckhouse-tools • descheduler • extended-monitoring • monitoring-custom • monitoring-deckhouse • monitoring-kubernetes • monitoring-ping • multitenancy-manager • namespace-configurator • operator-prometheus • prometheus • prometheus-metrics-adapter • secret-copier • user-authz • vertical-pod-autoscaler
Minimal	• deckhouse

Things to keep in mind when working with the Minimal module set

⚠ **Note** that several basic modules are not included in the `Minimal` set of modules (for example, the CNI module).

Deckhouse Platform with the `Minimal` module set and no basic modules included will only be able to operate in an already deployed cluster.

To install DP with the `Minimal` module set, enable at least the following modules by specifying them in the installer configuration file:

- cloud provider module (for example, `cloud-provider-aws` for AWS), in a case of deploying a cloud cluster;
- `cni-cilium` or another CNI control module (if necessary);
- `control-plane-manager`;
- `kube-dns`;
- `node-manager`;
- `registry-packages-proxy`;
- `terraform-manager`, in a case of deploying a cloud cluster.

Accessing documentation for the current version

The documentation for the running version of Deckhouse is available at `documentation.<cluster domain>`,
where `<cluster domain>` is the DNS name generated according to the template specified in the `modules.publicDomainTemplate` parameter of the global configuration.

⚠ Documentation is available only if the `documentation` module is enabled in the cluster.
It is enabled by default, except when using the `Minimal` delivery bundle.

Managing placement of Deckhouse components

Advanced scheduling

If no `nodeSelector/tolerations` are explicitly specified in the module parameters, the following strategy is used for all modules:

1. If the `nodeSelector` module parameter is not set, then Deckhouse will try to calculate the

`nodeSelector` automatically. Deckhouse looks for nodes with the specific labels in the cluster (see the list below). If there are any, then the corresponding `nodeSelectors` are automatically applied to module resources.
2. If the `tolerations` parameter is not set for the module, all the possible tolerations are automatically applied to the module's Pods (see the list below).
3. You can set both parameters to `false` to disable their automatic calculation.
4. If there are no nodes with a specific role in the cluster and `nodeSelector` is automatically selected (see point 1), `nodeSelector` will not be specified in the module resources. The module will then use any node with non-conflicting `taints`.

You cannot set `nodeSelector` and `tolerations` for modules:

- running on all cluster nodes (such as `cni-flannel` or `monitoring-ping`);
- running on all master nodes (such as `prometheus-metrics-adapter` or `vertical-pod-autoscaler`).

Module features that depend on its type

> **i** Below is the basic (general) logic for automatically selecting nodes to place module components when no explicit `nodeSelector` and `tolerations` values are set in the module settings. Some modules may extend or override this logic (for example, by using Kubernetes mechanisms such as affinity/anti-affinity, `topologySpreadConstraints`, or their own node selection rules). See the relevant module documentation for details.

If `nodeSelector` is not explicitly set in the module configuration, Deckhouse determines the placement of components automatically. The order in which nodes are selected depends on the module type.

- The `console` module:
  - If `nodeSelector` is not explicitly set in the module configuration, module components are placed on control plane nodes.
  - If control plane nodes are not available for such placement, nodes with the `node-role.deckhouse.io/system` label are used.
- The *monitoring*-related modules (`operator-prometheus`, `prometheus` and `vertical-pod-autoscaler`):
  - Deckhouse examines nodes to determine a `nodeSelector` in the following order:
    1. It checks if a node with the `node-role.deckhouse.io/MODULE_NAME` label is present in the cluster.
    2. It checks if a node with the `node-role.deckhouse.io/monitoring` label is present in the cluster.
    3. It checks if a node with the `node-role.deckhouse.io/system` label is present in the cluster.
  - Tolerations to add (note that tolerations are added all at once):
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"MODULE_NAME"}` (e.g., `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"operator-prometheus"}`).
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"monitoring"}`.
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"system"}`.
- The *frontend*-related modules (`ingress-nginx` only):
  - Deckhouse examines nodes to determine a `nodeSelector` in the following order:
    1. It checks if a node with the `node-role.deckhouse.io/MODULE_NAME` label is present in the cluster.
    2. It checks if a node with the `node-role.deckhouse.io/frontend` label is present in the cluster.
  - Tolerations to add (note that tolerations are added all at once):
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"MODULE NAME"}`.
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"frontend"}`.
- Other modules:
  - Deckhouse examines nodes to determine a `nodeSelector` in the following order:
    1. It checks if a node with the `node-role.deckhouse.io/MODULE_NAME` label is present in the cluster (e.g., `node-role.deckhouse.io/cert-manager`).
    2. It checks if a node with the `node-role.deckhouse.io/system` label is present in the cluster.
  - Tolerations to add (note that tolerations are added all at once):
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"MODULE_NAME"}` (e.g., `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"network-gateway"}`).
    - `{"key":"dedicated.deckhouse.io","operator":"Equal","value":"system"}`.

DP components registry

This section describes the settings for interacting with the DP component registry.

This section covers configuring DP interaction with the registry in a running cluster. If you need information about working with the registry during cluster installation, go to the “Platform installation” section.

The capabilities and processes for configuring the DP component registry depend on how the cluster is managed. In clusters fully managed by DP, configuration management is handled by the `registry` module (for more details, see the section “Managing the registry in DP-managed clusters”). In Managed Kubernetes clusters, the `helper change-registry` is used; the `registry` module is not used (for more details, see the section “Switching a Managed Kubernetes cluster to use third-party registry”).

Managing the registry in Deckhouse Platform-managed clusters

In clusters fully managed by Deckhouse Platform (Deckhouse Platform), you can configure the download paths:

- images of Deckhouse Platform component containers;
- images of containers from additional repositories (vendor repositories or your own).

The pull paths for container images are managed using the `registry` module.

Implementations of container image pull path management

Deckhouse Platform supports two implementations of the `registry` module for managing container image download paths:

- **The current implementation**. Used starting with Deckhouse Platform 1.78. Container image pull paths are configured through the `registry` ModuleConfig. The implementation is described in the “Current implementation” section.
- **The v1 implementation**. Used in Deckhouse Platform up to and including 1.77. The Deckhouse Platform component registry is configured through the `deckhouse` ModuleConfig. The implementation is described in the “V1 implementation” section.

The two implementations never manage a cluster at the same time: only one of them is active at any given moment. A cluster that has never run the v1 implementation uses the current one right away. A cluster running the v1 implementation keeps using it until the conditions for switching to the current one are met — control is then handed over to the current implementation automatically, with no separate command. The switching conditions and step-by-step instructions for each mode of the v1 implementation are given in the “Migrating from the v1 implementation to the current one” section

below.

⚠ Starting from version 1.78 Deckhouse Platform no longer uses the v1 implementation of the module. The cluster switches to the current implementation after the upgrade to Deckhouse Platform 1.78, and the preparation for that is done before the upgrade, on Deckhouse Platform 1.77.

✖ Prepare your cluster in advance for the transition to the current implementation. The update to Deckhouse Platform 1.78, which no longer contains the v1 implementation, is blocked as long as the cluster is running in `Proxy` or `Local` mode of the v1 implementation, or in `Direct` mode without a configured `registry` in ModuleConfig.

You can find out which implementation of the module the cluster uses by checking whether the `registry-v2-switch` secret exists. To do this, follow the instructions.

Current implementation

In the current implementation, container image pull paths are configured through the `registry` ModuleConfig.

Modes of operation

In the current implementation, Deckhouse Platform supports the following container image pull path management modes (the mode is set with the `mode` parameter in the `registry` ModuleConfig):

- `Unmanaged` (the default mode). The `registry` module does not manage the pull paths of Deckhouse Platform component images: the cluster pulls images from the registry it was installed with (the registry is specified during cluster bootstrap in the `deckhouse` parameter in InitConfiguration).
- `Managed`. In this mode, the `registry` module manages the pull paths for container images. The following independent settings are used in this mode:
  - `primary.upstream` — the container image registry DP component images are pulled from. If the parameter is not set, the cluster is considered isolated (air-gapped). In an isolated cluster, the only source of container images is the in-cluster cache, which is filled with the `d8 mirror push` command.
  - `storage.cache` — controls the in-cluster cache on the master nodes. If the parameter is enabled, a container image registry is deployed on the master nodes, and all nodes pull images from it, with the upstream registry staying a fallback path while the cache is being filled.

The `primary.upstream` and `storage.cache` parameters together cover every supported configuration:

primary.upstream	storage.cache	What the cluster does
Set	`false`	Nodes pull images directly from the upstream registry. Nothing is deployed on the master nodes
Set	`true`	The cache acts as a pass-through: filled from the upstream registry on demand and ahead of time
Not set	`true`	The cluster is isolated (air-gapped). The cache is the only source. The `d8 mirror push` command is used to fill it
Not set	`false`	The configuration is rejected: nodes would have nowhere to pull images from

You can reconfigure cache enablement and disablement, change the image storage location, and change your credentials at any time. However, when removing an upstream registry to transition to an isolated state, the module waits until the entire expected set of images appears in the intra-cluster

cache—only then does it stop using the upstream registry. If the upstream registry stopped being used before the in-cluster cache held the whole expected image set, nodes could be left with no image source while the cache is being filled.

For more details on the architecture of the current implementation (the node agent, the in-cluster cache, leader replica election, how isolated clusters work), see the `registry` module documentation.

Installer behavior when no container image registry is configured

The installer creates the `registry` ModuleConfig with `mode: Managed` and `primary.upstream` pointing to the public Deckhouse Open/CE registry `registry.deckhouse.io/deckhouse/ce`, and warns about it in its output when the installation configuration specifies no container image registry in any of the following places:

- InitConfiguration
- The `registry` section of the `deckhouse` ModuleConfig
- The `registry` ModuleConfig (the ModuleConfig is absent)

This applies only when the installation configuration contains a ClusterConfiguration and the container runtime is managed by Deckhouse Platform (`defaultCRI` is `Containerd` or `ContainerdV2`). In a Managed Kubernetes cluster (without ClusterConfiguration) and with `defaultCRI: NotManaged`, the installer does not create this ModuleConfig.

Under the same conditions, the installer rejects a configuration in which the `registry` ModuleConfig sets `mode: Unmanaged` (or omits `mode`, which means the same) or `enabled: false` and no registry is specified elsewhere. In this case, the nodes would have nowhere to pull images from. Specify the registry from which nodes pull images directly in one of the following ways:

- Via the `deckhouse` parameter in InitConfiguration (`imagesRepo` and `registryDockerCfg`).
- By setting `mode: Managed` with `primary.upstream` in the `registry` ModuleConfig. A private or mirror registry populated with `d8 mirror push` can serve as `primary.upstream`. To install an air-gapped cluster from an image bundle instead, set `enabled: true` and `mode: Managed` with `storage.cache: true` and `storage.source`, without `primary.upstream`, and pass the bundle to the installer with the `--img-bundle-path` flag.

The installer also rejects a `registry` ModuleConfig that specifies `primary` or `storage` without `mode: Managed`, as the module schema does: in the default `Unmanaged` mode, these settings have no effect.

Garbage collection

Deckhouse Platform has a garbage collection mechanism for the container image registry. Each registry replica runs the operation on its own store. Garbage collection does not block image pulls from the store.

Garbage collection starts in the following cases:

- Once a day at night (at 3:17 a.m. Moscow Standard Time). Garbage collection is enabled by default. It is scheduled at night because filling the replica’s store is paused during the operation. A `d8 mirror push` command started during garbage collection can therefore fail.
- When all replicas have received a new image set: after a Deckhouse Platform update or after the `registry` module is enabled or updated.
- When the image store refuses writes because it has exceeded its designated storage limit or reached the reserved free space threshold on its filesystem.

For details about when garbage collection starts and what happens during the operation, see the documentation for the `registry` module.

You can also start garbage collection manually.

If you need to disable or configure garbage collection, use the `storage.garbageCollection` parameter in the `registry` ModuleConfig.

> ⚠ Disabling garbage collection only makes sense if the storage uses a disk with sufficient capacity to accommodate unlimited storage growth.

To view the status and schedule of garbage collection, use the commands below.

- List the recent collections — what started them, how they went, and how much they freed. A finished collection is kept for a day:

  ```
  d8 k get registryoperation -o wide
  ```

- View the time of the last garbage collection on each replica and any errors, if any:

```
d8 k get registrystorage registry -o jsonpath='{.status.replicas}' | jq \
  'map({node, collectedAt, collectionError})'
```

- View the current garbage collection schedule:

```
d8 k get registrystorage registry -o jsonpath='{.spec.garbageCollection}' | jq
```

Garbage collection is the only mechanism that removes data from the registry. Each Deckhouse Platform release adds new images, so without garbage collection, the storage of a cluster that has been running for a long time will eventually fill up, and new images will no longer be added to it. However, for example, an isolated cluster with a full storage cannot be updated.

Collection removes the images of the releases the cluster has moved past. It keeps:

- the deployed release and the previous one, so that a rollback does not have to re-download anything;
- everything newer than the deployed release — an update in progress or, in an air-gapped cluster, a release pushed on purpose;
- every tag that is not a version: release channel names such as `stable`, floating tags, anything pushed by hand. The collector cannot know what these mean, so it does not touch them.

It also removes blobs that no image references, such as those left by an interrupted fill or by a collection whose cleanup failed. A collection removes them even when there are no images to delete.

The collector is deliberately cautious. In an isolated cluster, deleting a blob that is still needed is unrecoverable without another `d8 mirror push`, while keeping an unneeded one merely costs disk space. So a run that cannot determine what to keep — for example, when no deployed release is found — does nothing at all.

For more information about how the garbage collector works, see the `registry` module documentation.

Running garbage collection manually

> **i** Garbage collection created manually runs even when automatic collection is disabled.

Before starting garbage collection manually, assess whether it is needed. See the “Is a collection worth running now?” section of the `registry` module FAQ.

To start garbage collection manually, create a RegistryOperation object of type `GarbageCollection`:

```
d8 k create -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: RegistryOperation
metadata:
  generateName: gc-manual-
spec:
  type: GarbageCollection
  cause: Free space before pushing a new release.
EOF
```

It runs even when automatic collection is disabled. Replicas collect one at a time, exactly as on schedule. A replica starts only when its store is not being written to: while the cache is being filled or a `d8 mirror push` is in progress, the replica waits, and the reason is shown in `status.replicas[].reason`. A store that refuses writes is not waited for: a fill cannot go on until the collection frees room. A replica still held back an hour after the operation was accepted fails with the reason `DeadlineExceeded`. An operation created while another one is running fails with the reason `AnotherOperationActive`.

Follow the operation and see what it removed:

```
d8 k get registryoperation <NAME> -o jsonpath='{.status}' | jq \
  '{phase, reason, message, garbageCollection}'
```

To cancel an operation, including one a replica is already running, set the cancel label on it:

```
d8 k label registryoperation <NAME> registry.deckhouse.io/cancel=true
```

What was deleted before the cancellation stays deleted.

If a replica's `syncer` container stops answering while the replica collects or waits for its turn, for example because its master went `NotReady`, the replica fails with the reason `ReplicaLost`, so that the operation does not hold every collection after it for a day:

- A replica that was collecting, once it has not held the Lease `registry-storage-gc` in the `d8-system` namespace for five minutes.
- A replica that was waiting, once its node has not been `Ready` for ten minutes. A master that is back sooner keeps its replica's turn.

A replica that waits on a node that stays `Ready` while its `syncer` does not answer is released by the cancel label, by the 24-hour timeout (the reason `TimedOut`), or by deleting the operation:

```
d8 k delete registryoperation <NAME>
```

Additional container image registries

`primary.upstream` is the only image registry configured in the `registry` ModuleConfig itself. It is used to pull DP component images. If you need additional registries (a vendor's, one needed by some module, or your own), add them using the RegistryUpstream custom resource.

An example of adding an additional registry is given in the "Adding an additional container image registry" section.

Requirements for using the current implementation

Before enabling container image pull path management with the current implementation of the `registry` module, make sure the cluster meets the following requirements:

- Nodes use containerd or containerd v2, set with the `defaultCRI` parameter in ClusterConfiguration.
- The cluster is fully managed by Deckhouse Platform. The current implementation of the module does not work in Managed Kubernetes clusters — use switching to a third-party registry instead.

Examples of configuring the current implementation

⚠ If a module's image wasn't pulled again and the module wasn't reinstalled while switching to the current implementation, follow the instructions to resolve the issue.

Configuring pull path management for Deckhouse Platform component images

To enable pull path management for DP component container images with the `registry` module, enable the module in `Managed` mode and specify the image registry details in `primary.upstream`. Example of the `registry` ModuleConfig:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: registry
spec:
  version: 1
  enabled: true
  settings:
    mode: Managed
    primary:
      upstream:
        host: registry.deckhouse.io
        path: /deckhouse/ee
        scheme: HTTPS
        auth:
          license: <LICENSE_KEY> # Replace with your license key.
```

Instead of creating the ModuleConfig from scratch, you can use a ready-made one. The module publishes a ready-made configuration for your cluster, with the address, path, scheme, certificate authority, and credentials of the registry the cluster is already pulling images from.

To obtain a preconfigured ModuleConfig, run the following command:

```
d8 k -n d8-system get secret registry-suggested-config -o jsonpath='{.data.registry-mc\.yaml}'
| base64 -d
```

Review it and apply it — this avoids mistakes that are easy to make when retyping these values by hand (a truncated path, the wrong certificate authority, and so on).

To see how the change takes effect, use the commands below.

- View the state of the image registry configuration in Deckhouse Platform:

  ```
  d8 k get registryconfig registry -o jsonpath='{.status}' | jq
  ```

- Verify the implementation of the registry configuration on the nodes to ensure that everything has been successfully configured and to determine which backends are currently active:

  ```
  d8 k get registrynodes -o custom-columns=\
  NODE:.metadata.name,APPLIED:.status.observedGeneration,OK:.status.reconciled,BACKENDS:.status.activeBa
  ckends
  ```

Enabling the in-cluster cache

> **i** The in-cluster cache uses the disks of the master nodes and works in both static and cloud clusters managed by Deckhouse Platform. In a cloud cluster, that is the master node's root disk unless a separate disk is mounted at the cache directory (`/opt/deckhouse/registry`, or `/var/lib/deckhouse/registry` when the master NodeGroup has `systemType: DeckhouseEngine`). Size that disk for `storage.size` and the reserve the store keeps free for the node, on top of what the node itself uses. For details, see "Requirements for using the module" in the `registry` module documentation.

To enable the in-cluster cache, add the `storage.cache` setting to the `registry` ModuleConfig and specify the storage size:

```
spec:
  settings:
    mode: Managed
    primary:
      upstream:
        host: registry.deckhouse.io
        path: /deckhouse/ee
        auth:
          license: <LICENSE_KEY> # Replace with your license key.
    storage:
      cache: true
      size: 50Gi
```

Nothing on the nodes is reconfigured: the container runtime already turns to the agent for any registry, and the agent starts using the cache first. The upstream registry is used as a fallback path. So missing data in the cache right after the cache is enabled means a slower pull, not a failed one.

To check how full the in-cluster cache is, use the following command:

```
d8 k get registrystorage registry -o jsonpath='{.status}' | jq
'{phase,fill,leader,allReplicasFull}'
```

Turning the cache off is the same change in reverse, and just as safe. The blobs on disk are left untouched, and when the cache is turned on again, it is refilled from the data already accumulated. If you turn the in-cluster cache off and do not plan to turn it on again, remove the leftover cache data from the cluster nodes. For detailed instructions, see the `registry` module FAQ.

Switching the cluster into an air-gapped state

An isolated cluster has no upstream registry (it is not set in `primary.upstream`). For such a cluster, the cache is the only source of images. The `d8 mirror push` command is used to fill the storage. To verify that all required images are present in the cache, specify the expected set of images in the `storage.source` parameter

To move the cluster to air-gapped, follow these steps:

1. Pull the images on a machine that has internet access:

   ```
   d8 mirror pull --license <LICENSE_KEY> ./d8-bundle
   ```

2. Push them into the cluster through the publication endpoint:

   ```
   PUSH_SECRET=$(d8 k -n d8-system get secret registry-storage-push -o json)
   d8 mirror push ./d8-bundle registry.example.com/system/deckhouse \
     --registry-login "$(echo "$PUSH_SECRET" | jq -r .data.username | base64 -d)" \
     --registry-password "$(echo "$PUSH_SECRET" | jq -r .data.password | base64 -d)"
   ```

   The publication endpoint (the `registry` domain built from `publicDomainTemplate`, `registry.example.com` here) exists only while the cache is enabled, `publicDomainTemplate` is set and the `cert-manager` module is enabled. For details, see “Air-gapped clusters” in the `registry` module documentation.

3. Describe the expected image set in the cache and remove the `upstream` from the `registry` ModuleConfig:

   ```
   spec:
     settings:
       mode: Managed
       storage:
         cache: true
         size: 50Gi
         source:
           bundleRef: d8-mirror-bundle
           expectedDigests: 459
   ```

The upstream registry is removed from the nodes not at the moment the configuration is edited, but once the cache leader holds the whole expected image set — otherwise all nodes could be left with no image source. When the upstream is removed, the registry restarts, and the RegistryStorage resource may briefly report `Failed`: this is expected, wait for it to return to `Ready`. To check the status of the transition, use the following commands.

Check whether the cache leader holds the whole expected image set:

```
d8 k get registrystorage registry -o jsonpath='{.status}' | jq '{safeToDropUpstream,fill}'
```

Check whether the cluster is isolated (while `effectiveUpstream` is set, the cluster is using it; if it is empty, the cluster is isolated):

```
d8 k get registryconfig registry -o jsonpath='{.status.effectiveUpstream}' | jq
```

Adding an additional container image registry

> **i** Requests to additional registries are always routed through the node agent (credentials and the certificate authority are kept in one place), and images from them are not cached.

To add an additional image registry (not for DP system components), use the RegistryUpstream resource. Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: RegistryUpstream
metadata:
  name: virtualization-images
spec:
  match: images.virtualization.example.com
  upstream:
    host: vendor.example.com
    path: /virtualization
    auth:
      username: robot
      password: <PASSWORD>
```

After creating the RegistryUpstream, check that it has been accepted. The object is rejected in the following cases:

- It conflicts with the primary registry or another object claiming the same `match` value. The object is rejected rather than merged.
- It contains an invalid field, such as a `ca` that is not a PEM certificate.
- Adding the object exceeds either of the following limits:
  - Settings from no more than 256 RegistryUpstream objects can be applied at a time.
  - The combined size of the accepted objects' `spec` fields in JSON format must not exceed 256 KiB.

To check whether the object has been accepted, run the following command:

```
d8 k get registryupstreams -o custom-columns=\
NAME:.metadata.name,MATCH:.spec.match,ACCEPTED:.status.conditions[0].status,REASON:.status.conditions[0].rea
son
```

In the example above, after the additional registry is added, image pull requests for `images.virtualization.example.com` are routed by the agent on every node to `vendor.example.com/virtualization`, with the credentials and certificate authority held by the cluster rather than by each workload individually. Nothing on the nodes is reconfigured for this.

Pulling from a private container image registry without declaring it

To load images from a storage module that is unknown to the module, no additional declarations are required. The node agent proxies such requests untouched, along with whatever credentials the request already carried. So an ordinary `imagePullSecret` works exactly as it does in a cluster where the module was never enabled.

To create a secret with the credentials of the private container image registry, run:

```
d8 k create secret docker-registry my-private-registry \
  --docker-server=private.example.com \
  --docker-username=robot \
  --docker-password=<PASSWORD>
```

To use this secret when pulling images, specify it in the pod's `imagePullSecrets`:

```
apiVersion: v1
kind: Pod
metadata:
  name: example
spec:
  imagePullSecrets:
  - name: my-private-registry
  containers:
  - name: app
    image: private.example.com/team/app:v1
```

It is worth creating a RegistryUpstream for the registry only if you want the cluster to hold the credentials instead of every workload doing so individually, or if the registry needs a certificate authority the nodes do not have.

Turning off pull path management

To turn off pull path management, set `mode: Unmanaged` in the `registry` ModuleConfig:

```
spec:
  settings:
    mode: Unmanaged
```

After `mode: Unmanaged` is set, pull path management through the `registry` module is turned off. The cluster resumes downloading images from the container registry specified in the `deckhouse-registry` secret—that is, from the same source from which images were downloaded before the module was enabled. Cache data on the master nodes is deliberately preserved: when pull path management is turned on again, the cache is topped up only with the images missing from the container image registry rather than filled from scratch. If the cache is no longer needed, free up the space it occupies by following the instructions in the `registry` module documentation.

V1 implementation

> ⚠ The v1 implementation of the `registry` module described below was used in Deckhouse Platform up to and including 1.77. Deckhouse Platform 1.78 no longer contains it. For new clusters, and for existing ones at the first opportunity, use the current implementation.

In the v1 implementation, Deckhouse Platform supports several management modes for the platform component registry settings: `Unmanaged`, `Direct`, `Proxy`, and `Local`. In `Direct`, `Proxy`, and `Local` modes, a fixed virtual address is used to access the Deckhouse Platform component registry. This eliminates the need to restart all control plane components and re-download images when the platform component registry changes.

In `Unmanaged` mode, no virtual address is used. The external registry is accessed directly: if the registry changes, all Deckhouse Platform components are restarted.

Switching between modes and registries is done via the `deckhouse` ModuleConfig. The switch occurs automatically (see the switching examples below for more details).

The architecture of the v1 implementation's modes is described in the "Registry module" section.

Features of the Deckhouse Platform component registry settings management modes:

- `Direct`: Provides direct access to an **external** registry via the fixed virtual address `registry.d8-system.svc:5001/system/deckhouse`. The fixed address prevents images from being re-downloaded and components from being restarted when registry parameters change.

- `Proxy`: Uses an **internal caching proxy registry** that accesses an **external** registry. The caching proxy registry runs on control-plane (master) nodes. This mode reduces the number of requests to the external registry by caching images. The internal registry is accessed via the fixed virtual address `registry.d8-system.svc:5001/system/deckhouse`, similar to the `Direct` mode.
- `Local`: Uses a local **internal** registry, with the registry running on control-plane (master) nodes. This mode allows the cluster to operate in an isolated environment. The internal registry is accessed via the fixed virtual address `registry.d8-system.svc:5001/system/deckhouse`, similar to the `Direct` and `Proxy` modes.
- `Unmanaged` (configurable mode): Works without an internal registry. No virtual address is used. The **external** registry is accessed directly.

⚠ This document refers to the configurable `Unmanaged` mode (of the v1 implementation of the `registry` module) and the non-configurable `Unmanaged` mode (the fully deprecated format, without the `registry` module).

The non-configurable `Unmanaged` mode does not use the `registry` module at all (for example, in Managed Kubernetes clusters). The Deckhouse Platform component registry configuration parameters are set during cluster installation or, in a deployed cluster, using the `helper change registry` utility (deprecated).

Restrictions on Deckhouse Platform component registry settings

There are a number of restrictions and considerations regarding cluster installation, the v1 implementation's usage conditions, and switching between its modes.

Restrictions during cluster installation

The following restrictions apply when installing a cluster:

- A new cluster cannot be installed with the v1 implementation: the installer refuses `Proxy` and `Local` in the `deckhouse` ModuleConfig. A `Direct` section there is read only as the registry address, and the cluster is installed in `Unmanaged` mode. To install a cluster whose pull path the `registry` module manages, use the current implementation.
- To launch a cluster in the non-configurable `Unmanaged` mode (Legacy, without using the `registry` module), registry parameters must be specified in InitConfiguration.

Operating conditions restrictions

To manage Deckhouse Platform component registry settings using the v1 implementation, the following conditions must be met:

- CRI containerd or containerd v2 must be used on cluster nodes. To configure CRI, refer to the ClusterConfiguration configuration.
- The cluster must be fully managed by Deckhouse Platform. In Managed Kubernetes clusters, managing Deckhouse Platform component registry settings via the `registry` module is not available.

Restrictions on mode switching

Mode switching restrictions are as follows:

- Changing registry parameters and switching modes is only available after the bootstrap phase is fully complete.
- For the first switch, you must migrate user registry configurations. For more details, see the "Registry Module: FAQ" section.
- Switching to the non-configurable `Unmanaged` mode (without using the `registry` module) is only available from the configurable `Unmanaged` mode. For more details, see the "Registry Module: FAQ" section.

Examples of switching between the v1 implementation's modes

⚠ If a module's image wasn't pulled and the module wasn't reinstalled during the switch, follow the instructions to resolve the issue.

Switching to Unmanaged mode

To switch an already running cluster to `Unmanaged` mode, follow these steps:

✖ Changing the registry in `Unmanaged` mode will restart all Deckhouse Platform components.

1. Make sure the `registry` module is enabled and running. To do this, execute the following command:

   ```
   d8 k get module registry -o wide
   ```

   Example output:

   ```
   NAME       WEIGHT ...  PHASE   ENABLED   DISABLED MESSAGE   READY
   registry   38     ...  Ready   True                         True
   ```

2. Ensure the Deckhouse Platform queue is empty and has no errors:

   ```
   d8 system queue list
   ```

   Example output:

   ```
   Summary:
   - 'main' queue: empty.
   - 107 other queues (0 active, 107 empty): 0 tasks.
   - no tasks to handle.
   ```

3. Set the `Unmanaged` mode settings in the ModuleConfig `deckhouse`. If you are using a registry other than `registry.deckhouse.io`, refer to the `deckhouse` module configuration for correct setup.

   Configuration example:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: deckhouse
   spec:
     version: 1
     enabled: true
     settings:
       registry:
         mode: Unmanaged
         unmanaged:
           imagesRepo: registry.deckhouse.io/deckhouse/ee
           scheme: HTTPS
           license: <LICENSE_KEY> # Replace with your license key.
   ```

4. Check the registry mode switch status in the `registry-state` secret using the instruction.

   Example output:

   ```
   conditions:
   # ...
     - lastTransitionTime: "..."
       message: ""
       reason: ""
       status: "True"
       type: Ready
   hash: ..
   mode: Unmanaged
   target_mode: Unmanaged
   ```

5. If you need to disable automatic Deckhouse Platform updates from the configured image registry, remove the `releaseChannel` parameter from the `deckhouse` module configuration. After that, automatic platform updates will be disabled, and you will need to manage the Deckhouse Platform version manually.

If you need to switch to the legacy registry management method (without the `registry` module), see the instruction.

⚠ Managing the Deckhouse Platform component image registry without the `registry` module is a deprecated management format.

Migrating from the v1 implementation to the current one

This section describes the transition from the v1 implementation of the `registry` module to the current one. A cluster that does not use the `registry` module at all (the fully deprecated format) has nothing to hand over, since the v1 implementation never configured its nodes: it needs no preparation for the upgrade to Deckhouse Platform 1.78 and keeps pulling images from the registry it was installed with.

The migration is the handover of the pull path from the v1 implementation to the current one. It does not need to be started manually, and there is no separate command for it: the `registry` module takes over control automatically after the cluster is upgraded to Deckhouse Platform 1.78. The only condition is that by then the v1 implementation must have released the pull path. Both implementations configure the same thing on every node — which container image registry the container runtime pulls images from and with which credentials — so they never manage a cluster at the same time.

Determining the migration method and steps

What needs to be done to hand over pull path management to the current implementation of the `registry` module, and when, depends on the mode the v1 implementation is running in. The mode is set in the `settings.registry.mode` parameter of the `deckhouse` ModuleConfig. To view the mode, use the following command:

```
d8 k get mc deckhouse -o jsonpath='{.spec.settings.registry.mode}'
```

Empty output means `Unmanaged` mode: the registry settings of this cluster have never been set. Such a cluster needs no preliminary actions for the migration — the handover happens automatically.

The actions required to migrate from the v1 implementation to the current one are described in the table:

Mode of the v1 implementation	What to do	When
`Unmanaged`	Nothing — the handover happens on its own	—
`Direct`	Configure the `registry` ModuleConfig: set `mode: Managed` and `primary.upstream`	Before upgrading to Deckhouse Platform 1.78
`Proxy`	Switch the cluster to `Unmanaged`	Before upgrading to Deckhouse Platform 1.78
`Local`	Follow the separate procedure for air-gapped clusters	Before upgrading to Deckhouse Platform 1.78

⚠ Deckhouse Platform 1.78 no longer contains the v1 implementation of the module. The cluster switches to the current implementation after the upgrade to Deckhouse Platform 1.78, and the preparation for that is done before the upgrade, on Deckhouse Platform 1.77.

> ✖ Prepare your cluster in advance for the transition to the current implementation. The update to Deckhouse Platform 1.78, which no longer contains the v1 implementation, is blocked as long as the cluster is running in `Proxy` or `Local` mode of the v1 implementation, or in `Direct` mode without a configured `registry` in ModuleConfig.

When the v1 implementation is used in `Direct` mode, no mode switch is needed. The `registry` ModuleConfig settings are deliberately accepted already in Deckhouse Platform 1.77: written before the upgrade, they are stored without effect and take effect on the module's first reconciliation after the upgrade.

Checking which implementation the cluster uses

When the `registry` module takes over pull path management, it records that in the `registry-v2-switch` secret. Check whether the secret exists:

```
d8 k -n d8-system get secret registry-v2-switch >/dev/null 2>&1 \
  && echo "current implementation" || echo "v1 implementation"
```

If the cluster is still on the v1 implementation, the module reports the reason on every reconciliation, and the `D8RegistryMigrationPending` alert fires in the cluster. To see which actions are required, use the following command:

```
d8 k -n d8-system get secret registry-state -o jsonpath='{.data.state}' | base64 -d | head
```

Migrating from Unmanaged mode

In `Unmanaged` mode, the v1 implementation does not manage the pull path, so no preliminary preparation for switching to the current implementation is required — the handover happens automatically.

The migration procedure to the current implementation in this case is as follows:

1. If the cluster on the v1 implementation is being switched to `Unmanaged` from another mode, wait for the transition to complete. The status must show `mode: Unmanaged` with no pending target mode.

   To check, use the following command:

   ```
   d8 k -n d8-system get secret registry-state -o jsonpath='{.data.state}' | base64 -d | head
   ```

2. Upgrade the cluster to Deckhouse Platform 1.78 (or, if it has already been upgraded, wait for the next reconciliation). The module takes over image pull path management automatically, and the pull source does not change. The default mode of the `registry` module in the current implementation is also `Unmanaged`, so the cluster keeps pulling images from the same registry as before. On containerd v1 nodes, however, the takeover restarts containerd node by node if the v1 implementation left a node registry configuration, and enabling `mode: Managed` in the next step restarts it (a second time, if the takeover already did; for details, see "Does the migration restart containerd?").

3. To have the module manage the pull paths, set `mode: Managed` in the `registry` ModuleConfig and specify the registry to pull images from. A ready-made configuration for your cluster is published in the `registry-suggested-config` secret. For a configuration example, see the "Configuring pull path management for Deckhouse Platform component images" section.

Migrating from Direct mode

In `Direct` mode of the v1 implementation, nodes pull images through an in-cluster address served by the v1 implementation's proxy. The current implementation serves the same address, so the migration is a direct handover of the address: no switch through `Unmanaged` is needed, and no components are restarted.

The migration procedure to the current implementation in this case is as follows:

1. Configure the `registry` ModuleConfig before the upgrade — without this configuration the upgrade is blocked. To fill in the `registry` ModuleConfig, take the values from the `registry.direct` section of the `deckhouse` ModuleConfig:
   - split the `imagesRepo` value from the `deckhouse` ModuleConfig into `host` and `path` and

specify them in the corresponding fields of the `registry` ModuleConfig;
- use the credentials specified in the `deckhouse` ModuleConfig: the same `license` (or `username`/`password`), and `ca` if the registry requires one.

Example of the `registry` ModuleConfig for the switch:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: registry
spec:
  enabled: true
  version: 1
  settings:
    mode: Managed
    primary:
      upstream:
        scheme: HTTPS
        host: registry.deckhouse.io
        path: /deckhouse/ee
        auth:
          license: <LICENSE_KEY> # Replace with your license key.
```

The v1 implementation stores these settings but does not act on them, so nothing changes in the cluster until the upgrade.

2. Upgrade the cluster to Deckhouse Platform 1.78. The handover of container image pull path management happens on the next reconciliation, and image pulls keep working throughout: the Service and the proxy of the v1 implementation keep serving the in-cluster address until the agent of the current implementation takes it over on every node, and only then are they removed.
3. Track the progress of the handover using the following commands.
   - Check whether path management has been handed over to the current implementation:

     ```
     d8 k -n d8-system get secret registry-v2-switch >/dev/null 2>&1 && echo "handed over"
     ```

   - Check the state of the image registry nodes:

     ```
     d8 k get registrynode -o custom-columns='NODE:.metadata.name,READY:.status.reconciled,SERVING:.status.proxyListening'
     ```

   The handover is recorded a few minutes after the new version starts, the agent appears on the nodes a few minutes later, and the objects of the v1 implementation are removed shortly after that. Image pulls keep working at each of these stages.

Migrating from Proxy mode

When the v1 implementation is used in `Proxy` mode, a proxy of its own, with its own certificates, is deployed on every node. The current implementation cannot adopt this state. So the cluster must first be switched to `Unmanaged`, and this can only be done before the upgrade.

The migration procedure to the current implementation in this case is as follows:

1. In the `deckhouse` ModuleConfig, set `registry.mode: Unmanaged`, keeping the same registry address and credentials (for an example of the `deckhouse` ModuleConfig, see the “Switching to Unmanaged mode” section). All nodes are reconfigured to pull directly from the external registry, so the caching provided in `Proxy` mode is lost until the last step.
2. Wait for the transition to complete — `mode: Unmanaged` with no pending target mode. A cluster caught mid-transition cannot be migrated; the status shows which mode it is still switching to:

   ```
   d8 k -n d8-system get secret registry-state -o jsonpath='{.data.state}' | base64 -d | head
   ```

3. Upgrade the cluster to Deckhouse Platform 1.78. The handover happens on the next reconciliation, and the pull source does not change: in `Unmanaged` mode, the current

implementation does not manage the pull path either. On containerd v1 nodes, however, the takeover restarts containerd node by node, and enabling `mode: Managed` in the next step restarts it again (for details, see “Does the migration restart containerd?”).

4. To get in-cluster caching back, set `mode: Managed` with `storage.cache: true` and the same external registry. Note that the cache of the current implementation is built differently from `Proxy` mode of the v1 implementation: a single store with replicas on the master nodes instead of a proxy on every node. Before enabling it on a cluster with little free disk space on the master nodes, read how the cache is filled and cleaned up.

Migrating an air-gapped cluster from Local mode

In `Local` mode of the v1 implementation, the cluster has no external image registry — its role is played by a registry inside the cluster itself. So the standard migration procedure does not work here, since it goes through `Unmanaged` mode, where every node pulls images directly from an external registry, and such a cluster has nowhere to pull them from.

An external registry has to be connected to the cluster for the duration of the migration. It runs in the same cluster, but outside the Deckhouse Platform namespaces. The cluster is switched to it and upgraded, and once the registry of the current implementation is filled with images, the temporary registry is removed.

> ⚠ Before starting, make sure the master nodes have free disk space for **four image sets**: at the peak of the migration, three copies of the set exist at the same time — the `Local` store, the temporary registry, and the registry of the current implementation being filled — and the space for the fourth set is headroom the node must not run out of. The detailed disk space calculation and the verification procedure are described in the “Disk requirements” section of the `registry` module documentation.

Migration procedure:

1. Run a temporary external registry in its own namespace, outside Deckhouse Platform management. Any container image registry implementation will do, but it must serve TLS with a certificate the cluster can verify, and Deckhouse Platform must not manage it: whatever happens to the module’s objects, the temporary container image registry must keep working.

   In addition, the container image registry must be reachable **at the same address from two places**: in step 3, nodes pull images from it, and in step 6, the `registry` module’s syncer running in a pod reads it. The certificate must cover the chosen address. Options tested on a single cluster:

Address	From a node	From a pod
A `hostNetwork` port on the node’s own IP (`<NODE_IP>:5000`)	works	works
A Service name (`<SERVICE>.<NAMESPACE>.svc:<PORT>`)	does not resolve	works
A NodePort on the node’s IP	works	does not work: `operation not permitted`

   Use the first option: run the container image registry with `hostNetwork: true` on one node, address it by that node’s IP, and add that IP to the certificate’s SAN — then the whole migration goes through a single address. A Service name looks neater, but stops working in step 3, because the node’s container runtime does not resolve names through the cluster DNS.

2. Load the image set of the current version into the temporary registry: `d8 mirror pull` on a machine with internet access, then `d8 mirror push` into the temporary registry.
3. In the `deckhouse` ModuleConfig, set `registry.mode: Unmanaged` with the address, CA certificate, and credentials of the temporary registry. The data of the `Local` store stays where it is, in the `/opt/deckhouse/registry` directory on the master nodes.
4. Make sure the transition is complete and images are really pulled from the temporary registry (`mode: Unmanaged` with no pending target mode in the `registry-state` secret):

   ```
   d8 k -n d8-system get secret registry-state -o jsonpath='{.data.state}' | base64 -d | head
   ```

5. Upgrade the cluster to Deckhouse Platform 1.78. The handover happens on the next reconciliation, and the cluster keeps pulling images from the temporary registry throughout. On

containerd v1 nodes the takeover restarts containerd node by node, and enabling `mode: Managed` in the next step restarts it again (see Does the migration restart containerd?).

6. Enable the current implementation: set `mode: Managed` with `storage.cache: true`, specify the temporary registry as `primary.upstream` — **and add `storage.source` in the same edit** (without it, the next step is rejected). The registry of the current implementation uses the same host path that `Local` used, so the images already on disk are not downloaded again.

7. Wait until the storage reports that it holds the whole image set (`phase: Ready` and `safeToDropUpstream: true`), and remove `primary.upstream` from the `registry` ModuleConfig. The cluster is isolated again — now on the current implementation:

   ```
   d8 k get registrystorage registry -o jsonpath='{.status.phase}
   {.status.safeToDropUpstream}{"\n"}'
   ```

   Removing the upstream restarts the registry, and the RegistryStorage resource may briefly report `Failed`: this is expected, wait for it to return to `Ready`.

8. Delete the temporary registry and reclaim its disk space.

Migration to registry management format using the registry module

> **i** This procedure applies to Deckhouse Platform 1.77 and earlier only: it moves a cluster from the deprecated format (without the `registry` module, configured only via `InitConfiguration`) to the **v1 implementation** of the module, which Deckhouse Platform 1.78 no longer contains. It is not a step of the migration to the current implementation: a cluster in the deprecated format needs no preparation for the upgrade to Deckhouse Platform 1.78. See the “Migrating from the v1 implementation to the current one” section.

During the migration, containerd v1 will be switched to the new registry configuration scheme. containerd v2 uses the new scheme by default. For more details, see the section describing configuration methods.

To view the container runtime type used by default on cluster nodes (in NodeGroups), use the following command:

```
d8 system edit cluster-configuration
```

The container runtime type is specified in the `defaultCRI` parameter.

If containerd v2 is used as the container runtime, follow the containerd v2 migration instructions.

If containerd v1 is used as the container runtime, you can choose one of the following methods to migrate to the `registry` module’s image registry management format:

- Without switching to containerd v2. In this case, follow the instructions for containerd v1.
- With switching to containerd v2. In this case:
  1. Verify whether you can switch to containerd v2, and if so, perform the switch.
  2. After migrating, follow the instructions for containerd v2.

For containerd v2

1. Switch to using the `registry` module. To do this, specify the `Unmanaged` mode parameters in the `deckhouse` ModuleConfig. If you are using a registry other than `registry.deckhouse.io`, refer to the `deckhouse` module configuration for correct setup.

   You can view the current registry settings using the following command:

   ```
   d8 k -n d8-system exec -it svc/deckhouse-leader -c deckhouse -- deckhouse-controller global
   values | yq e '.modulesImages.registry' -
   ```

   Specify these settings when configuring the `Unmanaged` mode:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Unmanaged
      unmanaged:
        imagesRepo: registry.deckhouse.io/deckhouse/ee
        scheme: HTTPS
        license: <LICENSE_KEY> # Replace with your license key.
```

2. Wait for the switch to complete. Example status output:

```
conditions:
# ...
  - lastTransitionTime: "..."
    message: ""
    reason: ""
    status: "True"
    type: Ready
hash: ..
mode: Unmanaged
target_mode: Unmanaged
```

If you need to add configurations for an additional image repository, refer to the section “New way to add configuration for an additional registry”.

For containerd v1

- During the switch, containerd v1 will be restarted.
- During the switch, containerd v1 will be migrated to the new Deckhouse Platform component registry configuration scheme.
- During the switch, custom registry configurations for containerd v1 will be temporarily unavailable.

1. Make sure that nodes with containerd v1 do not have any custom registry configurations located in the `/etc/containerd/conf.d` directory.
2. If configurations are present, you need to migrate to the new registry configuration format in containerd. To do this, add new configuration files to the `/etc/containerd/registry.d` directory. These configurations will take effect after switching to the `registry` module. To add configurations, prepare a NodeGroupConfiguration. For more details, see the section with a description of configuration methods. Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-auth.sh
spec:
  # The step can be arbitrary, as restarting the containerd service is not
required.
  weight: 0
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p "/etc/containerd/registry.d/${REGISTRY_URL}"
    bb-sync-file "/etc/containerd/registry.d/${REGISTRY_URL}/hosts.toml" - <<
EOF
    [host]
      [host."https://${REGISTRY_URL}"]
        capabilities = ["pull", "resolve"]
        [host."https://${REGISTRY_URL}".auth]
          username = "username"
          password = "password"
    EOF
```

3. Apply the NodeGroupConfiguration. Wait until the configuration files appear in the `/etc/containerd/registry.d` directory on all nodes.
4. Verify that the configurations are working correctly. To do this, use the following command:

```
# For HTTPS.
ctr -n k8s.io images pull --hosts-dir=/etc/containerd/registry.d/
private.registry.example/registry/path:tag

# For HTTP.
ctr -n k8s.io images pull --hosts-dir=/etc/containerd/registry.d/ --plain-http
private.registry.example/registry/path:tag
```

5. Switch to using the `registry` module. To do this, specify the `Unmanaged` mode parameters in the `deckhouse` ModuleConfig. If you are using a registry other than `registry.deckhouse.io`, refer to the `deckhouse` module configuration for correct setup.

   You can view the current registry settings using the following command:

   ```
   d8 k -n d8-system exec -it svc/deckhouse-leader -c deckhouse -- deckhouse-controller global
   values | yq e '.modulesImages.registry' -
   ```

   Specify these settings when configuring the `Unmanaged` mode:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Unmanaged
      unmanaged:
        imagesRepo: registry.deckhouse.io/deckhouse/ee
        scheme: HTTPS
        license: <LICENSE_KEY> # Replace with your license key.
```

6. After applying, wait for the following message in the switch status:

   Example output:

   ```
   conditions:
   # ...
   - lastTransitionTime: "2025-08-13T15:22:34Z"
     message: |
       Check current nodes configuration
       2/2 node(s) Unready:
       - master-0: has custom toml merge containerd configuration
       - worker-5e389be0-578df-s5sm5: has custom toml merge containerd
   configuration
     reason: Processing
     status: "False"
     type: ContainerdConfigPreflightReady
   ```

   This message means that there are old registry configurations on the nodes located in the `/etc/containerd/conf.d` directory. The switch to the new containerd configuration is currently blocked. To allow the switch, you need to remove the old configuration files.

7. Remove the old configuration files to allow switching to the `registry` module. To do this, create a NodeGroupConfiguration. Example of a NodeGroupConfiguration manifest:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-auth-delete.sh
spec:
  # This step must be completed before '032_configure_containerd.sh'.
  weight: 0
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    file="/etc/containerd/conf.d/old-config.toml"

    [ -f "$file" ] && rm -f "$file"
```

8. After removing the old configurations, make sure that the switch has resumed. Example of the switch status:

```
conditions:
# ...
- lastTransitionTime: "2025-08-13T16:42:09Z"
  message: ""
  reason: ""
  status: "True"
  type: ContainerdConfigPreflightReady
```

9. Wait for the switch to complete. Example of the switch status:

```
conditions:
# ...
  - lastTransitionTime: "..."
    message: ""
    reason: ""
    status: "True"
    type: Ready
hash: ..
mode: Unmanaged
target_mode: Unmanaged
```

10. Delete the NodeGroupConfiguration created in the step for deleting old configuration files:

```
d8 k delete nodegroupconfiguration containerd-additional-config-auth-delete.sh
```

To verify that NodeGroupConfiguration has been deleted, use the command:

```
d8 k get nodegroupconfiguration
```

The list should not contain the NodeGroupConfiguration to be deleted (for this example, `containerd-additional-config-auth-delete.sh`).

Migration to the deprecated registry management format (without the registry module)

✖
- This is a deprecated Deckhouse Platform component registry management format.
- During the switch, containerd v1 will be restarted.
- During the switch, containerd v1 will be migrated to the legacy registry configuration scheme.
- During the switch, custom registry configurations for containerd v1 will be temporarily unavailable.

1. Switch the `registry` module to configurable `Unmanaged` mode. If you are using a registry other than `registry.deckhouse.io`, refer to the `deckhouse` module configuration for correct setup.

   Example configuration:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: deckhouse
   spec:
     version: 1
     enabled: true
     settings:
       registry:
         mode: Unmanaged
         unmanaged:
           imagesRepo: registry.deckhouse.io/deckhouse/ee
           scheme: HTTPS
           license: <LICENSE_KEY> # Replace with your license key.
   ```

2. Check the switch status using the instruction. Example output:

   ```
   conditions:
   # ...
   - lastTransitionTime: "..."
     message: ""
     reason: ""
     status: "True"
     type: Ready
   hash: ..
   mode: Unmanaged
   target_mode: Unmanaged
   ```

3. Switch the registry to the non-configurable `Unmanaged` mode (without `registry` module). Example configuration:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: deckhouse
   spec:
     version: 1
     enabled: true
     settings:
       registry:
         mode: Unmanaged
   ```

4. Check the switch status using the instruction. Example output:

```
conditions:
# ...
- lastTransitionTime: "..."
  message: ""
  reason: ""
  status: "True"
  type: Ready
hash: ..
mode: Unmanaged
target_mode: Unmanaged
```

5. If containerd v1 is used and custom registry configurations are applied in the cluster, they must be replaced with the old format. To do this, prepare the registry configurations in the old format. These configurations do not need to be applied at this stage. Example configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-auth.sh
spec:
  # To add a file before the '032_configure_containerd.sh' step.
  weight: 31
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/additional_registry.toml - << EOF
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry]
          [plugins."io.containerd.grpc.v1.cri".registry.mirrors]

[plugins."io.containerd.grpc.v1.cri".registry.mirrors."${REGISTRY_URL}"]
            endpoint = ["https://${REGISTRY_URL}"]
          [plugins."io.containerd.grpc.v1.cri".registry.configs]

[plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".auth]
            username = "username"
            password = "password"
            # OR
            auth = "<BASE64_AUTH_STRING>"
    EOF
```

6. Delete the `registry-bashible-config` secret. This will trigger containerd v1 to switch back to

the legacy registry format:

```
d8 k -n d8-system delete secret registry-bashible-config
```

7. After deletion, wait for the switch to complete. Use the instruction to track the progress. Example output:

```
conditions:
# ...
- lastTransitionTime: "..."
  message: ""
  reason: ""
  status: "True"
  type: Ready
hash: ..
mode: Unmanaged
target_mode: Unmanaged
```

8. If containerd v1 is used, apply the previously prepared NodeGroupConfiguration with custom registry configurations.
9. Disable the `registry` module. Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: registry
spec:
  enabled: false
  settings: {}
  version: 1
```

Checking the registry mode switch status in the v1 implementation

The status of the Deckhouse Platform component registry mode switch in the v1 implementation can be retrieved using the following command:

```
d8 k -n d8-system -o yaml get secret registry-state | yq -C -P '.data | del .state |
map_values(@base64d) | .conditions = (.conditions | from_yaml)'
```

Example output:

```
conditions:
  - lastTransitionTime: "2025-07-15T12:52:46Z"
    message: 'registry.deckhouse.io: all 157 items are checked'
    reason: Ready
    status: "True"
    type: RegistryContainsRequiredImages
  - lastTransitionTime: "2025-07-11T11:59:03Z"
    message: ""
    reason: ""
    status: "True"
    type: ContainerdConfigPreflightReady
  - lastTransitionTime: "2025-07-15T12:47:47Z"
    message: ""
    reason: ""
    status: "True"
    type: TransitionContainerdConfigReady
  - lastTransitionTime: "2025-07-15T12:52:48Z"
    message: ""
    reason: ""
    status: "True"
    type: InClusterProxyReady
  - lastTransitionTime: "2025-07-15T12:54:53Z"
    message: ""
    reason: ""
    status: "True"
    type: DeckhouseRegistrySwitchReady
  - lastTransitionTime: "2025-07-15T12:55:48Z"
    message: ""
    reason: ""
    status: "True"
    type: FinalContainerdConfigReady
  - lastTransitionTime: "2025-07-15T12:55:48Z"
    message: ""
    reason: ""
    status: "True"
    type: Ready
mode: Direct
target_mode: Direct
```

The output displays the status of the switch process. Each condition can have a status of `True` or `False`, and may contain a `message` field with additional details.

Description of conditions:

Condition	Description
`ContainerdConfigPreflightReady`	State of the containerd configuration preflight check. Verifies there are no custom containerd auth configurations on the nodes
`TransitionContainerdConfigReady`	State of preparing the containerd configuration for the new mode. Verifies that the configuration contains both the old and new mode settings
`FinalContainerdConfigReady`	State of finalizing the switch to the new containerd mode. Verifies that the containerd configuration has been successfully applied and contains only the new mode settings
`DeckhouseRegistrySwitchReady`	State of switching Deckhouse Platform and its components to use the new registry. `True` means Deckhouse Platform successfully switched and is ready to operate

Condition	Description
`InClusterProxyReady`	State of In-Cluster Proxy readiness. Checks that the In-Cluster Proxy has started successfully and is running
`CleanupInClusterProxy`	State of cleaning up the In-Cluster Proxy if it is not needed in the selected mode. Verifies that all related resources have been removed
`NodeServicesReady`	State of Node Services Manager and Static-Pod registry readiness. Verifies that the Node Services Manager is successfully launched and operational, and that the Static-Pod registry has been successfully deployed by it
`CleanupNodeServices`	State of cleaning up the Node Services Manager and Static-Pod registry if they are not needed in the selected mode. Verifies that all related resources have been removed
`RegistryContainsRequiredImages`	State of checking the registry for the presence of required images
`Ready`	Overall state of registry readiness in the selected mode. Indicates that all other conditions are met and the module is ready to operate

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Switching a Managed Kubernetes cluster to use third-party registry

> ⚠ This page applies only to Managed Kubernetes clusters. Registry management through the `registry` module is not available in these clusters.
>
> For clusters fully managed by Deckhouse Platform (DP), registry settings are configured using the `registry` module (or, in clusters still running its previous implementation, in the `registry` section of the `deckhouse` module configuration). For configuration examples and descriptions of the implementations, see “Managing the registry in DP-managed clusters”.
>
> The information on this page applies to clusters that use containerd v1 or containerd v2 as their primary container runtime. However, containerd v2 is the current standard for DP. If you need to migrate to containerd v2, refer to the section “Migrating container runtime to containerd v2” to verify availability and perform the migration.

> The methods for adding a configuration for a registry are described in the section “Adding a configuration for an additional registry”.

To switch the cluster to use an external registry, follow these steps:

1. Run the `deckhouse-controller helper change-registry` command from the DP pod with the

parameters of the new registry.
Example:

```
d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry --user MY-USER --password MY-PASSWORD registry.example.com/deckhouse/ee
```

2. If the registry uses self-signed certificates, place the corresponding root certificate in the file `/tmp/ca.crt` inside the DP pod and add the `--ca-file /tmp/ca.crt` option to the command. Alternatively, insert the CA content into a variable, as shown below:

```
CA_CONTENT=$(cat <<EOF
-----BEGIN CERTIFICATE-----
CERTIFICATE
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
CERTIFICATE
-----END CERTIFICATE-----
EOF
)
d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- bash -c "echo '$CA_CONTENT' >
/tmp/ca.crt && deckhouse-controller helper change-registry --ca-file
/tmp/ca.crt --user MY-USER --password MY-PASSWORD
registry.example.com/deckhouse/ee"
```

   To view the list of available flags for the `deckhouse-controller helper change-registry` command, run:

```
d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry --help
```

   Example output:

```
usage: deckhouse-controller helper change-registry [<flags>] <new-registry>
Change registry for deckhouse images.
Flags:
  --help               Show context-sensitive help (also try --help-long and --
help-man).
  --user=USER          User with pull access to registry.
  --password=PASSWORD  Password/token for registry user.
  --ca-file=CA-FILE    Path to registry CA.
  --scheme=SCHEME      Used scheme while connecting to registry, http or https.
  --dry-run            Don't change deckhouse resources, only print them.
  --new-deckhouse-tag=NEW-DECKHOUSE-TAG
                       New tag that will be used for deckhouse deployment image
(by default
                       current tag from deckhouse deployment will be used).
Args:
  <new-registry>  Registry that will be used for deckhouse images (example:
                  registry.deckhouse.io/deckhouse/ce). By default, https will
be used, if you need
                  http - provide '--scheme' flag with http value
```

3. Wait until the `registry` Pod reaches the `Ready` status. If the Pod is in the `ImagePullBackoff` state, restart it.

4. Wait for bashible to apply the new settings on the master node.

   Check the bashible system service log on the master node, for example, using the following command:

```
journalctl -u bashible -n 20
```

   The log should contain the message `Configuration is in sync, nothing to do`.

Example of output when viewing the bashible service log:

```
Aug 13 05:03:08 kube-master-0 systemd[1]: Started Bashible service.
Aug 13 05:03:10 kube-master-0 bash[1847265]: Configuration is in sync, nothing
to do.   <--
Aug 13 05:03:10 kube-master-0 systemd[1]: bashible.service: Deactivated
successfully.
Aug 13 05:03:10 kube-master-0 systemd[1]: bashible.service: Consumed 1.075s CPU
time.
```

5. If you need to disable automatic DP upgrades through the external registry, remove the `releaseChannel` parameter from the `deckhouse` module configuration. After that, automatic platform upgrades will be disabled, and you will need to manage the DP version manually.
6. Check if any pods in the cluster are still using the original registry address:

```
d8 k get pods -A -o json | jq -r '.items[] | select(.spec.containers[]
  | select(.image | startswith("registry.deckhouse"))) | .metadata.namespace +
"\t" + .metadata.name' | sort | uniq
```

⚠ If a module's image wasn't pulled and the module wasn't reinstalled during the switch, follow the instructions to resolve the issue.

Additional resources

- Module `deckhouse` parameters
- Module `registry` documentation

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Authentication

Authentication is the process of verifying a user's identity, providing access control to all interfaces of the Deckhouse Platform (DP) and cluster resources.
The platform implements end-to-end authentication, allowing a unified mechanism to be applied both to internal components and user applications.

The core of the authentication mechanism is a federated OpenID Connect (OIDC) provider — `Dex`.
Learn more about how authentication works in the Architecture section.

Depending on the configuration, DP supports two authentication approaches:

- Local authentication — users and groups are created directly in the cluster and stored as User and Group resources.
  The User resource stores a hashed version of the password (bcrypt), not the plain-text password.
- Integration with external providers — enables connection to systems like LDAP, GitLab, GitHub, and others to support single sign-on across multiple DP clusters.

From the perspective of a cluster user or application developer, the method chosen by the administrator to configure authentication in DP does not matter — the authentication interface and integration steps are the same. You can learn about configuring authentication for applications in the section Usage → IAM → Authentication.

The platform also provides capabilities for:

- Enabling authentication for any web application in the cluster.
- Configuring authenticated access to the Kubernetes API via a load balancer.

Additional resources

- Module `user-authn` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with external authentication providers

Connecting an external authentication provider allows you to use a single set of credentials to access multiple clusters and simultaneously work with multiple providers.

DP supports integration with the following external authentication providers and protocols:

- LDAP (for example, Active Directory);
- OIDC (for example, Okta, Keycloak, Gluu, Blitz Identity Provider);
- SAML 2.0;
- GitHub integration;
- GitLab integration;
- Atlassian Crowd integration;
- Bitbucket Cloud integration.

> Password policies (such as complexity requirements, expiration, history, two-factor authentication, etc.) are fully controlled by the external authentication provider.
> DP does not manage passwords or interfere with policy enforcement on the provider side.

General integration workflow

> The `allowedGroups` parameter in the DexProvider resource allows you to restrict login access to users who belong to specific groups.
> If the `allowedGroups` list is specified, the user **must** be a member of at least one of these groups — otherwise, authentication will be considered unsuccessful.
> If the parameter is not specified, no group-based filtering will be applied.

1. Create an OAuth application in the authentication provider:
   - Set the redirect URI to `https://dex.<publicDomainTemplate>/callback`.
   - Obtain the `clientID` and `clientSecret`.

   > **Important**: When specifying the redirect URI, substitute the actual value of `publicDomainTemplate` without `%s`.
   > For example, if `publicDomainTemplate: '%s.sandbox1.deckhouse-docs.flant.com'`, the actual URI would be:
   > `https://dex.sandbox1.deckhouse-docs.flant.com/callback`.
   >
   > To retrieve the Dex address (URI), run:
   >
   > ```
   > d8 k -n d8-user-authn get ingress dex -o jsonpath="{.spec.rules[*].host}"
   > ```

2. Create a DexProvider resource tailored to the specifics of your selected identity provider.
3. Enable the `user-authn` module (if it is currently disabled).

   This can be done either via the Deckhouse admin web interface or through the CLI.
   Below is an example using the Deckhouse CLI (requires kubectl context configured to access the cluster):

   Check the module status:

   ```
   d8 k get module user-authn
   ```

   Example output:

```
NAME         STAGE   SOURCE     PHASE       ENABLED   READY
user-authn           Embedded   Available   True      True
```

Enable the module via CL:

```
d8 system module enable user-authn
```

4. Configure the `user-authn` module.
   - Open the `user-authn` module settings (create a ModuleConfig resource named `user-authn` if it doesn't exist):

     ```
     d8 k edit mc user-authn
     ```

   - Specify the required module parameters in the `spec.settings` section. For more details about the `user-authn` module settings, refer to the module reference.

     Example `user-authn` configuration:

     ```
     apiVersion: deckhouse.io/v1alpha1
     kind: ModuleConfig
     metadata:
       name: user-authn
     spec:
       version: 3
       enabled: true
       settings:
         kubeconfigGenerator:
         - id: direct
           masterURI: https://159.89.5.247:6443
           description: "Direct access to kubernetes API"
     ```

   - To publish the Kubernetes API via an Ingress controller or Gateway API, enable the `apiserver.publishAPI.ingress.enabled` parameter in the `control-plane-manager` module settings:

     ```
     apiVersion: deckhouse.io/v1alpha1
     kind: ModuleConfig
     metadata:
       name: control-plane-manager
     spec:
       version: 3
       enabled: true
       settings:
         apiserver:
           publishAPI:
             ingress:
               enabled: true
     ```

   For more information on how to expose the Kubernetes API, see the `control-plane-manager` module documentation.

After setting up integration in the cluster with an external authentication provider, authentication through it will become possible in the platform's web interfaces. Information on setting up authentication for user applications can be found in the section Usage → IAM → Authentication.

Limiting the identities of a provider

A user who signs in through a DexProvider gets the email and the groups that the identity provider reports. The email is the Kubernetes username. As a result, users of the provider receive all permissions already granted in the cluster to those email addresses and groups.

To restrict the identities a provider can assert, use the `spec.allowedIdentities` parameter:

- `emails` and `emailDomains` describe the emails that the provider may assert. Dex refuses sign-in for any other email.
- `groups` describes the group names that the provider may assert. Dex keeps only the listed groups in the token and refuses sign-in if none is left.

The limits apply to every provider type, in addition to the group filters of the type, such as `oidc.allowedGroups`, `gitlab.groups` or `crowd.groups`. Group names are compared exactly. Nesting of Group objects does not extend the list.

Dex checks the limits at sign-in, at every refresh-token request and at Basic Authentication to the API server through an LDAP provider. Dex revokes refresh tokens for identities that no longer satisfy the limits, so narrowing the limits ends the existing sessions of the excluded users. For a Crowd or OIDC provider, basic-auth-proxy checks the credentials with the provider directly, so the limits do not apply to Basic Authentication.

The same limits define who can create or change the provider: you must be able to assign every role already granted to the emails and groups that the provider can report. Only a SuperAdmin can create or change a provider without an email limit. A Crowd or OIDC provider with `enableBasicAuth: true` counts as a provider without an email limit, so only a SuperAdmin can create it or turn on `enableBasicAuth` in it.

Example of a provider limited by an email domain and a group:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: contractors
spec:
  type: OIDC
  displayName: Contractors
  oidc:
    issuer: https://idp.contractor.example
    clientID: dex
    clientSecret: secret
  allowedIdentities:
    emailDomains: [contractor.example]
    groups: [contractors]
```

The following changes are not checked: changing `clientSecret` or `bindPW`, changing `displayName`, disabling the provider, narrowing the limits, reapplying the same manifest, and deleting the provider. Any other change is checked as connecting a new provider, including enabling a disabled provider.

If the check fails, the error lists the roles that the provider could receive, for example:

```
dexproviders.deckhouse.io "corp": the provider can assert identities that already carry roles [user-
authz:super-admin]; the requester's can-assign range is basic<=ClusterAdmin and does not cover them.
Narrow spec.allowedIdentities (emails, emailDomains, groups) or ask a SuperAdmin
```

Checking provider connectivity

The provider page of the DP web UI has the “Check connection” action. It creates a DexProviderCheck resource and waits until the `user-authn` controller writes the check result to its `status`.

The check verifies the following:

- the specified DexProvider exists and is enabled;
- the Dex discovery endpoint inside the cluster is reachable;
- the endpoint of the external provider is reachable.

For OIDC providers, the discovery document and JWKS are also read. For LDAP providers, TCP/TLS/StartTLS reachability is checked and, if Kerberos is enabled, the presence of the keytab Secret. The check also verifies that the provider accepts the client or service account credentials (GitHub, GitLab, Bitbucket Cloud, Crowd, OIDC, bind in LDAP) and warns about disabled TLS verification and certificates that expire soon. The check does not perform a full sign-in flow and does not check the password of a test user.

To run the check without the web UI, create a DexProviderCheck resource:

```
apiVersion: deckhouse.io/v1
kind: DexProviderCheck
metadata:
  name: check-github
spec:
  providerName: github
```

Then read its status:

```
d8 k get dexproviderchecks check-github -o yaml
```

OIDC (OpenID Connect) integration

Authentication via an OIDC provider requires registering a client (or creating an application). Follow your provider's documentation to do this (e.g., Okta, Keycloak, Gluu, or Blitz).

Specify the `clientID` and `clientSecret` obtained during setup in the DexProvider resource.

> **i** When registering an application with any OIDC provider, you must specify a redirect URI.
> For integration with DexProvider, use the following format: `https://dex.<publicDomainTemplate>/callback`, where `publicDomainTemplate` is the DNS name template of your cluster as defined in the `global` module.

> **i** To ensure proper token revocation on logout and to force re-authentication, set the `promptType` parameter to `login`.
> This guarantees that the user will be prompted to re-enter credentials during subsequent logins.

To configure fine-grained access control for users in applications:

- Add the `allowedUserGroups` parameter to the ModuleConfig of the target application.
- Assign the appropriate groups to the user, using identical group names on both the provider and Deckhouse sides.

Keycloak

During Keycloak configuration, select the appropriate `realm`, add a user in the Users section, and create a client in the Clients section with authentication enabled, which is required to generate a `clientSecret`. Then follow these steps:

1. In the Client scopes section, create a `scope` named `groups` and assign it a mapper `Group Membership` ("Client scopes" → "Client scope details" → "Mappers" → "Configure a new mapper"). Set values of "Name" and "Token Claim Name" as `groups` and turn off "Full group path".
2. In the previously created client, add this `scope` in the Client scopes tab ("Clients" → "Client details" → "Client Scopes" → "Add client scope").
3. In the "Valid redirect URIs", "Valid post logout redirect URIs", and "Web origins" fields in the client configuration, specify `https://dex.<publicDomainTemplate>/*`, where `publicDomainTemplate` is the cluster DNS name template defined in the `global` module.

Example provider configuration for Keycloak integration:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: keycloak
spec:
  type: OIDC
  displayName: My Company Keycloak
  oidc:
    issuer: https://keycloak.my-company.com/realms/myrealm # Use your realm name
    clientID: plainstring
    clientSecret: plainstring
    insecureSkipEmailVerified: true
    getUserInfo: true
    scopes:
      - openid
      - profile
      - email
      - groups
```

If email verification is not enabled in Keycloak, to properly use it as an identity provider, adjust the `Client Scopes` settings in one of the following ways:

- Delete the `Email verified` mapping (“Client Scopes” → “Email” → “Mappers”). This is required for proper processing of the `insecureSkipEmailVerified` field when it’s set to `true` and for correct permission assignment to users with unverified emails.
- If you can’t modify or delete the `Email verified` mapping, create a new Client Scope named `email_dkp` (or any other name) and add two mappings:
  - `email`: “Client Scopes” → `email_dkp` → “Add mapper” → “From predefined mappers” → `email`.
  - `email verified`: “Client Scopes” → `email_dkp` → “Add mapper” → “By configuration” → “Hardcoded claim”. Specify the following fields:
    - “Name”: `email verified`
    - “Token Claim Name”: `emailVerified`
    - “Claim value”: `true`
    - “Claim JSON Type”: `boolean`

  After that, in the client registered for the DP cluster in “Clients”, change `Client scopes` from `email` to `email_dkp`.

  In the DexProvider resource, specify `insecureSkipEmailVerified: true` and in the `.spec.oidc.scopes` field, change the Client Scope name to `email_dkp` following the example:

  ```
  scopes:
   - openid
   - profile
   - email_dkp
   - groups
  ```

⚠ With `insecureSkipEmailVerified: true`, Dex accepts unverified email addresses. Permissions are granted by email, so use this parameter only if the identity provider does not let users set an arbitrary email address.

Blitz Identity Provider

Example configuration of a provider for integration with Blitz Identity Provider:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: blitz
spec:
  displayName: Blitz Identity Provider
  oidc:
    basicAuthUnsupported: false
    claimMapping:
      email: email
      groups: your_claim # Claim for obtaining user groups; groups are configured on
the Blitz Identity Provider side.
    clientID: clientID
    clientSecret: clientSecret
    getUserInfo: true
    insecureSkipVerify: false
    issuer: https://yourdomain.idblitz.ru/blitz
    promptType: consent
    scopes:
    - profile
    - openid
    userIDKey: sub
    userNameKey: email
  type: OIDC
```

Okta

Example configuration of a provider for integration with Okta:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: okta
spec:
  type: OIDC
  displayName: My Company Okta
  oidc:
    issuer: https://my-company.okta.com
    clientID: plainstring
    clientSecret: plainstring
    getUserInfo: true
```

After enabling integration with Okta, you can use Okta user groups to manage access rights. For example, you can specify a list of groups whose members are allowed to access Grafana.

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: prometheus
spec:
  version: 2
  settings:
    auth:
      allowedUserGroups:
        - adm-grafana-access
        - grafana-access
```

SAML 2.0 integration

The example shows the provider’s settings for integration with a SAML 2.0 Identity Provider (e.g., AD FS, Okta, Keycloak).

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: saml-provider
spec:
  type: SAML
  displayName: Corporate SAML
  saml:
    ssoURL: https://saml-idp.example.com/saml/sso
    rootCAData: |
      -----BEGIN CERTIFICATE-----
      MIIFaDC...
      -----END CERTIFICATE-----
    entityIssuer: https://dex.example.com/callback
    ssoIssuer: https://saml-idp.example.com
    usernameAttr: name
    emailAttr: email
    groupsAttr: groups
    nameIDPolicyFormat: persistent
```

To configure the SAML Identity Provider:

1. Register Dex as a Service Provider (SP) in your IdP with the following settings:
   - **ACS URL (Assertion Consumer Service)**: `https://dex.<modules.publicDomainTemplate>/callback`
   - **Entity ID**: `https://dex.<modules.publicDomainTemplate>/callback`
   - **NameID format**: `persistent` or `emailAddress`
2. Configure attribute mappings in the IdP to send `email`, `name` (username), and `groups` attributes in the SAML assertion.
3. Export the IdP signing certificate and specify it in the `rootCAData` field of the DexProvider resource.

> **i** SAML does not support refresh tokens. Dex caches the user data from the first SAML assertion and returns it on subsequent refresh-token requests. The session lifetime is limited by the `refreshTokenAbsoluteLifetime` parameter of the `user-authn` module.

LDAP integration

To configure authentication, create a read-only account (service account) in your LDAP directory. This account will be used to perform search queries in the LDAP catalog. You can also configure user lockout after failed sign-in attempts for this type of integration. To do this, specify the provider type in the `passwordPolicy.lockout.applyToConnectors` parameter of the `user-authn` module.

In the DexProvider resource, specify the following parameters:

- `bindDN`: Full Distinguished Name (DN) of the created service account. For example: `cn=readonly,dc=example,dc=org`.
- `bindPW`: Password for the specified `bindDN`.

> **i** If your LDAP server allows anonymous access for search queries, the `bindDN` and `bindPW` parameters can be omitted.
> However, using authenticated access is recommended for improved security.
>
> The `bindPW` parameter must contain the password in plain text. Dex does not support hashed passwords in this field.

You can also enable support for:

- Basic Authentication for accessing the Kubernetes API using LDAP credentials. To do this, set the `enableBasicAuth: true` parameter in the DexProvider resource. For more information, see Access using Basic Authentication.
- Kerberos SSO (SPNEGO) for LDAP. To do this, enable the `spec.ldap.kerberos` block in the DexProvider resource, specify the keytab Secret in `keytabSecretName` and configure the other

parameters in it. For more details, see Kerberos SSO (SPNEGO) for LDAP.

Example configuration for integrating with Active Directory (Basic Authentication):

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: active-directory
spec:
  type: LDAP
  displayName: Active Directory
  ldap:
    host: ad.example.com:636
    rootCAData: |
      -----BEGIN CERTIFICATE-----
      MIIFaDC...
      -----END CERTIFICATE-----

    bindDN: cn=dex-readonly,cn=users,dc=example,dc=com
    bindPW: <PASSWORD>

    enableBasicAuth: true

    usernamePrompt: Email Address

    userSearch:
      baseDN: cn=Users,dc=example,dc=com
      filter: "(objectClass=person)"
      username: userPrincipalName
      idAttr: DN
      emailAttr: userPrincipalName
      nameAttr: cn

    groupSearch:
      baseDN: cn=Users,dc=example,dc=com
      filter: "(objectClass=group)"
      userMatchers:
      - userAttr: DN
        groupAttr: member
      nameAttr: cn
```

GitHub integration

You need to create a new application in your GitHub organization.

To do this, follow these steps:

1. Go to “Settings → Developer settings → OAuth Apps → New OAuth App”, and set the “Authorization callback URL” to `https://dex.<publicDomainTemplate>/callback`.
2. Use the generated `Client ID` and `Client Secret` in the DexProvider resource.

If the organization restricts third-party applications:

1. Go to “Settings → Applications → Authorized OAuth Apps → `<APPLICATION_NAME>`” and click “Send Request” to submit an approval request.
2. Ask an organization owner to approve the request.

Example configuration for integrating with GitHub:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: github
spec:
  type: Github
  displayName: My Company GitHub
  # Optional: disable the provider without deleting CR
  # enabled: false
  github:
    clientID: plainstring
    clientSecret: plainstring
```

GitLab integration

You need to create a new application in your GitLab project.

To do this, follow these steps:

1. For self-hosted GitLab: go to “Admin Area → Applications → New application” and set the “Redirect URI (Callback URL)” to `https://dex.<publicDomainTemplate>/callback`. Also, select the following scopes: `read_user`, `openid`.
2. For GitLab Cloud (gitlab.com): under the main account of the project, go to “User Settings → Applications → Add new application”, set the “Redirect URI (Callback URL)” to `https://dex.<publicDomainTemplate>/callback`, and select the **scopes**: `read_user`, `openid`.
3. Use the obtained `Application ID` and secret in the DexProvider resource.

> **i** For GitLab version 16 and above, enable the “Trusted” option when creating the application. This option is available under “Admin Area → Applications”. Marking the app as trusted allows skipping the authorization step for users, which can be useful in controlled environments.

Example configuration for integrating with GitLab:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: gitlab
spec:
  type: Gitlab
  displayName: Dedicated Gitlab
  gitlab:
    baseURL: https://gitlab.example.com
    clientID: plainstring
    clientSecret: plainstring
    groups:
    - administrators
    - users
```

Atlassian Crowd integration

In the relevant Atlassian Crowd project, you need to create a new Generic application.

You can also configure user lockout after failed sign-in attempts for this type of integration. To do this, specify the provider type in the `passwordPolicy.lockout.applyToConnectors` parameter of the `user-authn` module.

To do this, follow these steps:

1. Go to “Applications → Add application”.
2. Specify the obtained “Application Name” and “Password” in the DexProvider resource.
3. When specifying groups in the DexProvider resource, make sure their names are written in lowercase.
   This is necessary for correct group matching between Crowd and DP.

Example configuration for integrating with Atlassian Crowd:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: crowd
spec:
  type: Crowd
  displayName: Crowd
  crowd:
    baseURL: https://crowd.example.com/crowd
    clientID: plainstring
    clientSecret: plainstring
    groups:
    - administrators
    - users
```

Basic Authentication to the Kubernetes API through a Crowd provider (`enableBasicAuth`) bypasses the identity limits of the provider, so only a SuperAdmin can enable it.

Bitbucket Cloud Integration

To configure authentication, you need to create a new OAuth consumer in the Bitbucket team menu.

Follow these steps:

1. Go to “Personal settings → Access management → OAuth consumers → Add consumer”, and specify `https://dex.<publicDomainTemplate>/callback` as the “Callback URL”.
2. Grant access:
   - “Account: Read” → allows retrieval of basic user information (e.g., email, username).
   - “Workspace membership: Read” → allows retrieval of user workspace membership information.
3. Use the obtained `Key` and secret in the DexProvider resource.

Example configuration for integrating with Bitbucket:

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: bitbucket
spec:
  type: BitbucketCloud
  displayName: Bitbucket
  bitbucketCloud:
    clientID: plainstring
    clientSecret: plainstring
    includeTeamGroups: true
    teams:
    - administrators
    - users
```

Additional resources

- Global parameters
- Module `control-plane-manager` documentation
- Module `user-authn` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Local authentication

In addition to external authentication providers, DP also supports local authentication.

Local authentication provides user verification and access management with support for configurable password policies, two-factor authentication (2FA), and group management. In the module parameters, you can configure password complexity, password history, password rotation, lockout after failed sign-in attempts and per-IP rate limiting of failed attempts. No external authentication system is required.

Local authentication involves creating User and Group resources in the cluster for static users and groups:

- A User object stores user information, including email and a hashed password (the password is not stored in plain text).
- A Group object defines a list of users grouped together.

Creating a static user

The recommended way to create a local user is the `d8 iam user create` command. It supports interactive password entry, automatic password generation, group assignment, and TTL for temporary users.

Examples:

Interactive password prompt (default when stdin is a terminal):

```
d8 iam user create anton --email anton@abc.com
```

Automatically generate a password (the generated password is shown in the command output once):

```
d8 iam user create anton --email anton@abc.com --generate-password
```

Read the password from stdin (for CI/CD pipelines):

```
echo "s3cret" | d8 iam user create anton --email anton@abc.com --password-stdin
```

Create the user and add them to groups (auto-creating groups if missing):

```
d8 iam user create anton --email anton@abc.com --generate-password --member-of admins --
create-groups
```

Create a temporary user with a TTL:

```
d8 iam user create anton --email anton@abc.com --generate-password --ttl 24h
```

As an alternative, you can create a User resource manually.

Example resource definition (note that the example includes a ttl):

```
apiVersion: deckhouse.io/v1
kind: User
metadata:
  name: admin
spec:
  email: admin@yourcompany.com
  password: $2a$10$etblbZ9yfZaKgbvysf1qguW3WULdMnxwWFrkoKpRH1yeWa5etjjAa
  ttl: 24h
```

Come up with a password and specify it in the `password` field as a raw bcrypt hash or a Base64-encoded bcrypt hash. To generate a Base64-encoded bcrypt hash, use the following command:

```
echo -n '<PASSWORD>' | htpasswd -BinC 10 "" | cut -d: -f2 | tr -d '\n' | base64 -w0; echo
```

> **i** If the `htpasswd` command is not available, install the appropriate package:
>
> - `apache2-utils` — for Debian-based distributions.
> - `httpd-tools` — for CentOS-based distributions.
> - `apache2-htpasswd` — for ALT Linux.

> **⚠** You cannot create a User whose `spec.email` matches a `User` subject of an existing ClusterAuthorizationRule or AuthorizationRule: the new user would get the permissions of the rule unnoticed. If the match is intentional, add the `user-authz.deckhouse.io/allow-authorization-rule-collision: "true"` annotation to the User. For details, see How rules are applied.

Deleting a user

To delete a local user, use the `d8 iam user delete` command. By default, it also removes the user from all Group resources they belong to.

Examples:

Delete the user (and automatically remove them from all groups):

```
d8 iam user delete anton
```

Delete the user but keep their references in groups:

```
d8 iam user delete anton --keep-memberships
```

Local user operations

Password reset, forced password change, 2FA reset, user lock/unlock and logout operations are performed via the UserOperation resource. The `initiatorType` field indicates who initiated the operation: an administrator (`admin`), the system (`system`), or the user (`self`).

Administrative operations

Use the `d8 iam user` commands for administrative actions on local users. They create a UserOperation resource with `initiatorType: admin`, wait for the operation to complete, and print the result.

> **i** Deleting, recreating, or running a `ResetPassword`, `Reset2FA`, `Lock`, or `Unlock` operation on a user is allowed only if you already have permissions covering the roles that the user receives through their email or group membership, or you are explicitly allowed to assign those roles. The value of the `initiatorType` field does not affect this check: setting `initiatorType: self` does not bypass it. For details, see the `user-authn` module documentation. The same rule applies to DexProvider objects, see Limiting the identities of a provider.

The `ResetPassword`, `Reset2FA`, `Lock` and `Logout` operations end the sessions of the user at once, and the user has to authenticate again. For what ends and how fast, see UserOperation lifecycle and side effects. Only `Reset2FA` removes the user's 2FA secret.

After an administrator resets the password with `ResetPassword`, the user signs in with that password once. Dex then asks the user to set a new password that complies with the password policy.

Examples of using the `d8 iam user` commands:

- Interactive password reset:

  ```
  d8 iam user reset-password admin
  ```

- Reading the new password from stdin:

  ```
  echo "N3wPa$$wo#d" | d8 iam user reset-password admin --password-stdin
  ```

- Generating a new password automatically:

```
d8 iam user reset-password admin --generate-password
```

- Reset the password in hashed form (if the password is hashed, provide the bcrypt hash without Base64 encoding):

```
d8 iam user reset-password admin --password-hash '$2y$10$abcdef...'
```

- 2FA reset:

```
d8 iam user reset2fa admin
```

- Locking a user for 30 minutes:

```
d8 iam user lock admin 30m
```

  The `d8 iam user lock` command locks a local user and accepts a duration in seconds, minutes or hours, for example `30s`, `10m` or `1h`. To lock a user for several days (`lock.for: 7d`) or permanently (`lock.for: permanent`), create a UserOperation as described in Creating UserOperation manually.

- User unlock:

```
d8 iam user unlock admin
```

By default, commands wait for the operation to complete. To only create a UserOperation and print its name, use the `--wait=false` flag.

Self-service operations

In the Deckhouse web interface, a user can sign out on all devices, and a local user can change their password. The web interface creates a UserOperation with `initiatorType: self` for the user who is signed in:

- Signing out on all devices creates a `Logout` operation. It ends every session of the user, including kubeconfig files.
- Changing the password creates a `RequirePasswordChange` operation. At the next sign-in, Dex asks for the current password and a new one that complies with the password policy. The operation ends no sessions.

Changing the password is available only for local accounts (the built-in `Local` connector). Users who sign in through external authentication providers change their password in the corresponding system.

For user-facing password change and reset scenarios, see Configuring authentication for applications.

Creating UserOperation manually

When running the `d8 iam user` CLI command is unavailable (e.g. in CI/CD, GitOps, or automation), you can create a UserOperation resource directly. Example — reset a local user's password (the `newPasswordHash` contains a bcrypt hash without Base64 encoding; the module encodes it automatically):

```
apiVersion: deckhouse.io/v1
kind: UserOperation
metadata:
  name: reset-password-admin
spec:
  user: admin
  type: ResetPassword
  initiatorType: admin
  resetPassword:
    newPasswordHash: "$2y$10$..."
```

For users of external providers of any type (LDAP, Atlassian Crowd, OIDC, SAML, GitHub, GitLab, Bitbucket Cloud), use `spec.target` instead of `spec.user`. The `Lock`, `Unlock` and `Logout` operations

are supported for external users. Example — lock an external user for 30 minutes:

```
apiVersion: deckhouse.io/v1
kind: UserOperation
metadata:
  name: lock-external-user
spec:
  target:
    connectorID: my-ldap
    email: jane.doe@example.org
  type: Lock
  initiatorType: admin
  lock:
    for: "30m"
```

A lock applies only to sign-ins through the provider set in `connectorID`. It does not block a local user or a user of another provider with the same email. The operation fails if the user has never signed in through this provider.

A UserOperation is a **single-use** object: after creation, the module processes it and writes the result to `status.phase` (`Succeeded` or `Failed`). A UserOperation runs once, and changes to its spec after creation are ignored. Completed operations are **automatically deleted** after 24 hours.

⚠ The `ResetPassword`, `Reset2FA`, `Lock` and `Logout` operations end the sessions of the user at once, and the user has to authenticate again. For what ends and how fast, see UserOperation lifecycle and side effects. `ResetPassword`, `Lock` and `Logout` keep the user's 2FA secret.

Viewing account state

The `user-authn` module keeps a UserAccount object for each local user and for each user who has signed in through an external provider. It shows whether the account is locked, until when, and how many failed sign-in attempts were counted. Do not create or edit UserAccount objects.

To list the accounts, run:

```
d8 k get useraccounts
```

Adding a user to a group

⚠ It is forbidden to use users and groups with the `system:` prefix.
Authentication attempts by such users or members of such groups will be rejected, and a corresponding warning will appear in the `kube-apiserver` logs.

⚠ You cannot create a Group whose `spec.name` matches a `Group` subject of an existing ClusterAuthorizationRule or AuthorizationRule: the members of the new group would get the permissions of the rule unnoticed. If the match is intentional, add the `user-authz.deckhouse.io/allow-authorization-rule-collision: "true"` annotation to the Group. For details, see How rules are applied.

The recommended way to manage groups is the `d8 iam group` command. Examples:

Create a group:

```
d8 iam group create admins
```

Add a user to a group:

```
d8 iam group add-member admins user anton
```

Remove a user from a group:

```
d8 iam group remove-member admins user anton
```

Delete a group:

```
d8 iam group delete admins
```

As an alternative, you can create a Group resource manually.

Example resource definition:

```
apiVersion: deckhouse.io/v1alpha1
kind: Group
metadata:
  name: admins
spec:
  name: admins
  members:
    - kind: User
      name: admin
```

Where `members` is a list of users belonging to the group.

Once the group is created and includes all necessary users, proceed by configuring authorization.

Configuring password policy

Password policy allows controlling password complexity, rotation, and automatic lockout after consecutive failed login attempts.

An administrator can lock or unlock a user with `d8 iam user lock` / `unlock` (or a UserOperation) without enabling `passwordPolicy.lockout`. The `lockout` section only turns on automatic lockout after the configured number of failed attempts.

Dex stores an automatic lock itself and does not create a UserOperation for it. Local users are always covered. LDAP and Atlassian Crowd users are locked only if their provider type is listed in `passwordPolicy.lockout.applyToConnectors`. To limit failed sign-in attempts per client IP address, use the `rateLimit` parameter.

To set up a password policy, use the `passwordPolicy` field in the configuration of the `user-authn` module.

Examples of policies:

- Without custom complexity rules
- With custom complexity rules

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: user-authn
spec:
  version: 3
  enabled: true
  settings:
    passwordPolicy:
      complexityLevel: Fair
      passwordHistoryLimit: 10
      lockout:
        lockDuration: 15m
        maxAttempts: 3
      rotation:
        interval: "30d"
```

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: user-authn
spec:
  version: 3
  enabled: true
  settings:
    passwordPolicy:
      complexityLevel: Custom
      custom:
        minLength: 10
        specialCharacters: true
        numbers: false
        capitalized: true
        repeatedChars: false
      passwordHistoryLimit: 10
```

Configuring two-factor authentication (2FA)

2FA increases security by requiring a code from a TOTP authenticator application (for example, Google Authenticator) during login.

To set up 2FA, use the `twoFactor` field in the configuration of the `user-authn` module:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: user-authn
spec:
  version: 4
  enabled: true
  settings:
    twoFactor:
      enabled: true
      issuerName: "awesome-app"
```

Field description:

- `enabled`: Enables or disables 2FA for all static users.
- `issuerName`: Name displayed in the authenticator application when adding an account.

> **i** After enabling 2FA, each user must register in the authenticator application during their first login.

- Module `user-authn` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Accessing the Kubernetes API via load balancer

DP allows using authentication when accessing the Kubernetes API. In this case, a user can generate a `kubectl` configuration via the DP web UI to securely access the Kubernetes API through a traffic balancer (Ingress controller).

To configure access, follow these steps:

1. Enable Kubernetes API publishing. To do this, set the parameter `apiserver.publishAPI.ingress.enabled: true` in the `control-plane-manager` module settings or via the Deckhouse Platform web interface.

   Example module configuration:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: control-plane-manager
   spec:
     enabled: true
     version: 3
     settings:
       apiserver:
         publishAPI:
           ingress:
             enabled: true
   ```

2. Open the DP web UI.
   The published API becomes available for kubeconfig generation automatically after enabling API publishing (the `apiserver.publishAPI.ingress.enabled` parameter) in the `control-plane-manager` module.

3. Generate the `kubectl` configuration.
   The web UI provides a set of commands to configure `kubectl`.
   These commands can be copied and pasted into the terminal.
   Authentication will be performed using an OIDC token issued by Dex.
   If the provider supports session renewal, the configuration will include a `refresh token`, allowing access to be extended without re-authentication.

4. Configure additional API access points.
   In the `user-authn` module configuration, you can specify additional connection points (kube-apiserver), each with its own description and CA certificates.
   This may be useful if the cluster is accessible through different networks — for example, via VPN or public IP:

   ```
   settings:
     kubeconfigGenerator:
     - id: direct
       masterURI: https://159.89.5.247:6443
       description: "Direct access to kubernetes API"
     - id: second
       masterURI: https://5.6.7.8:6443
       description: "Second access to kubernetes API"
   ```

How API access protection works in Kubernetes

In Deckhouse Platform, you can safely expose the Kubernetes API externally using an Ingress controller or Gateway API while maintaining access control (for more information on how to expose the Kubernetes API, see the `control-plane-manager` module documentation). API exposure is configured via the `control-plane-manager` module, while authentication is handled via the `user-authn` module. You can configure:

- A list of trusted IP addresses or networks allowed to access the API.
- The Ingress controller through which access will be provided.

To configure:

1. Enable API publishing as shown in the example above.
2. Configure access restrictions. In the `control-plane-manager` module configuration, you can specify:
   - A list of IP addresses or networks allowed to access (`apiserver.publishAPI.ingress.whitelistSourceRanges`).
   - The Ingress controller to be used for publishing (`apiserver.publishAPI.ingress.ingressClass`).

3. Use the DP web UI.
   Users will be able to securely access the API using the kubeconfig generated there.
   This kubeconfig will include the OIDC token and the Ingress connection settings.

The following will be automatically configured when API publishing is enabled:

- A CA certificate will be generated and added to the kubeconfig.
- Login via Dex with OIDC support will be configured.

The JWT authenticator for Dex does not depend on API publishing. It is enabled together with the `user-authn` module: using the `control-plane-manager` module, DP passes kube-apiserver an AuthenticationConfiguration with a JWT authenticator for Dex.

Access using Basic Authentication (LDAP)

In addition to OIDC, you can configure direct access to the API using Basic Authentication (username and password). In this case, credentials are verified against LDAP-compatible directory service.

To configure:

1. Enable API publishing (the `apiserver.publishAPI` parameter of the `control-plane-manager` module).
2. Configure an LDAP provider in the `user-authn` module and enable the `enableBasicAuth: true` option.

> ⚠ Only one provider in the cluster can have `enableBasicAuth` enabled.

Basic Authentication is also available for Crowd and OIDC providers (the `enableBasicAuth` parameter in the `crowd` or `oidc` section). Through an LDAP provider, Basic Authentication goes through Dex and keeps the identity limits of the provider. Through a Crowd or OIDC provider, it bypasses these limits, so only a SuperAdmin can enable it.

After this, users can configure their `kubeconfig` by specifying their LDAP username and password:

```
apiVersion: v1
kind: Config
clusters:
- name: my-cluster
  cluster:
    server: https://api.example.com
    # Path to CA certificate or insecure-skip-tls-verify: true
    certificate-authority: /path/to/ca.crt
users:
- name: ldap-user
  user:
    username: janedoe@example.com
    password: userpassword
contexts:
- name: default
  context:
    cluster: my-cluster
    user: ldap-user
current-context: default
```

Kerberos (SPNEGO) SSO for LDAP

Dex supports passwordless Kerberos (SPNEGO) flow for the LDAP connector. The mechanism works as follows:

1. The browser, trusting the Dex host, sends `Authorization: Negotiate …`.
2. Dex validates the Kerberos ticket against the keytab and skips the login/password input form.
3. Dex matches the principal with the LDAP name, retrieves the groups, and completes the OIDC flow.

> **i** To configure Kerberos (SPNEGO) SSO, LDAP must have an account with read-only privileges (service account). For more information on configuration, see the section LDAP Integration.

Enabling Kerberos (SPNEGO) SSO for LDAP:

1. In AD/KDC, create/provision an SPN `HTTP/<DEX_FQDN>` for a service account and generate a keytab.
2. In the cluster, create a Secret in the `d8-user-authn` namespace with the `krb5.keytab` data key.
3. In the LDAP DexProvider resource, enable `spec.ldap.kerberos`:
   - `enabled: true`
   - `keytabSecretName: <secret name>`
   - optional: `expectedRealm`, `usernameFromPrincipal`, `fallbackToPassword`

Dex will mount the keytab automatically and start accepting SPNEGO. A server-side `krb5.conf` is not required — tickets are validated using the keytab.

Example of configuring SSO via Kerberos (SPNEGO) for LDAP (extension of the LDAP provider specification):

```
apiVersion: deckhouse.io/v1
kind: DexProvider
metadata:
  name: active-directory
spec:
  type: LDAP
  displayName: Active Directory
  ldap:
    host: ad.example.com:636
    bindDN: cn=dex-readonly,cn=users,dc=example,dc=com
    bindPW: <PASSWORD>
    userSearch:
      baseDN: cn=Users,dc=example,dc=com
      username: sAMAccountName
      idAttr: uid
      emailAttr: mail
      nameAttr: cn
    groupSearch:
      baseDN: cn=Users,dc=example,dc=com
      nameAttr: cn
      userMatchers:
      - userAttr: uid
        groupAttr: memberUid
    kerberos:
      enabled: true
      keytabSecretName: dex-kerberos-keytab  # Secret in d8-user-authn with key
'krb5.keytab'.
      expectedRealm: EXAMPLE.COM           # Optional, case-insensitive match.
      usernameFromPrincipal: SAMAccountName  #
Localpart|SAMAccountName|UserPrincipalName.
      fallbackToPassword: false            # The default is false; if true, a
login/password form is rendered when the `Authorization: Negotiate` header is
missing or invalid.
```

Notes:

- The Secret `dex-kerberos-keytab` must exist in the `d8-user-authn` namespace and have a data key named exactly `krb5.keytab`.
- A single Dex Pod can serve multiple LDAP+Kerberos providers. Each provider mounts its own keytab; a shared `krb5.conf` is not required (Dex validates tickets offline using the keytab).
- A DexProvider with `enabled: true` in `spec.ldap.kerberos` must have `keytabSecretName` set, otherwise the object is rejected when saved. To turn Kerberos off and keep its settings, set `enabled: false`.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Resource configuration

Deckhouse Platform allows you to configure resource limits and requests for all components. By default, the following values are used:

- **Dex OIDC Provider** — 10m CPU / 25Mi memory (requests), 100m CPU / 100Mi memory (limits)
- **Kubeconfig Generator** — 10m CPU / 25Mi memory (requests), 100m CPU / 100Mi memory (limits)
- **Basic Auth Proxy** — 10m CPU / 25Mi memory (requests), 100m CPU / 100Mi memory (limits)
- **Dex Authenticator** — 10m CPU / 25Mi memory (requests), 100m CPU / 100Mi memory (limits)
- **Redis** (used by Dex Authenticator) — 10m CPU / 25Mi memory (requests), 100m CPU / 100Mi memory (limits)

> When Vertical Pod Autoscaler (VPA) is enabled, the resource limits are managed automatically by VPA, but you can still configure the minimum and maximum allowed values through the `resources` section.

Example configuration

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: user-authn
spec:
  version: v1
  settings:
    resources:
      dex:
        requests:
          cpu: "10m"
          memory: "25Mi"
        limits:
          cpu: "20m"
          memory: "50Mi"
      kubeconfigGenerator:
        requests:
          cpu: "10m"
          memory: "25Mi"
        limits:
          cpu: "20m"
          memory: "50Mi"
      basicAuthProxy:
        requests:
          cpu: "10m"
          memory: "25Mi"
        limits:
          cpu: "20m"
          memory: "50Mi"
      dexAuthenticator:
        requests:
          cpu: "10m"
          memory: "25Mi"
        limits:
          cpu: "20m"
          memory: "50Mi"
      redis:
        requests:
          cpu: "10m"
          memory: "25Mi"
        limits:
          cpu: "20m"
          memory: "50Mi"
```

Authorization

In Deckhouse Platform (DP), authorization is based on the standard Kubernetes Role-Based Access Control (RBAC) mechanism. This allows for flexible access control for different users, groups, and service accounts, ensuring security and operational control in the cluster.

DP supports two role models:

- Granular (recommended). Access permissions are configured the standard Kubernetes RBAC way: by creating RoleBinding or ClusterRoleBinding resources — or, for project-wide access, the ProjectRoleBinding and ClusterProjectRoleBinding resources of the `multitenancy-manager` module.
- Basic. The end-to-end authorization subsystem extends the standard RBAC mechanism with custom resources — ClusterAuthorizationRule and AuthorizationRule. Support for this model will be discontinued in future releases.

Both models are supported by the `user-authz` module and can be used at the same time — the permissions they grant are summed up (for details, see the `user-authz` module FAQ). The choice of model depends on security requirements and usage scenarios.

Combined use of ClusterAuthorizationRule, AuthorizationRule, and RBAC

If multitenancy mode is enabled in the cluster (`enableMultiTenancy: true`), a user's effective permissions are the union of the permissions from all of the following sources:

- **permissions from ClusterAuthorizationRule** — apply only within the namespaces allowed by the `namespaceSelector` parameter (or the deprecated `limitNamespaces` parameter);
- **permissions from AuthorizationRule** — apply within the namespace where the AuthorizationRule resource is created;
- **permissions from plain RoleBinding resources** — apply within the namespace where the RoleBinding resource is created;
- **permissions from plain ClusterRoleBinding resources** not created by the `user-authz` module — apply cluster-wide.

The namespace restrictions set in a ClusterAuthorizationRule apply only to the permissions granted by that ClusterAuthorizationRule. They do not override permissions granted via a RoleBinding, ClusterRoleBinding, or AuthorizationRule in other namespaces. At the same time, the permissions granted by the ClusterAuthorizationRule do not extend to those other namespaces.

The namespace restrictions are enforced by the authorization webhook, so they do not apply to the identities that the webhook does not check: control plane components, kubelets, and the ServiceAccounts of `kube-system` and of the namespaces whose names start with `d8-`. A ClusterAuthorizationRule that names such a ServiceAccount, directly or through a group such as `system:serviceaccounts`, grants its access level in every namespace. Create the ServiceAccounts of external systems in ordinary namespaces.

For example, if a user has a ClusterAuthorizationRule with `accessLevel: Editor` restricted to the `ns-a` namespace, as well as a RoleBinding with the `view` role in the `ns-b` namespace, they get `Editor`-level permissions in `ns-a` and read-only permissions in `ns-b`. The permissions granted via the RoleBinding are not restricted by the ClusterAuthorizationRule, and the `Editor` access level set by the ClusterAuthorizationRule does not extend to the `ns-b` namespace.

Who gets access and when

There are two scenarios for granting access in DP:

- Granting access to users for working via command-line clients, web UI, and other tools used for administration, development, and cluster management.
- Granting access to service accounts for automating tasks such as application deployment and updates (most commonly using the IaC approach). Examples of such services include CI/CD systems, monitoring systems, and others.

After successful authentication, users and service accounts are granted access to cluster resources based on the configured authorization settings.

User authentication

DP supports multiple user authentication methods. For details, refer to User authentication.

Service account authentication

In Kubernetes, service accounts (ServiceAccount) are special accounts used to automate tasks and interact with the cluster API. They enable applications and services to securely communicate with the Kubernetes API.

⚠ Do not create ServiceAccounts for external systems in `kube-system` or in namespaces whose names start with `d8-`. The authorization webhook does not check the ServiceAccounts of these namespaces, so the namespace limits of a ClusterAuthorizationRule (`namespaceSelector`, `limitNamespaces`, `allowAccessToSystemNamespaces`) do not apply to them. Their access level applies in every namespace of the cluster, including system namespaces.

You may need to create a ServiceAccount with access to the Kubernetes API, for example, when setting up application deployment through a CI system. To create a ServiceAccount and grant it access, follow these steps:

i The example uses the basic role model.

1. Create a namespace for CI and a ServiceAccount in it:

```
d8 k create -f - <<EOF
apiVersion: v1
kind: Namespace
metadata:
  name: ci
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: gitlab-runner-deploy
  namespace: ci
---
apiVersion: v1
kind: Secret
metadata:
  name: gitlab-runner-deploy-token
  namespace: ci
  annotations:
    kubernetes.io/service-account.name: gitlab-runner-deploy
type: kubernetes.io/service-account-token
EOF
```

2. Grant the ServiceAccount the necessary permissions using the ClusterAuthorizationRule custom resource:

```
d8 k create -f - <<EOF
apiVersion: deckhouse.io/v1
kind: ClusterAuthorizationRule
metadata:
  name: gitlab-runner-deploy
spec:
  subjects:
  - kind: ServiceAccount
    name: gitlab-runner-deploy
    namespace: ci
  accessLevel: Editor
EOF
```

   If multitenancy mode is enabled (the `enableMultiTenancy` parameter of the `user-authz` module), limit the namespaces available to the ServiceAccount with the `namespaceSelector` parameter.

3. Set the variable values (they are used later) by running the following commands (**insert your own values**):

```
export CLUSTER_NAME=my-cluster
export USER_NAME=gitlab-runner-deploy.my-cluster
export CONTEXT_NAME=${CLUSTER_NAME}-${USER_NAME}
export FILE_NAME=kube.config
```

4. Generate the `cluster` section in the kubectl configuration file:

   Use one of the following options to access the cluster API server:

   - If there is direct access to the API server:
     1. Get the Kubernetes cluster CA certificate:

        ```
        d8 k get cm kube-root-ca.crt -o jsonpath='{ .data.ca\.crt }' > /tmp/ca.crt
        ```

     2. Generate the `cluster` section (the API server IP address is used for access):

        ```
        d8 k config set-cluster $CLUSTER_NAME --embed-certs=true \
          --server=https://$(d8 k get endpointslices -l kubernetes.io/service-name=kubernetes
        -o json | jq -rc '.items[0] | "\(.endpoints[0].addresses[0]):\
        (.ports[0].port)"') \
          --certificate-authority=/tmp/ca.crt \
          --kubeconfig=$FILE_NAME
        ```

   - If there is no direct access to the API server, use one of the following options:
     - enable access to the API server through the Ingress controller (the apiserver.publishAPI parameter of the `control-plane-manager` module) and specify the addresses requests will come from (the whitelistSourceRanges parameter);
     - specify the addresses requests will come from in a separate Ingress controller (the acceptRequestsFrom parameter).
   - If a non-public CA is used:
     1. Get the CA certificate from the Secret of the `kubernetes-api` Ingress in the `kube-system` namespace. This is the certificate of the `api.%s` domain:

        ```
        d8 k -n kube-system get secrets -o json \
          $(d8 k -n kube-system get ing kubernetes-api -o jsonpath="
        {.spec.tls[0].secretName}") \
          | jq -rc '.data."ca.crt" // .data."tls.crt"' \
          | base64 -d > /tmp/ca.crt
        ```

     2. Generate the `cluster` section (an external domain and the CA are used for access):

        ```
        d8 k config set-cluster $CLUSTER_NAME --embed-certs=true \
          --server=https://$(d8 k -n kube-system get ing kubernetes-api -ojson | jq
        '.spec.rules[].host' -r) \
          --certificate-authority=/tmp/ca.crt \
          --kubeconfig=$FILE_NAME
        ```

   - If a public CA is used, generate the `cluster` section (an external domain is used for access):

     ```
     d8 k config set-cluster $CLUSTER_NAME \
       --server=https://$(d8 k -n kube-system get ing kubernetes-api -ojson | jq
     '.spec.rules[].host' -r) \
       --kubeconfig=$FILE_NAME
     ```

   - If the API server is published via Gateway API, the cluster has the `kubernetes-api` HTTPRoute in the `kube-system` namespace instead of the Ingress. In the commands above, use the host from it instead of `.spec.rules[].host`:

     ```
     d8 k -n kube-system get httproute kubernetes-api -o jsonpath='{.spec.hostnames[0]}'
     ```

     Take the name of the Secret with the CA certificate from the `control-plane-manager`

ListenerSet instead of `.spec.tls[0].secretName`:

```
d8 k -n kube-system get listenerset control-plane-manager -o
jsonpath='{.spec.listeners[?(@.name=="api")].tls.certificateRefs[0].name}'
```

5. Generate the `user` section with the token from the ServiceAccount Secret in the kubectl configuration file:

```
d8 k config set-credentials $USER_NAME \
  --token=$(d8 k -n ci get secret gitlab-runner-deploy-token -o json |jq -r
'.data["token"]' | base64 -d) \
  --kubeconfig=$FILE_NAME
```

6. Generate the context in the kubectl configuration file:

```
d8 k config set-context $CONTEXT_NAME \
  --cluster=$CLUSTER_NAME --user=$USER_NAME \
  --kubeconfig=$FILE_NAME
```

7. Set the generated context as the default one in the kubectl configuration file:

```
d8 k config use-context $CONTEXT_NAME --kubeconfig=$FILE_NAME
```

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Basic authorization model

To use the basic role model, the `user-authz` module must be enabled in the cluster. This module creates a set of cluster roles (ClusterRole) suitable for most user and group access management tasks.

> The module implements two role-based models: the granular one (recommended) and the basic one (this page), built around the ClusterAuthorizationRule and AuthorizationRule resources — its support will be discontinued in future releases.
>
> The models are not resource-compatible — automatic conversion is impossible — but they can be used at the same time: the permissions of both models are summed up.

Key features of the basic role model:

- Implements a role-based end-to-end authorization subsystem that extends the standard RBAC functionality.
- Access is configured with the custom resources ClusterAuthorizationRule and AuthorizationRule, on top of Kubernetes RBAC.
- Controls access to scaling tools (via the `allowScale` parameter in the ClusterAuthorizationRule or AuthorizationRule resource).
- Controls access to port forwarding (via the `portForwarding` parameter in the ClusterAuthorizationRule or AuthorizationRule resource).
- Manages the list of allowed namespaces using the labelSelector format (via the `namespaceSelector` parameter in the ClusterAuthorizationRule resource).
- Namespace restrictions (multitenancy mode, `namespaceSelector`, `limitNamespaces`) are available in the DP Ultimate/EE, Certified Lite, Certified Pro, BE, SE, SE+, and CSE editions.

High-level roles used in the basic model

In addition to RBAC, the basic role model implemented via the `user-authz` module provides a convenient set of high-level roles:

Role	Examples of allowed actions	Limitations
User	View Pods, logs, and Deployments	Can’t access secrets, ports, or containers
PrivilegedUser	Access containers (via `kubectl exec`), view secrets, remove Pods	Can’t modify a Deployment or Service
Editor	Create and remove a Deployment, Service, or ConfigMap	Can’t access a ReplicaSet or ClusterRoles
Admin	Create and modify Pods, create ServiceAccount tokens (`serviceaccounts/token`), manage Role, RoleBinding, and AuthorizationRule objects, delete auxiliary objects (for example, ReplicaSet and the challenges and orders of the `acme.cert-manager.io` group)	Can’t access cluster-wide resources
ClusterEditor	Manage a limited set of cluster-wide objects used in application tasks: DaemonSet, StorageClass, CustomResourceDefinition, GatewayClass, and the objects that modules add at this level (for example, KeepalivedInstance)	Can’t manage namespaces, quotas, ClusterRole (read-only access), and ClusterRoleBinding
ClusterAdmin	Manage cluster-wide service objects: namespaces, quotas, NetworkPolicy, the proxy subresources of nodes, ClusterAuthorizationRule, ClusterRole, and ClusterRoleBinding	Can create ClusterAuthorizationRule objects only up to the `ClusterAdmin` level, and ClusterRoleBinding objects only to roles whose permissions it already holds
SuperAdmin	Any actions are allowed (including `*` in RBAC), but with consideration to `limitNamespaces`	Limitations can be applied only using cluster policies

⚠ Multitenancy mode restricts access to namespaced resources only. Subjects with the `ClusterAdmin` or `SuperAdmin` access level can still create cluster-wide bindings. The authorization webhook does not check control plane components, kubelets, and the ServiceAccounts of `kube-system` and of the namespaces whose names start with `d8-`, so the namespace restrictions do not apply to them.

The `limitNamespaces` and `allowAccessToSystemNamespaces` parameters of the ClusterAuthorizationRule resource are deprecated. To restrict a rule to certain namespaces, use `namespaceSelector`. To grant access to all namespaces, including the system ones, use `namespaceSelector.matchAny: true`. If `namespaceSelector` is set, the deprecated parameters are ignored.

In multitenancy mode, if the authorization webhook becomes unavailable, requests are **denied**, not allowed: the webhook runs before RBAC and is configured with `failurePolicy: Deny`, so a request it cannot answer does not reach RBAC. The exception is the identities listed in `matchConditions` of the AuthorizationConfiguration: control plane components, `kubernetes-api-proxy`, kubelets, the ServiceAccounts of the `kube-system` and `d8-*` namespaces, and anonymous kube-apiserver health probes (`/livez`, `/readyz`, `/healthz`) bypass the webhook, so the cluster keeps running and Deckhouse can restore the webhook.

Some platform components place their objects into user namespaces (for example, Dex authenticator

pods) and label them `heritage: deckhouse`. No access level, `SuperAdmin` included, allows creating, modifying and deleting such objects or running `exec`, `attach` and `port-forward` in such pods. For details, see Admin level restrictions and superadmin rights.

Default access list for each high-level role

> **i** This list is a static snapshot. The actual set of rules also depends on which DP modules are enabled in the cluster.

Verb shortcuts:

- read: `get`, `list`, `watch`
- read-write: `get`, `list`, `watch`, `create`, `delete`, `deletecollection`, `patch`, `update`
- write: `create`, `delete`, `deletecollection`, `patch`, `update`

Role `User`:

To get an additional list of access rules for a cluster module role (rules added by the administrator and non-default rules of other Deckhouse modules), use the following command:

```
D8_ROLE_NAME=Editor
d8 k get clusterrole -o jsonpath="{range .items[?(@.metadata.annotations.user-
authz\.deckhouse\.io/access-level=='$D8_ROLE_NAME')]}{.rules}{'\n'}{end}" | jq -s add
```

AuthorizationRule example

Use AuthorizationRule to set access rules for users within a specific namespace.

```
apiVersion: deckhouse.io/v1alpha1
kind: AuthorizationRule
metadata:
  name: test-rule
spec:
  accessLevel: Admin
  subjects:
  - kind: User
    name: admin@example.com
```

ClusterAuthorizationRule example

Use ClusterAuthorizationRule to set access rules for users either cluster-wide or for specific namespaces.

```
apiVersion: deckhouse.io/v1
kind: ClusterAuthorizationRule
metadata:
  name: test-rule
spec:
  subjects:
  - kind: User
    name: some@example.com
  - kind: ServiceAccount
    name: gitlab-runner-deploy
    namespace: ci
  - kind: Group
    name: some-group-name
  accessLevel: PrivilegedUser
  portForwarding: true
  # This option is only available if the enableMultiTenancy parameter is set.
  namespaceSelector:
    labelSelector:
      matchExpressions:
      - key: stage
        operator: In
        values:
        - test
        - review
      matchLabels:
        team: frontend
```

How rules are applied

ClusterAuthorizationRule and AuthorizationRule objects grant access through ordinary ClusterRoleBinding and RoleBinding objects. The `user-authz-controller` component creates these bindings for every rule, keeps them in sync with the rule, and writes the result to the rule's `status`. To view the state of the rules, run:

```
d8 k get clusterauthorizationrules
d8 k get authorizationrules -A
```

The `READY` column shows whether the bindings match the rule, and the `BINDINGS` column shows how many bindings the rule has. A rule with an unsupported `accessLevel` gets `Ready=False` with the `InvalidSpec` reason. The other reasons and the controller metrics are described in the `user-authz` module FAQ.

If several ClusterAuthorizationRule objects match the same subject, the allowed namespaces are combined, and the effective `accessLevel` is the most powerful among the matching rules. For an example, see the `user-authz` module FAQ.

Creating, updating, and deleting a ClusterAuthorizationRule counts as assigning roles: the request is admitted only if the requester can assign the roles of the rule. An update is checked against both the previous and the new grants, so lowering `SuperAdmin` to `User` still requires being able to assign `SuperAdmin`. Who can assign which levels is described in Who can assign roles.

A `User` or `Group` subject is matched by name against the identity in the token, and a local identity is indistinguishable from one asserted by an external authentication provider. Therefore, you cannot create a User whose `spec.email` or a Group whose `spec.name` matches a subject of an existing ClusterAuthorizationRule or AuthorizationRule. The restriction is checked when a User or Group is created and when its `spec.email` or `spec.name` is changed. If the match is intentional, for example, the rule was written in advance, set the `user-authz.deckhouse.io/allow-authorization-rule-collision: "true"` annotation on the User or Group. The annotation only acknowledges the name collision: it does not let the requester assign roles they cannot assign otherwise.

Extending permissions for high-level roles

To add permissions to a specific high-level role, create a ClusterRole with the annotation `user-authz.deckhouse.io/access-level: <AccessLevel>`.

The annotation accepts `User`, `PrivilegedUser`, `Editor`, `Admin`, `ClusterEditor`, and

`ClusterAdmin`. Other values, including `SuperAdmin`, are ignored. In the name of the aggregated role, the level is written in kebab case, for example, `user-authz:cluster-editor:custom`. The rules of a level are also included in the aggregated roles of every higher level.

Example:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  annotations:
    user-authz.deckhouse.io/access-level: Editor
  name: user-editor
rules:
- apiGroups:
  - kuma.io
  resources:
  - trafficroutes
  - trafficroutes/finalizers
  verbs:
  - get
  - list
  - watch
  - create
  - update
  - patch
  - delete
- apiGroups:
  - flagger.app
  resources:
  - canaries
  - canaries/status
  - metrictemplates
  - metrictemplates/status
  - alertproviders
  - alertproviders/status
  verbs:
  - get
  - list
  - watch
  - create
  - update
  - patch
  - delete
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Granular authorization model

The granular role model is built on the principle of aggregation: it combines low-level roles into larger ones that cover common tasks. This makes the model easy to extend by adding your own roles.

To use the granular role model, the `user-authz` module must be enabled in the cluster. The module creates a set of special aggregated cluster roles (ClusterRole) suitable for most user and group access

management tasks.

⚠ The module implements two role-based models: the granular one (this page, recommended) and the basic one, built around the ClusterAuthorizationRule and AuthorizationRule resources (its support will be discontinued in future releases).

The models are not resource-compatible — automatic conversion is impossible — but they can be used at the same time: the permissions of both models are summed up.

Unlike the basic role model, the granular one does not use ClusterAuthorizationRule or AuthorizationRule resources. Access rights are configured the standard Kubernetes RBAC way: by creating RoleBinding or ClusterRoleBinding resources and specifying one of the roles prepared by the `user-authz` module in them. To grant access to all namespaces of a project at once, use the ProjectRoleBinding and ClusterProjectRoleBinding resources of the `multitenancy-manager` module.

i Access does not have to be granted by hand-writing YAML manifests: the Deckhouse web UI provides an access grant wizard. It walks you through the steps (who gets access → where → at which level), picks the right binding kind itself (RoleBinding, ClusterRoleBinding, ProjectRoleBinding, or ClusterProjectRoleBinding), and lets you assemble a custom role from ready-made building blocks without writing YAML.

The module creates special aggregated cluster roles (ClusterRole). By using these roles in RoleBinding or ClusterRoleBinding, you can do the following:

- Manage access to modules of a specific subsystem.

  For example, you can use the `d8:subsystem:network:manager` role in a ClusterRoleBinding to allow a network administrator to configure *network* modules (such as `cni-cilium`, `ingress-nginx`, `istio`, etc.).

- Manage access to *user* resources of modules within namespaces.

  For example, the `d8:namespace:manager` role in a RoleBinding enables deleting/creating/editing the PodLoggingConfig resource in the namespace. At the same time, it does not grant access to the cluster-wide ClusterLoggingConfig and ClusterLogDestination resources of the `log-shipper` module, nor does it allow configuration of the `log-shipper` module itself.

The roles created by the module are divided into the following classes:

- Namespace roles — for assigning rights to users (such as application developers) **in a specific namespace**.
- Project roles — for assigning rights **in all namespaces of a project at once**.
- System and subsystem roles — for assigning rights to platform administrators and administrators of a part of the platform.

Role scopes

Every role operates in one of four scopes. The scope defines *where* the granted permissions apply and *which resource* is used to assign the role:

Scope	Role name format	Intended for	Which resource is used to assign the role
Namespace	`d8:namespace:<level>`	Application users (developers)	RoleBinding in a specific namespace
Project	`d8:project:<level>`	Teams working with projects	ProjectRoleBinding or ClusterProjectRoleBinding for the whole project, RoleBinding for one namespace of the project
Subsystem	`d8:subsystem:<subsystem>:<level>`	Administrators of a part of the platform	ClusterRoleBinding
Whole platform	`d8:system:<level>`	Platform administrators	ClusterRoleBinding

Access levels

Each scope provides several access levels for roles:

- The “namespace” and “project” scopes have five levels: `viewer` → `user` → `manager` → `admin` → `superadmin`.
- The “subsystem” and “whole platform” scopes have three levels: `viewer` → `manager` → `superadmin`. There are no `user` and `admin` levels here: the system level has no “user” resources that could be used without administering them.

Access levels form a hierarchy with a cumulative principle: each next level inherits all permissions of the previous one and extends them. For example, the `manager` level in the namespace scope includes everything the `user` level allows, which in turn includes everything the `viewer` level allows.

Namespace roles

⚠ A namespace role cannot be assigned through a ClusterRoleBinding. Use a RoleBinding in a namespace, or a ProjectRoleBinding or ClusterProjectRoleBinding for all namespaces of a project.

Namespace roles are intended to assign rights to a user **in a specific namespace**. Users refer to, for example, developers who use a cluster configured by an administrator to deploy their applications. Such users don’t need to manage DP modules or a cluster, but they need to be able to, for example, create their Ingress resources, configure application authentication, and collect logs from applications.

A namespace role defines permissions for accessing namespaced resources of modules and standard namespaced resources of Kubernetes (Pod, Deployment, Secret, ConfigMap, etc.).

DP creates the following namespace roles:

Role	Allowed actions
`d8:namespace:viewer`	View standard Kubernetes resources (except Secrets and RBAC resources), Gateway API resources, pod logs and metrics, and authenticate in the cluster
`d8:namespace:user`	Everything `viewer` allows, plus: view secrets, `kubectl exec/attach`, delete pods (but not create or modify them), `kubectl port-forward/proxy`, change controller replica counts
`d8:namespace:manager`	Everything `user` allows, plus: manage module resources (for example, Certificate, PodLoggingConfig) and standard namespaced Kubernetes resources (Pod, Deployment, ConfigMap, Secret, Service, Ingress, NetworkPolicy, CronJob, etc.), as well as Gateway API resources (Gateway, ListenerSet, HTTPRoute, GRPCRoute, ReferenceGrant, etc.)
`d8:namespace:admin`	Everything `manager` allows, plus: manage ResourceQuota, LimitRange, ServiceAccount, Role, RoleBinding
`d8:namespace:superadmin`	Everything `admin` allows, plus security-sensitive operations: minting ServiceAccount tokens, making requests on behalf of ServiceAccounts

The detailed split of permissions between `admin` and `superadmin` is described in Admin level restrictions and superadmin rights.

Automatic access to cluster-wide catalog resources

Working in a namespace requires reading some cluster-wide “catalogs”: for example, to set `storageClassName` or `ingressClassName` in a manifest, one needs to see the list of StorageClasses and IngressClasses. Therefore, every subject that receives a RoleBinding to any `d8:namespace:*` or `d8:project:*` role automatically also gets read access to such catalog resources (StorageClass, IngressClass, PriorityClass, RuntimeClass, VolumeSnapshotClass, ClusterLogDestination, etc.).

Technically, this looks like an automatically created ClusterRoleBinding to the `d8:dict` role with the `rbac.deckhouse.io/dict: "true"` label. Such objects are managed by the platform: they appear when the subject is granted their first namespace binding and are removed once none are left — there is no need to edit them manually.

Project roles

> ⚠ A project role cannot be assigned via ClusterRoleBinding — such an attempt is rejected. To assign a role across a whole project, use ProjectRoleBinding or ClusterProjectRoleBinding. A plain RoleBinding in one of the project namespaces is also allowed — the role then applies in that namespace only.

Project roles (`d8:project:<level>`) are intended for working with projects — isolated environments that may span several namespaces. The levels are the same as for namespace roles: `viewer`, `user`, `manager`, `admin`, `superadmin`.

Each project role includes all permissions of the namespace role of the same level and additionally grants permissions to manage the project itself:

- `d8:project:viewer` — the permissions of `d8:namespace:viewer` plus viewing the project's ProjectNamespace and ProjectRoleBinding resources;
- `d8:project:user` — the permissions of `d8:namespace:user` plus viewing the project's ProjectNamespace and ProjectRoleBinding resources;
- `d8:project:manager` — the permissions of `d8:namespace:manager` plus managing the project's additional namespaces (ProjectNamespace resources);
- `d8:project:admin` — the permissions of `d8:namespace:admin` plus managing access to the project (ProjectRoleBinding resources) and the right to bind the built-in `d8:project:*` and `d8:namespace:*` roles (except the `superadmin` level) to other users within the project;
- `d8:project:superadmin` — analogous to the relation between `d8:namespace:superadmin` and `d8:namespace:admin`.

A role assigned via ProjectRoleBinding automatically applies in **all** namespaces of the project — the main one as well as the additional ones, including those created later.

System and subsystem roles

> ⚠ System and subsystem roles do not grant access to the namespaces of user applications.
>
> They grant access only to system namespaces (starting with `d8-` or `kube-`), and only to those system namespaces where the modules of the corresponding role subsystem are running.
>
> Whether a role lets you grant access to other people is described in Who can assign roles.

System and subsystem roles are intended for assigning rights to manage the entire platform or a part of it (the subsystem), but not the user applications themselves. The subsystem role, for example, can allow a security administrator to manage security modules (responsible for the security functions of the cluster). Thus, the security administrator will be able to configure security policies, certificate issuance, etc., but will not be able to manage other cluster functions (such as access management, network and monitoring settings) or change settings in the namespaces of user applications.

> ⚠ A system/subsystem role limits which modules and namespaces a subject can address, but it does not limit the privileges a subject can obtain through the modules it is allowed to manage. This matters most for the `iam` subsystem: the right to manage authentication and authorization is equivalent to full control over the cluster — a subject that can manage the `user-authn` module can register an identity provider or reset the credentials of any local user, and a subject that can manage the `user-authz` module can modify authorization rules. In both cases, they can obtain an identity with any privileges, including cluster administrator, so treat an `iam` subsystem role as a cluster administrator role when planning access.

The system/subsystem role defines access rights:

- to cluster-wide Kubernetes resources;
- to manage DP modules (ModuleConfig resource) within the subsystem of the role, or to all DP modules for the role `d8:system:*`;
- to manage cluster-wide resources of DP modules within the subsystem of the role, or to all resources of DP modules for the role `d8:system:*`;
- to read the namespaces of the modules of the role's subsystem, or of all DP modules for the role `d8:system:*`; writing there is reserved for the `superadmin` level (see Access of system and subsystem roles to the namespaces of the modules).

The role name format is `d8:system:<ACCESS_LEVEL>` for the system roles and `d8:subsystem:<SUBSYSTEM>:<ACCESS_LEVEL>` for the subsystem roles, where:

- `SUBSYSTEM` is the role's subsystem;
- `ACCESS_LEVEL` is the access level.

Role examples:

- `d8:system:viewer` — access to view the configuration of all DP modules (ModuleConfig resource), their cluster-wide resources, their namespaced resources, and standard Kubernetes objects (except Secrets and RBAC resources) in the namespaces of all DP modules;
- `d8:system:manager` — similar to `d8:system:viewer`, but with the right to view/create/modify/delete the configuration of all DP modules (ModuleConfig resource) and their cluster-wide resources; in the namespaces of DP modules it keeps the read access of `d8:system:viewer`;
- `d8:subsystem:observability:viewer` — access to view the configuration of DP modules (ModuleConfig resource) from the `observability` subsystem, their cluster-wide resources, their namespaced resources, and standard Kubernetes objects (except Secrets and RBAC resources) in the system namespaces `d8-log-shipper`, `d8-monitoring`, `d8-okmeter`, `d8-operator-prometheus`, `d8-upmeter`, `kube-prometheus-pushgateway`.

DP has three access levels for system and subsystem roles:

- `viewer` — allows viewing standard Kubernetes resources, the configuration of modules (ModuleConfig resources), cluster-wide resources of modules, and namespaced resources of modules in the module namespace;
- `manager` — in addition to `viewer`, allows managing the configuration of modules (ModuleConfig resources) and the cluster-wide resources of modules; in the module namespaces it grants the same read access as `viewer`;
- `superadmin` — in addition to `manager`, allows everything in the module namespaces: managing standard Kubernetes resources and the namespaced resources of modules, reading Secrets, connecting to pods, issuing ServiceAccount tokens, and managing the system resources of the subsystem modules.

Access of system and subsystem roles to the namespaces of the modules

The holder of a system or subsystem role automatically gets a RoleBinding to a namespace role in every system namespace in which the modules of the role's subsystem run (a `d8:system:*` role covers the namespaces of all DP modules): the `viewer` and `manager` levels get `d8:namespace:viewer`, the `superadmin` level gets `d8:namespace:superadmin`. The platform creates and removes these RoleBindings itself (they carry the `rbac.deckhouse.io/automated: "true"` label), one per ClusterRoleBinding of the role.

The namespaces of the modules belong to the platform. They hold ServiceAccounts with cluster-wide rights (the Deckhouse controller among them) and the credentials of the modules, so any write there, and any read of a Secret there, is in effect the right to act as those ServiceAccounts anywhere in the cluster. This is why a `manager` configures its subsystem through ModuleConfig objects and the cluster-wide resources of the modules, and in the module namespaces only views objects, logs, metrics, and events. A `manager` cannot read Secrets, run `kubectl exec`, `attach`, or `port-forward`, delete or scale pods, or create anything there. A `superadmin` can do all of that. Grant this level deliberately and to a named subject: it is the emergency path into the platform, and its actions are visible in the audit log. Do not use impersonation of system users (`--as`) as a substitute.

When working with system and subsystem roles, keep in mind the following:

- A RoleBinding to `d8:namespace:user` or a higher level in a system namespace, created by hand, grants the subject the rights of every ServiceAccount of that namespace. The same holds for the `allowAccessToSystemNamespaces: true` option of a ClusterAuthorizationRule of the basic role model: with it, the `Admin` and `ClusterAdmin` access levels are equivalent to a cluster administrator.
- The system namespaces are those the `multitenancy-manager` module never turns into projects: `d8-*`, `kube-*`, `upmeter-*`, `default`, and the namespaces labeled `heritage: deckhouse` or `heritage: upmeter`.
- A custom system or subsystem role (`d8:custom:*`) is projected as `viewer` whatever its `rbac.deckhouse.io/use-role` label says: the webhook refuses a higher value, and a role created with one earlier is projected as `viewer` with a `ProjectionCapped` event on the role.

Who can assign roles

A system or subsystem role does not, by itself, let you grant access to other people.

Creating a User or Group that is not already a grant subject is ordinary object creation.

Creating a User for an email that already carries a grant, writing or deleting a ClusterAuthorizationRule, or resetting that identity through UserOperation, is granting roles. The request is admitted only if the

requester already has covering permissions or is explicitly allowed to assign those roles.

Connecting a DexProvider is measured the same way against the identities the provider can assert: `spec.allowedIdentities` (emails, email domains, groups) and the provider's own group filters bound that set, and only the roles already granted inside it count. A provider without an email limit can assert every email, including the ones that hold `SuperAdmin`, so writing it requires `SuperAdmin`. Basic Authentication of an OIDC or a Crowd provider bypasses Dex and its limits, so such a provider counts as one without an email limit, and an OIDC one also without a group limit; a Crowd provider keeps only `crowd.groups` on the group axis. Details and the list of changes admitted without a check are in the `user-authn` module documentation.

The ClusterAuthorizationRule `spec.accessLevel` field is a basic model level: `User`, `PrivilegedUser`, `Editor`, `Admin`, `ClusterEditor`, `ClusterAdmin`, `SuperAdmin`. An `iam` subsystem manager and a holder of `d8:system:manager` assign the levels `ClusterEditor` includes: `User`, `PrivilegedUser`, `Editor`, and `ClusterEditor`, but not `Admin`, `ClusterAdmin`, or `SuperAdmin`, and neither the Kubernetes `cluster-admin` ClusterRole.

A ClusterAuthorizationRule that opens the system namespaces counts as a `ClusterAdmin` assignment whatever its `accessLevel`, so these managers cannot write it. Such a rule is a rule with `allowAccessToSystemNamespaces: true`, with `namespaceSelector.matchAny`, with a `namespaceSelector.labelSelector` that does not name its namespaces by the `kubernetes.io/metadata.name` label, a rule for a subject that another rule already lets into them (the rules of a subject add up), or any rule while multitenancy mode is disabled. Without multitenancy mode, as in DP Open/CE, these managers therefore cannot write ClusterAuthorizationRule objects at all.

The rules of a request add up: those of its user, of every group in its token, and of its ServiceAccount. A rule therefore also opens the system namespaces when another rule already lets in one of the requests it applies to:

- a local user it names or a member of its groups at any depth of nesting, with the groups that user is in and the groups above them;
- the requester, with the groups of its own token;
- any request, through `system:authenticated` (a ServiceAccount also through `system:serviceaccounts` and `system:serviceaccounts:<namespace>`).

A rule for `system:authenticated` applies to every request, so it opens the system namespaces as soon as any other rule opens them. A rule for `system:serviceaccounts` does so as soon as another rule lets in a ServiceAccount, and a rule for `system:serviceaccounts:<namespace>` as soon as another rule lets in a ServiceAccount of that namespace. A User subject named `system:serviceaccount:<namespace>:<name>` is that ServiceAccount.

A member of a Group gets the rules of every group above it, so writing a Group needs the range for their roles too. For the same reason, these managers cannot add a member that another rule already lets into the system namespaces to a Group that has a ClusterAuthorizationRule, or is in a group that has one. The groups an identity provider asserts for other users are unknown to the webhook and are not taken into account.

For the same reason, a user or a group that such a rule names counts as a `ClusterAdmin` target: these managers cannot create a User for its email, add members to such a Group, run a UserOperation on such a user, or connect a DexProvider that can assert such an identity. Turning multitenancy mode off in the `user-authz` ModuleConfig opens the system namespaces to every rule and requires the `ClusterAdmin` range as well. Within the granular model, the IAM manager assigns the `iam` subsystem roles up to `d8:subsystem:iam:manager`, and the system manager assigns the roles of any scope up to the `manager` level.

These managers do not write admission webhooks and policies (ValidatingWebhookConfiguration, MutatingWebhookConfiguration, ValidatingAdmissionPolicy, and ValidatingAdmissionPolicyBinding): the superadmins of the `security` and `cluster` subsystems and `d8:system:superadmin` do. A mutating webhook can change any object the platform creates, its own pods included, and removing a webhook or a policy switches off what it enforces, such as the limits above. The `d8-deckhouse-validating-webhook-handler-*` ValidatingWebhookConfigurations, which hold the webhooks of the Deckhouse modules, can be created, changed, or deleted only by `webhook-handler`, the platform components, and the superadmins, including the holders of a role that grants every verb on everything.

A requester with every permission across the cluster counts as `SuperAdmin` in these checks and can assign any role, including `SuperAdmin` and `cluster-admin`. For example, a subject of the Kubernetes `cluster-admin` ClusterRole has such permissions if the role is granted by a ClusterRoleBinding or by a ClusterAuthorizationRule without `namespaceSelector` and `limitNamespaces`. If multitenancy mode is enabled, such a rule reaches the system namespaces only with `namespaceSelector.matchAny: true` (or the deprecated `allowAccessToSystemNamespaces: true`).

Permissions from a ClusterAuthorizationRule with `namespaceSelector` or `limitNamespaces` do not count toward this, even if the rule grants `cluster-admin`. Any non-empty `limitNamespaces` counts as a limit on purpose, even if its entries match every namespace, such as `.*` together with `allowAccessToSystemNamespaces: true`. Such a rule still counts through its `accessLevel`. For

example, `accessLevel: SuperAdmin` gives the `SuperAdmin` range whatever the namespace limits of the rule.

`limitNamespaces` and `namespaceSelector` restrict access to namespaced resources only. A subject with the `ClusterAdmin` or `SuperAdmin` access level can still create ClusterRoleBinding and ClusterAuthorizationRule objects, so these fields do not confine what it can grant across the cluster. Give these levels only to subjects that may hold access to the whole cluster. A ClusterAuthorizationRule counts only through the bindings that `user-authz-controller` has created for it.

Webhook deny messages call the `accessLevel` values basic, so they are not confused with the granular role levels (`viewer`, `manager`, `superadmin`).

Permission to create User and Group objects in the `user-authn` module is not enough: it does not grant the roles already attached to that email.

Global resource dictionaries

In addition to the roles and capabilities of the granular model, the module creates a special ClusterRole `d8:dict`. It grants read access to cluster-wide “reference” resources that users often need to view when creating objects. For example, a user creating a PersistentVolumeClaim needs to see the available StorageClasses, and a user creating an Ingress needs to see the IngressClasses.

The role grants `get`, `list`, `watch` on the following resources:

- `storageclasses` (storage.k8s.io), plus `csidrivers`, `csinodes`, `volumeattachments`;
- `volumesnapshotclasses` (snapshot.storage.k8s.io);
- `ingressclasses` (networking.k8s.io);
- `priorityclasses` (scheduling.k8s.io);
- `runtimeclasses` (node.k8s.io);
- `virtualmachineclasses`, `clustervirtualimages` (virtualization.deckhouse.io);
- `clusterlogdestinations` (deckhouse.io);
- `customresourcedefinitions` (apiextensions.k8s.io) — `get`, `list` only.

Automatic binding

`user-authz-controller` keeps one ClusterRoleBinding to `d8:dict` for every subject that holds one of the following RoleBindings:

- a RoleBinding to a `d8:namespace:*` or `d8:project:*` role, including the RoleBindings that `multitenancy-manager` creates from a ProjectRoleBinding or a ClusterProjectRoleBinding;
- a RoleBinding that the module creates for an AuthorizationRule (the `User`, `PrivilegedUser`, `Editor`, and `Admin` levels).

The `system:multitenancy-manager:*` users, which `multitenancy-manager` acts as, get none. This means that project users can discover reference resources without any manual configuration. The binding is removed when the subject has no such RoleBinding left. You do not create it yourself.

> **i** The `d8:dict` role is independent of the `multitenancy-manager` cluster-wide resource access management mechanism: it only gives **read** access to reference resources so users can discover them. The mechanism controls **which resource values** a project may actually reference when creating objects.

Role model subsystems

Each DP module belongs to a specific subsystem. For each subsystem, there is a set of roles with different levels of access. Roles are updated automatically when the module is enabled or disabled.

The subsystems of the platform are `iam`, `security`, `cluster`, `delivery`, `network`, `storage`, `observability`, and `managed-services`.

For example, for the `network` subsystem, there are the following subsystem roles that can be used in ClusterRoleBinding:

- `d8:subsystem:network:viewer`;
- `d8:subsystem:network:manager`;
- `d8:subsystem:network:superadmin`.

The scope of a role depends on which subsystem it belongs to:

- The scope of the `d8:system:*` roles is the namespaces of all enabled DP modules, that is, the namespaces that their capabilities name in the `rbac.deckhouse.io/namespace` label.
- The scope of subsystem roles includes the namespaces in which the subsystem’s modules operate

(see the subsystem composition table below), as well as all cluster-wide objects of the subsystem’s modules.

Role model subsystems composition table.

Subsystem	Subsystem modules	Namespaces in which modules of a scope operate
all	All modules	All namespaces
iam	• multitenancy-manager • namespace-configurator • user-authn • user-authz	• d8-multitenancy-manager • d8-system • d8-user-authn
security	• admission-policy-engine • cert-manager • neuvector • operator-trivy • runtime-audit-engine • secret-copier • secrets-store-integration	• d8-admission-policy-engine • d8-cert-manager • d8-operator-trivy • d8-runtime-audit-engine
cluster	• chrony • cloud-provider-aws • cloud-provider-azure • cloud-provider-dynamix • cloud-provider-gcp • cloud-provider-huaweicloud • cloud-provider-openstack • cloud-provider-vcd • cloud-provider-vsphere • cloud-provider-yandex • cloud-provider-zvirt • commander-agent • console • control-plane-manager • csi-vsphere • dashboard • deckhouse • deckhouse-tools • descheduler • documentation • node-manager • pod-reloader • registry • registry-packages-proxy • terraform-manager • vertical-pod-autoscaler • virtualization	• d8-chrony • d8-cloud-instance-manager • d8-cloud-provider-aws • d8-cloud-provider-azure • d8-cloud-provider-dynamix • d8-cloud-provider-gcp • d8-cloud-provider-huaweicloud • d8-cloud-provider-openstack • d8-cloud-provider-vcd • d8-cloud-provider-vsphere • d8-cloud-provider-yandex • d8-cloud-provider-zvirt • d8-csi-vsphere • d8-descheduler • d8-system • kube-system
delivery	• delivery-kit • operator-helm	• d8-operator-helm

Subsystem	Subsystem modules	Namespaces in which modules of a scope operate
network	• cilium-hubble • cni-cilium • cni-flannel • cni-simple-bridge • ingress-nginx • istio • keepalived • kube-dns • kube-proxy • metallb • monitoring-ping • network-gateway • network-policy-engine • node-local-dns • openvpn • sdn • service-with-healthchecks • static-routing-manager	• d8-cni-cilium • d8-cni-flannel • d8-cni-simple-bridge • d8-ingress-nginx • d8-istio • d8-keepalived • d8-metallb • d8-monitoring • d8-network-gateway • d8-openvpn • d8-service-with-healthchecks • d8-static-routing-manager • d8-system • kube-system

managed-services	• managed-memcached • managed-postgres	

How the roles are built: aggregation and capabilities

No built-in role contains a list of permissions directly. Permissions are described in separate small cluster roles — **capabilities**. Each capability is responsible for one kind of action (for example, “view logs”, “manage quotas”, “connect to pods”) and contains concrete RBAC rules. A role (`d8:namespace:admin`, `d8:system:viewer`, etc.) is an empty ClusterRole with an aggregation rule (`aggregationRule`): Kubernetes automatically collects into it the rules from all capabilities with matching labels.

This design has two practical consequences:

- DP modules extend the roles automatically: when a module is enabled, its capabilities are added to the corresponding built-in roles; when it is disabled, they are removed. The permission list of a role always matches the set of enabled modules.
- You can assemble your own roles from ready-made capabilities without writing RBAC rules by hand, as shown below.

The names of built-in roles and capabilities start with the `d8:` prefix. This prefix is reserved: you cannot create your own ClusterRole with a `d8:*` name — the only exception is the `d8:custom:*` prefix, which is dedicated to user-defined roles and capabilities.

Creating a new subsystem role

If, for example, the current subsystems do not fit the role distribution in the company, you need to create a new subsystem that includes roles from the `cluster` subsystem, the `network` subsystem, and the `user-authn` module.

To meet this need, create the following role:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: d8:custom:mycustom:manager
  labels:
    rbac.deckhouse.io/use-role: viewer
    rbac.deckhouse.io/kind: custom-role
    rbac.deckhouse.io/scope: subsystem
    rbac.deckhouse.io/subsystem: mycustom
aggregationRule:
  clusterRoleSelectors:
    - matchLabels:
        rbac.deckhouse.io/aggregate-to-cluster-as: manager
    - matchLabels:
        rbac.deckhouse.io/aggregate-to-network-as: manager
    - matchLabels:
        rbac.deckhouse.io/scope: system
        module: user-authn
rules: []
```

The labels for the new role listed at the top suggest that:

- The namespace role that the subjects of the role get in the module namespaces (`user-authz-controller` creates the RoleBinding objects); a custom role is projected as `viewer` at most:

  ```
  rbac.deckhouse.io/use-role: viewer
  ```

- The role is a custom role (custom roles never define their own rules, they only aggregate capabilities):

  ```
  rbac.deckhouse.io/kind: custom-role
  ```

  > **i** This label is mandatory.

- The role is a subsystem one, and it shall be handled accordingly:

  ```
  rbac.deckhouse.io/scope: subsystem
  ```

- There is a subsystem for which the role is responsible:

  ```
  rbac.deckhouse.io/subsystem: mycustom
  ```

Then there are selectors that implement aggregation:

- This one aggregates the manager role from the `cluster` subsystem:

  ```
  rbac.deckhouse.io/aggregate-to-cluster-as: manager
  ```

- This one aggregates all the system-scope capabilities defined for the `user-authn` module:

  ```
  rbac.deckhouse.io/scope: system
  module: user-authn
  ```

> **i** For more information on role labels and annotations, see Reference of role labels and annotations.

This way, your role will combine the permissions of the `cluster` subsystem, `network` subsystem, and the `user-authn` module.

Specifics of using custom roles:

- Custom roles and capabilities must be named with the `d8:custom:` prefix (all other names with the `d8:` prefix are reserved for DP built-in objects). The name must agree with the declared scope: a subsystem role is `d8:custom:<subsystem>:<name>` (the segment is the subsystem itself, as in the example above), a namespace or project role is `d8:custom:namespace:<name>` or `d8:custom:project:<name>`, and a capability is `d8:custom:<scope>-capability:<name>`. A name that disagrees with the `rbac.deckhouse.io/scope` label is rejected.
- RoleBindings with a namespace role (`d8:namespace:<level>`) will be created in the namespaces of the aggregated subsystems' modules; the level is specified by the `rbac.deckhouse.io/use-role` label, `viewer` at most for a custom role. Without the label, no such RoleBinding is created.
- A custom role cannot be aggregated into `d8:system:<level>`, because only a custom capability may carry the `rbac.deckhouse.io/aggregate-to-system-as` label. To give the role to the holders of `d8:system:manager`, bind it to them with a ClusterRoleBinding.

Extending a custom role

Suppose a new cluster CRD object, MySuperResource, has been created in the cluster (a subsystem role example), and you need to extend the custom role from the example above to include the permissions to interact with this resource. Follow these steps:

1. Add a new selector to the role:

   ```
   rbac.deckhouse.io/aggregate-to-mycustom-as: manager
   ```

   For more information on role labels and annotations, see Reference of role labels and annotations.

   This selector enables capabilities to be aggregated to the new subsystem by specifying this label. After adding the new selector, the role looks as follows:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: d8:custom:mycustom:manager
  labels:
    rbac.deckhouse.io/use-role: viewer
    rbac.deckhouse.io/kind: custom-role
    rbac.deckhouse.io/scope: subsystem
    rbac.deckhouse.io/subsystem: mycustom
aggregationRule:
  clusterRoleSelectors:
    - matchLabels:
        rbac.deckhouse.io/aggregate-to-cluster-as: manager
    - matchLabels:
        rbac.deckhouse.io/aggregate-to-network-as: manager
    - matchLabels:
        rbac.deckhouse.io/scope: system
        module: user-authn
    - matchLabels:
        rbac.deckhouse.io/aggregate-to-mycustom-as: manager
rules: []
```

2. Create a new capability that defines the permissions for the new resource. For example, read-only access:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  labels:
    rbac.deckhouse.io/aggregate-to-mycustom-as: manager
    rbac.deckhouse.io/kind: custom-capability
    rbac.deckhouse.io/scope: subsystem
    rbac.deckhouse.io/subsystem: mycustom
    rbac.deckhouse.io/capability: "custom.subsystem-
capability.mycustom.superresource_view"
  name: d8:custom:subsystem-capability:mycustom:superresource:view
rules:
- apiGroups:
  - mygroup.io
  resources:
  - mysuperresources
  verbs:
  - get
  - list
  - watch
```

   The capability adds its permissions to the subsystem role, granting the right to view the new object.

Specifics:

- Name a custom capability `d8:custom:<SCOPE>-capability:<NAME>`, where `<SCOPE>` is the value of its `rbac.deckhouse.io/scope` label. A name that disagrees with the label is rejected.

Extending existing subsystem roles

To extend an existing role, follow the same steps as in the section above, but change the labels and the role name. For more information on role labels and annotations, see Reference of role labels and annotations.

For example, here’s how you can extend the manager role from the `cluster` (`d8:subsystem:cluster:manager`) subsystem:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  labels:
    rbac.deckhouse.io/aggregate-to-cluster-as: manager
    rbac.deckhouse.io/kind: custom-capability
    rbac.deckhouse.io/scope: subsystem
    rbac.deckhouse.io/subsystem: cluster
    rbac.deckhouse.io/capability: "custom.subsystem-
capability.cluster.superresource_view"
  name: d8:custom:subsystem-capability:cluster:superresource:view
rules:
- apiGroups:
  - mygroup.io
  resources:
  - mysuperresources
  verbs:
  - get
  - list
  - watch
```

This way, the new capability will extend the `d8:subsystem:cluster:manager` role.

Extending subsystem roles by adding a new namespace

The namespaces where the holders of a system or subsystem role get a RoleBinding with the namespace role are the namespaces of its modules. `user-authz-controller` takes them from the `rbac.deckhouse.io/namespace` label of the system capabilities Deckhouse ships, which have a `d8:` name and the `heritage: deckhouse` label. On a custom capability, the label is ignored: the capability adds its rules to the roles that aggregate it, but no namespace.

To give the subjects of such a role access to another namespace, bind them to a namespace role there with a RoleBinding:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: cluster-managers-viewer
  namespace: my-namespace
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: d8:namespace:viewer
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: Group
  name: cluster-managers
```

Extending existing namespace roles

If the resource belongs to a namespace, you need to extend the namespace role instead of the system/subsystem role. The only difference is the labels and the name:

```
 apiVersion: rbac.authorization.k8s.io/v1
 kind: ClusterRole
 metadata:
   labels:
     rbac.deckhouse.io/aggregate-to-namespace-as: user
     rbac.deckhouse.io/kind: custom-capability
     rbac.deckhouse.io/scope: namespace
     rbac.deckhouse.io/capability: "custom.namespace-
capability.mycustom.superresource_view"
   name: d8:custom:namespace-capability:mycustom:superresource:view
 rules:
 - apiGroups:
   - mygroup.io
   resources:
   - mysuperresources
   verbs:
   - get
   - list
   - watch
```

This capability will be added to the `d8:namespace:user` role.

For more information on role labels and annotations, see Reference of role labels and annotations.

Creating a custom namespace or project role

Sometimes the built-in hierarchy of levels does not fit: for example, you need a “developer” role — full view of the namespace plus terminal access to pods (`exec`, `attach`), but without the right to change quotas or RBAC. Such a role is assembled from ready-made capabilities, without writing RBAC rules by hand.

The rules for custom roles:

- the name must start with `d8:custom:` (for example, `d8:custom:namespace:developer`);
- the role must carry the `rbac.deckhouse.io/kind: custom-role` label;
- a namespace or project role that will be used in a RoleBinding must also carry `rbac.deckhouse.io/delegatable: "true"`. Every user namespace is a project, and a RoleBinding there is accepted only for roles with this label. Do not put it on system or subsystem roles — the admission webhook rejects that;
- the role **cannot contain its own rules** (`rules`) — it may only aggregate capabilities via `aggregationRule`. Permissions are described in separate capabilities, so the contents of the role stay transparent;
- a single role cannot aggregate capabilities of the user-facing scopes (`namespace`, `project`) together with the administrative ones (`system`, subsystems) — such a role is rejected.

For more information on role labels and annotations, see Reference of role labels and annotations.

An example: a role that includes everything allowed by `d8:namespace:viewer`, plus one specific capability (connecting to pods), selected precisely by its unique `rbac.deckhouse.io/capability` label:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: d8:custom:namespace:developer
  labels:
    rbac.deckhouse.io/kind: custom-role
    rbac.deckhouse.io/scope: namespace
    rbac.deckhouse.io/delegatable: "true"   # Required for a RoleBinding inside a
project namespace.
  annotations:
    custom.meta.deckhouse.io/title: "Developer"
    custom.meta.deckhouse.io/description: "View resources and connect to pods,
without managing quotas and RBAC"
aggregationRule:
  clusterRoleSelectors:
    # Everything included in the viewer level of the namespace lineage.
    - matchLabels:
        rbac.deckhouse.io/aggregate-to-namespace-as: viewer
    # Plus one specific capability selected by its unique name.
    - matchLabels:
        rbac.deckhouse.io/capability: "namespace-
capability.kubernetes.access_terminal"
rules: []
```

If no existing capability grants the permissions you need, create your own (a `custom-capability` may contain rules) and add a selector by its `rbac.deckhouse.io/capability` label to the role's `aggregationRule` (in the example below — `matchLabels: {rbac.deckhouse.io/capability: "custom.namespace-capability.port-forward"}`). The label value of a custom capability is `custom.<SCOPE>-capability.<NAME>`, and a role that is bound in a project may select only the `namespace-capability` and `project-capability` scopes:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: d8:custom:namespace-capability:port-forward
  labels:
    rbac.deckhouse.io/kind: custom-capability
    rbac.deckhouse.io/scope: namespace
    rbac.deckhouse.io/capability: "custom.namespace-capability.port-forward"
rules:
  - apiGroups: [""]
    resources: ["pods/portforward"]
    verbs: ["create"]
```

To get a list of all available capabilities and their unique names, use the command:

```
d8 k get clusterroles -l rbac.deckhouse.io/kind=capability -o custom-
columns='NAME:.metadata.name,CAPABILITY:.metadata.labels.rbac\.deckhouse\.io/capabili
ty'
```

The created role is assigned exactly like a built-in one: via a RoleBinding in a namespace or via a ProjectRoleBinding across a whole project (for project roles, use `rbac.deckhouse.io/scope: project` and aggregate `aggregate-to-project-as`). A RoleBinding in a project namespace requires the `delegatable` label on the role; a ProjectRoleBinding does not (it has its own prefix allow-list). The role cannot be assigned via a ClusterRoleBinding — just like the built-in roles of these scopes.

> **i** You can also assemble such a role without YAML — with the access grant wizard in the Deckhouse web UI: it shows the available capabilities, builds a role out of them, and immediately creates the required binding.

Admin level restrictions and superadmin rights

The role model provides two administration levels:

- `admin` — the everyday administrator. Manages resources, quotas, and access within their scope, but cannot perform operations that would let them break out of that scope or disrupt platform components.
- `superadmin` — the “break-glass” administrator. Has all the rights of `admin` and can additionally perform dangerous operations. Grant this level deliberately and only to those who really need it.

Only the `superadmin` level allows **minting ServiceAccount tokens** (`kubectl create token`) **and making requests on behalf of a ServiceAccount** (`kubectl --as system:serviceaccount:...`). A ServiceAccount token is a ready-to-use identity: by obtaining the token of a platform component’s service account, one could gain its permissions far beyond the namespace. Therefore `admin` manages the `ServiceAccount` objects themselves (create, delete) but cannot mint tokens for them or act on their behalf.

Objects labeled `heritage: deckhouse` belong to the platform: nobody may create, modify or delete them, `superadmin` and cluster administrators included. Some platform components place such objects in user namespaces, for example the pods of a DexAuthenticator. `kubectl exec`, `kubectl attach`, `kubectl port-forward` and `kubectl debug` into such pods and `kubectl scale` of such Deployment, StatefulSet, ReplicaSet and ReplicationController objects are denied too. `kubectl rollout restart` of such objects is allowed. The users these checks do not apply to are listed in the FAQ of the `deckhouse` module.

`superadmin` also has some restrictions: resources created from a project template (the `heritage: multitenancy-manager` label) cannot be modified by **anyone**, including `superadmin` and a cluster administrator — they are managed exclusively by the project controller. A role is assigned via RoleBinding and applies only in the namespace where it was granted: a `superadmin` of one namespace gets no special rights in another.

Built-in protection mechanisms of the role model

The role model is protected by a set of checks at the API server level. They require no configuration and prevent typical mistakes and privilege escalation attempts:

- **A scoped role cannot be granted cluster-wide.** A ClusterRoleBinding to the `d8:namespace:*` or `d8:project:*` roles (and their `d8:custom:*` variants) is rejected — otherwise a role designed for one namespace or project would apply in every namespace at once. Use a RoleBinding in the desired namespace, or ProjectRoleBinding/ClusterProjectRoleBinding for a project.
- **A capability cannot be granted cluster-wide.** A ClusterRoleBinding to any capability is rejected: a capability is a building block for roles, not a standalone role. Binding a capability via a RoleBinding in a single namespace is allowed.
- **Project management cannot be obtained through a custom role.** Creating a Role or ClusterRole that grants permissions to modify project management resources (`projects`, `projecttemplates`, `projectrolebindings`, `clusterprojectrolebindings`, `projectnamespaces`) is rejected — these permissions are granted only by the built-in `d8:project:*` roles.
- **A namespace or project role cannot include platform capabilities.** A custom role with `scope: namespace`, `scope: project`, or no scope may not select system or subsystem capabilities by the `rbac.deckhouse.io/capability` label, nor the `system` or a subsystem scope by the `rbac.deckhouse.io/aggregate-to-<scope>-as` label. No custom role may combine the capabilities of the `namespace`/`project` scopes with those of the `system`/`subsystem` scopes.
- **A custom capability carries rules and cannot have an `aggregationRule`.**
- **The name must match the scope**: `d8:custom:namespace:<name>`, `d8:custom:project:<name>`, `d8:custom:system:<name>`, `d8:custom:<subsystem>:<name>`, and `d8:custom:<scope>-capability:<name>` for a capability.
- **Only a custom capability may carry an `rbac.deckhouse.io/aggregate-to-<scope>-as` label of a platform scope.**
- **The `rbac.deckhouse.io/delegatable: "true"` label is accepted only on a role that aggregates only namespace and project capabilities.**
- **Custom roles cannot contain direct RBAC rules** — they may only aggregate capabilities.
- **The `rbac.deckhouse.io/kind: role` and `rbac.deckhouse.io/kind: capability` labels are reserved for DP built-in objects.** A ClusterRole with one of these labels is rejected. For your own objects, use `custom-role` and `custom-capability`.

Display names of roles

Every built-in role and capability carries a localized title and description in annotations:

- `ru.meta.deckhouse.io/title`, `ru.meta.deckhouse.io/description` — in Russian;
- `en.meta.deckhouse.io/title`, `en.meta.deckhouse.io/description` — in English.

These annotations are used, for example, by the Deckhouse web UI when displaying the list of roles.

If the standard title does not fit (for example, you want to name roles in your company's terms), add the `custom.meta.deckhouse.io/title` and `custom.meta.deckhouse.io/description` annotations to the role — the interface will show them instead of the standard ones. Example:

```
d8 k annotate clusterrole d8:namespace:admin custom.meta.deckhouse.io/title='Team administrator'
```

This is the only allowed modification of built-in roles: changing their rules, aggregation, or labels is rejected.

Deprecated role names

The previous role names of the granular model (`d8:manage:<subsystem>:<level>`, `d8:manage:all:<level>`, and `d8:use:role:<level>`) are deprecated and will be removed in the next release. For backward compatibility they are temporarily kept as alias roles. A binding to an alias aggregates the **new** role's capabilities, except where the list of subsystems changed (see below).

The rights of an alias are not identical to the pre-migration ones. The deprecated `d8:use:role:admin` no longer grants ServiceAccount token minting or impersonation, which moved to `superadmin`. The `d8:manage:*` aliases are not `delegatable`. The `d8:use:role:*` aliases are, so a RoleBinding to them inside a project namespace keeps working, but a new ProjectRoleBinding or ClusterProjectRoleBinding to an old name is refused.

Name mapping:

Deprecated name	New name
`d8:manage:all:<level>`	`d8:system:<level>`
`d8:manage:deckhouse:<level>`, `d8:manage:infrastructure:<level>`, `d8:manage:kubernetes:<level>`	`d8:subsystem:cluster:<level>`, which grants more. The modules that moved to other subsystems come with the roles of those subsystems
`d8:manage:networking:<level>`	`d8:subsystem:network:<level>`, which also grants the rights for `keepalived`
`d8:manage:security:<level>`	`d8:subsystem:security:<level>` together with `d8:subsystem:iam:<level>`, which grants the rights for `user-authz` and `user-authn` and more
`d8:manage:observability:<level>`	`d8:subsystem:observability:<level>`
`d8:manage:storage:<level>`	`d8:subsystem:storage:<level>`
`d8:use:role:<level>`	`d8:namespace:<level>`
`d8:use:role:<level>:kubernetes`	`d8:namespace:<level>` (full namespace role, not kubernetes-only)

The list of subsystems changed together with the role names. `deckhouse`, `infrastructure`, and `kubernetes` were merged into `cluster`, which also took over modules from other subsystems, `networking` was renamed to `network`, and `user-authz`, `user-authn`, and `multitenancy-manager` moved to `iam`.

The aliases of the `deckhouse`, `infrastructure`, and `kubernetes` roles therefore do not aggregate the whole `cluster` subsystem. They select the capabilities of the platform modules that were in the old subsystem, wherever those modules are now. `d8:subsystem:cluster:<level>` grants more, so when you recreate such a binding, check which subsystem roles its subjects need.

The alias of `d8:manage:security:<level>` also keeps the rights for `user-authz` and `user-authn`, which now come with `d8:subsystem:iam:<level>`. That role also grants the rights for `multitenancy-manager` and, at the `manager` level, the right to assign roles, which `d8:subsystem:security:<level>` does not grant. So a binding to `d8:manage:security:<level>` is replaced by two bindings with the same subjects, to `d8:subsystem:iam:<level>` and to `d8:subsystem:security:<level>`. The `rbac.deckhouse.io/deprecated-replaced-by` annotation of the alias names only the second one.

The alias of `networking` leaves out `keepalived`, which moved to `network` from `infrastructure`, so the new role grants more than this alias.

The `rbac.deckhouse.io/deprecated-replaced-by` annotation of an alias names its main replacement, and the description of the alias names the roles of the other subsystems its modules moved to. These roles cover whole subsystems. To grant the rights for some modules only, create a custom role that selects their system capabilities by the `rbac.deckhouse.io/capability` label, for

example `system-capability.multitenancy-manager.view` (see Creating a new subsystem role).

The aliases of the `deckhouse`, `infrastructure`, `kubernetes`, and `networking` roles and `d8:manage:all:<level>` also select the labels of these old subsystems, such as `rbac.deckhouse.io/aggregate-to-deckhouse-as`. Modules released on their own and custom capabilities may still carry them. No role of the new model collects these labels, so such capabilities reach the holders of the old names only, and the `D8UserAuthzRetiredAggregationLabel` alert names them.

As long as bindings to the deprecated names remain in the cluster, the `D8UserAuthzDeprecatedRBACv2RoleInUse` (a binding to an alias role) and `D8UserAuthzDeprecatedRBACv2CapabilityInUse` (a binding to a deprecated name that no ClusterRole has, such as a capability of the previous release, so the binding grants nothing) alerts fire. The release that removes the aliases carries the `deprecatedRBACv2BindingsCount` release requirement: the upgrade stays pending, with the offending bindings listed in the DeckhouseRelease status, until every binding to an alias role is recreated on a new role name. A binding that grants nothing does not hold the release.

Migrate your existing RoleBinding and ClusterRoleBinding objects to the new role names:

- A ClusterRoleBinding named `user-authz:<rule>:additional-role:<role>` is rendered by `user-authz-controller` from `spec.additionalRoles` of the ClusterAuthorizationRule `<rule>`, and the controller creates it again when it is deleted. Change the role name in `spec.additionalRoles` of that rule, not the binding.
- A binding that a project template renders is changed in the ProjectTemplate, because `multitenancy-manager` renders it again from the template.

You can find bindings that still use the deprecated names, without the RoleBindings that `user-authz-controller` keeps for them, with the following command:

```
d8 k get clusterrolebindings,rolebindings -A -o json \
  | jq -r '.items[] | select(.roleRef.name | test("^d8:(manage|use):")) |
select(.metadata.labels["rbac.deckhouse.io/automated"] != "true") | "\(.kind) \
(.metadata.namespace // "-") \(.metadata.name) -> \(.roleRef.name)"'
```

Custom roles of the previous scheme

> ⚠ The built-in capabilities no longer carry the `rbac.deckhouse.io/kind: manage` and `rbac.deckhouse.io/kind: use` labels. A custom role of the previous scheme that selects capabilities by these labels has lost their permissions, and so have its subjects. Custom roles get no compatibility aliases.

The `D8UserAuthzLegacyRBACv2CustomRoleFound` alert lists such roles. How to find and repair them, along with the mapping of the previous labels to the new ones, is described in the `user-authz` FAQ section on migrating custom roles to the new scheme.

Getting an equivalent of the basic model's ClusterAdmin and SuperAdmin roles

The granular model has no roles that combine permissions into a single entity, like the `ClusterAdmin` and `SuperAdmin` roles of the basic model. It separates platform administration (system roles) from application access (namespace and project roles). The equivalent is assembled from **two bindings**: a ClusterRoleBinding to a system role and a ClusterProjectRoleBinding to a project role (the latter applies in all projects, including those created later).

Approximate level mapping:

Basic model role	Granular model equivalent
`User`	`d8:namespace:viewer` (via RoleBinding or ProjectRoleBinding)
`PrivilegedUser`	`d8:namespace:user`
`Editor`	`d8:namespace:manager`
`Admin`	`d8:namespace:admin`

Basic model role	Granular model equivalent
`ClusterEditor`	No direct counterpart: assemble it from a ClusterProjectRoleBinding to `d8:project:manager` (all projects) plus a system role for the platform part
`ClusterAdmin`	`d8:system:manager` + a ClusterProjectRoleBinding to `d8:project:admin`
`SuperAdmin`	`d8:system:superadmin` + a ClusterProjectRoleBinding to `d8:project:superadmin`

An example for `ClusterAdmin` (the `k8s-admins` group):

```
# Platform: DP module configuration, cluster-wide resources, viewing the namespaces
of DP modules.
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: k8s-admins-platform
subjects:
  - kind: Group
    name: k8s-admins
    apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: ClusterRole
  name: d8:system:manager
  apiGroup: rbac.authorization.k8s.io
---
# Applications: administrator in all namespaces of all projects (including future
ones).
apiVersion: deckhouse.io/v1alpha3
kind: ClusterProjectRoleBinding
metadata:
  name: k8s-admins-projects
spec:
  subjects:
    - kind: Group
      name: k8s-admins
  roleRef:
    kind: ClusterRole
    name: d8:project:admin
```

For `SuperAdmin`, replace the roles with `d8:system:superadmin` and `d8:project:superadmin`.

> **i**
>
> Every user namespace is a project: a namespace created directly becomes a project automatically. Therefore, the “system role + ClusterProjectRoleBinding” pair covers both the platform and all user namespaces. The pair does not cover the `default` namespace: it is a system namespace that belongs to the virtual project `default`, ClusterProjectRoleBinding does not extend to virtual projects, and no DP module runs in it.
>
> You cannot create a custom “all permissions” role (`apiGroups: ["*"], resources: ["*"], verbs: ["*"]`) — it is rejected by the built-in protection mechanisms. If you need unrestricted access outside the platform role model, use a ClusterRoleBinding to the built-in Kubernetes `cluster-admin` role — only someone who already has such permissions can assign it.

Cluster admin access model

Deckhouse Platform (DP) supports the presence of multiple kubeconfig files on master nodes (this feature is implemented by the `control-plane-manager` module). Understanding their purpose is important for secure cluster administration.

Kubeconfig files on master nodes

The following kubeconfig files are located on the master nodes:

File	Identity	Purpose
`/etc/kubernetes/admin.conf`	`kubernetes-admin` (`kubeadm:cluster-admins` group)	Machine kubeconfig for kubeadm internals (join, renewal). The group is bound to the built-in `cluster-admin` role. With the `user-authz` module enabled, the group is additionally bound to two DP ClusterRoles
`/etc/kubernetes/super-admin.conf`	`kubernetes-super-admin` (`system:masters` group)	Break-glass emergency credential. Bypasses RBAC entirely. Restrict access to this file to trusted recovery scenarios
`/etc/kubernetes/controller-manager.conf`	`system:kube-controller-manager`	Used by kube-controller-manager
`/etc/kubernetes/scheduler.conf`	`system:kube-scheduler`	Used by kube-scheduler

RBAC-based admin access

Starting from Kubernetes 1.29, kubeadm generates `admin.conf` with the `kubeadm:cluster-admins` group instead of `system:masters`. This provides RBAC-controlled admin access that can be revoked by removing the `kubeadm:cluster-admins` ClusterRoleBinding(s).

DP binds the `kubeadm:cluster-admins` group to the built-in wildcard ClusterRole `cluster-admin`, regardless of whether the `user-authz` module is enabled. This is the same effective model as in a plain kubeadm cluster without extra RBAC.

If `user-authz` is **enabled**, two more ClusterRoleBindings bind the group to the following ClusterRoles:

- `d8:control-plane-manager:admin-kubeconfig-supplement` — rules for nodes, certificates, and other cluster machinery;
- `d8:user-authz:admin-kubeconfig` — managing AuthorizationRule and ClusterAuthorizationRule.

Recommended admin access

If the `user-authn` module is enabled, use a personalized OIDC-based kubeconfig obtained through the DP web interface. This provides individual accountability and audit trail.

If `user-authn` is disabled, administrators can explicitly use the admin kubeconfig on a master node:

```
d8 k --kubeconfig=/etc/kubernetes/admin.conf <command>
```

Root kubeconfig symlink

By default, the `control-plane-manager` module creates a symlink `/root/.kube/config` → `/etc/kubernetes/admin.conf` on master nodes, allowing root to run `d8 k` without specifying `--kubeconfig`.

When the `user-authz` module is enabled, you can disable this symlink by setting `rootKubeconfigSymlink: false` in the `control-plane-manager` module configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  enabled: true
  settings:
    rootKubeconfigSymlink: false
```

If `user-authz` is disabled, `control-plane-manager` does not apply this setting and keeps the default symlink behavior.

When the symlink is disabled (and `user-authz` is enabled), the symlink is removed when it pointed to `admin.conf`. Use personalized credentials or pass `--kubeconfig` explicitly.

Security hardening

The `control-plane-manager` module automatically restricts file permissions on `admin.conf` and `super-admin.conf` to `0600` (owner read/write only) during every reconciliation cycle. This prevents unauthorized users from reading these sensitive credentials.

Break-glass access

In emergency situations (RBAC misconfiguration, webhook failures), use `super-admin.conf`:

```
d8 k --kubeconfig=/etc/kubernetes/super-admin.conf <command>
```

This credential bypasses all RBAC checks. Use it only as a last resort and restrict who can read the file.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Granting permissions to users and service accounts

To grant permissions in Deckhouse Platform (DP), you need to define a `subjects` block. Its format and contents depend on the resource type:

- In AuthorizationRule and ClusterAuthorizationRule resources (basic role model), as well as ProjectRoleBinding and ClusterProjectRoleBinding of the `multitenancy-manager` module (granular role model, project scope) — use the `subjects` block shown below.
- In standard Kubernetes RoleBinding and ClusterRoleBinding resources (granular role model, namespace/subsystem/whole-platform scope), the format differs: for `kind: User` and `kind: Group`, a `subjects` item additionally requires the `apiGroup: rbac.authorization.k8s.io` field (not needed for `kind: ServiceAccount`). For details, see the examples in Granting permissions using ClusterRoleBinding and RoleBinding below.

For users, it should be specified in the following format:

```
subjects:
- kind: User
  name: <user email>
```

⚠ If you are using the `user-authn` module and static users, make sure to specify the user's email in `subjects`, not the name of the User resource.

or

```
subjects:
- kind: Group
  name: <name of the group the user belongs to>
```

For a service account, the `subjects` block should be specified as follows:

```
subjects:
- kind: ServiceAccount
  name: <service account name>
  namespace: <namespace where the service account is created>
```

Granting permissions using AuthorizationRule and ClusterAuthorizationRule (basic role model)

When using the basic role model in DP, you can grant permissions to users via the AuthorizationRule and ClusterAuthorizationRule resources.

⚠ Support for the basic role model will be discontinued in future releases. For new roles, use the granular role model below — it can be used at the same time as the basic model, since the permissions they grant are summed up.

AuthorizationRule and ClusterAuthorizationRule objects can also be managed without writing YAML manifests, with the `d8 iam access` command: `d8 iam access grant` creates them, and `d8 iam access revoke` deletes them. For example, to grant the `Admin` access level to a user in the `dev` namespace, run:

```
d8 iam access grant user anton --access-level Admin -n dev
```

For more examples, see the `user-authz` module documentation.

Granting permissions to a user within a single namespace

To grant a user permissions within a single namespace, use the AuthorizationRule resource. It is applied within a single namespace.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: AuthorizationRule
metadata:
  name: dev-access
  namespace: dev-namespace
spec:
  subjects:
  - kind: User
    name: dev-user@example.com
  accessLevel: Admin
  portForwarding: true
```

Granting permissions to a user in all namespaces

To grant a user permissions across all namespaces (for example, to assign administrator permissions), use the ClusterAuthorizationRule resource. It is applied cluster-wide.

> **i** In multitenancy mode, a ClusterAuthorizationRule without `namespaceSelector` does not grant access to system namespaces: they require `namespaceSelector.matchAny: true` or the deprecated `allowAccessToSystemNamespaces: true`.

If needed, you can restrict the scope of permissions granted via ClusterAuthorizationRule to one or several namespaces. To do this, you can set the corresponding restrictions in the manifest. However, if possible, it is recommended that you use the AuthorizationRule resource for this purpose.

Example:

```
apiVersion: deckhouse.io/v1
kind: ClusterAuthorizationRule
metadata:
  name: admin-access
spec:
  subjects:
  - kind: User
    name: dev-user@example.com
  # Available only with the enableMultiTenancy parameter of the user-authz module
  # turned on (BE, SE, SE+, EE, and CSE editions).
  namespaceSelector:
    labelSelector:
      matchLabels:
        env: review
  accessLevel: Admin
  portForwarding: true
```

> **⚠** The `namespaceSelector` and `limitNamespaces` parameters only restrict access to objects in namespaces. A subject with the `ClusterAdmin` or `SuperAdmin` access level keeps its cluster-wide permissions, including creating ClusterRoleBinding and ClusterAuthorizationRule objects, so these parameters do not limit the permissions it can grant across the whole cluster. Grant these levels only to those who may be given access to the whole cluster.

Granting permissions using ClusterRoleBinding and RoleBinding (granular role model)

When using the granular role model in DP, you can grant permissions to users via the ClusterRoleBinding and RoleBinding resources — or, to grant access across all namespaces of a project at once, the ProjectRoleBinding and ClusterProjectRoleBinding resources of the `multitenancy-manager` module.

Roles of the granular model operate in one of four scopes — namespace, project, subsystem, or the whole platform — each with its own role name format and access levels. For details, see Role scopes in the granular role model documentation.

> **i** Access can also be granted without writing YAML manifests, with the access grant wizard in the Deckhouse web UI. The wizard walks you through the steps (who gets access → where → at which level), picks the binding kind itself (RoleBinding, ClusterRoleBinding, ProjectRoleBinding, or ClusterProjectRoleBinding), and lets you assemble a custom role from ready-made capabilities.

Assigning cluster administrator permissions (granular role model)

To assign cluster administrator permissions, use the system role `d8:system:manager` in a ClusterRoleBinding resource.

Example of assigning cluster administrator permissions to the user `jane.doe@example.com`:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: cluster-admin-jane
subjects:
- kind: User
  name: jane.doe@example.com
  apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: ClusterRole
  name: d8:system:manager
  apiGroup: rbac.authorization.k8s.io
```

Permissions the user will obtain

The user gets access to cluster-wide resources, to the configuration of DP modules, and to the namespaces of the enabled DP modules. The user gets no access to the namespaces of user applications.

The user will have the following permissions:

- View, modify, delete, and create cluster-wide Kubernetes resources and the cluster-wide resources of DP modules.
- Modify module configurations (view, edit, delete, and create ModuleConfig resources).
- View objects, logs, metrics, and events in the namespaces of DP modules, without access to Secrets.

The `d8:system:manager` role does not allow writing to the namespaces of DP modules, reading Secrets there, or running `kubectl exec`, `kubectl attach`, and `kubectl port-forward` on their Pods. These operations require the `d8:system:superadmin` role. For details, see Access of system and subsystem roles to the namespaces of the modules.

Assigning networking administrator permissions (granular role model)

To assign networking administrator permissions for managing the cluster's network subsystem, use the subsystem role `d8:subsystem:network:manager` in a ClusterRoleBinding resource.

Example of assigning networking administrator permissions to the user `jane.doe@example.com`:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: network-admin-jane
subjects:
- kind: User
  name: jane.doe@example.com
  apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: ClusterRole
  name: d8:subsystem:network:manager
  apiGroup: rbac.authorization.k8s.io
```

Permissions the user will obtain

The user's permissions will be limited to the following DP module namespaces from the `network` subsystem (the actual list depends on the modules enabled in the cluster):

- `d8-cni-cilium`
- `d8-cni-flannel`
- `d8-cni-simple-bridge`
- `d8-ingress-nginx`
- `d8-istio`
- `d8-keepalived`
- `d8-metallb`
- `d8-monitoring`
- `d8-network-gateway`
- `d8-openvpn`
- `d8-service-with-healthchecks`

- `d8-static-routing-manager`
- `d8-system`
- `kube-system`

The user will have the following permissions:

- View objects, logs, metrics, and events in the module namespaces from the `network` subsystem, without access to Secrets.
- View, modify, create, and delete the following resources of the modules from the `network` subsystem:
  - EgressGateway
  - EgressGatewayPolicy
  - FlowSchema
  - IngressClass
  - IngressIstioController
  - IngressNginxController
  - IPRuleSet
  - IstioFederation
  - IstioMulticluster
  - KeepalivedInstance
  - RoutingTable
- Modify module configurations (view, modify, create, and delete ModuleConfig resources) in the `network` subsystem.

  Modules the user will be able to manage:

  - `cilium-hubble`
  - `cni-cilium`
  - `cni-flannel`
  - `cni-simple-bridge`
  - `ingress-nginx`
  - `istio`
  - `keepalived`
  - `kube-dns`
  - `kube-proxy`
  - `metallb`
  - `monitoring-ping`
  - `network-gateway`
  - `network-policy-engine`
  - `node-local-dns`
  - `openvpn`
  - `sdn`
  - `service-with-healthchecks`
  - `static-routing-manager`

The `d8:subsystem:network:manager` role does not allow writing to the module namespaces, reading Secrets there, or running `kubectl exec`, `kubectl attach`, and `kubectl port-forward` on their Pods. These operations require the `d8:subsystem:network:superadmin` role. For details, see Access of system and subsystem roles to the namespaces of the modules.

Granting administrator permissions to a user within a namespace (granular role model)

To assign or restrict user permissions to specific namespaces, apply a namespace role with the corresponding access level in a RoleBinding resource.

For example, to allow a user to manage application resources in a namespace (without giving them access to DP module configurations), use the `d8:namespace:admin` role in a RoleBinding resource for the corresponding namespace. To grant the same access across all namespaces of a project at once, use a ProjectRoleBinding with the equivalent `d8:project:admin` role instead.

Example of granting application developer `app-developer` permissions within the `myapp` namespace:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: myapp-developer
  namespace: myapp
subjects:
- kind: User
  name: app-developer@example.com
  apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: ClusterRole
  name: d8:namespace:admin
  apiGroup: rbac.authorization.k8s.io
```

Permissions the user will obtain

The user's permissions will be limited to the following within the `myapp` namespace:

- View, modify, create, and delete Kubernetes resources. Example resources:
  - Certificate
  - CertificateRequest
  - ConfigMap
  - ControllerRevision
  - CronJob
  - DaemonSet
  - Deployment
  - Event
  - HorizontalPodAutoscaler
  - Ingress
  - Issuer
  - Job
  - Lease
  - LimitRange
  - NetworkPolicy
  - PersistentVolumeClaim
  - Pod
  - PodDisruptionBudget
  - ReplicaSet
  - ReplicationController
  - ResourceQuota
  - Role
  - RoleBinding
  - Secret
  - Service
  - ServiceAccount
  - StatefulSet
  - VerticalPodAutoscaler
  - VolumeSnapshot
- View, modify, create, and delete the following DP module resources:
  - DexAuthenticator
  - DexClient
  - PodLoggingConfig
- Run the following commands on Pods and Services:
  - `kubectl attach`
  - `kubectl exec`
  - `kubectl port-forward`
  - `kubectl proxy`

Checking user permissions

Quick check of a single permission

The quickest way to check a single permission is the `d8 k auth can-i` command:

```
d8 k auth can-i --as=user@example.com get pods -n other-namespace
```

To see the full set of actions that a user, group, or ServiceAccount is allowed to perform — not just a single action on a single resource — use the SubjectAccessReport resource described below.

Checking whether a user has access

To check whether a user has access permissions, run the following command, which specifies:

- `resourceAttributes` (as in RBAC) — what access is checked for;
- `user` — the user name;
- `groups` — the user groups.

> When used together with the `user-authn` module, the user name and groups can be found in the Dex logs with the `d8 k -n d8-user-authn logs -l app=dex` command. They appear in the logs only after the user signs in.

```
cat  <<EOF | 2>&1 d8 k create --raw
/apis/authorization.k8s.io/v1/subjectaccessreviews -f - | jq .status
{
  "apiVersion": "authorization.k8s.io/v1",
  "kind": "SubjectAccessReview",
  "spec": {
    "resourceAttributes": {
      "namespace": "dev",
      "verb": "watch",
      "version": "v1",
      "resource": "pods"
    },
    "user": "user@example.com",
    "groups": [
      "developers"
    ]
  }
}
EOF
```

The response will show whether access is allowed and which role grants it.

Example response if the user has access permissions:

```
{
  "allowed": true,
  "reason": "RBAC: allowed by RoleBinding \"<BINDING_NAME>/dev\" of ClusterRole
\"<ROLE_NAME>\" to User \"user@example.com\""
}
```

Example response if the user does not have access permissions:

```
{
  "allowed": false
}
```

In **multitenancy** mode, the namespace restrictions of the basic role model (ClusterAuthorizationRule/AuthorizationRule) are enforced by the authorization webhook. The answer of the API server already includes the decision of the webhook. To see the answer of the webhook alone, run the following command as root on a master node:

```
cat <<EOF | 2>&1 d8 k --kubeconfig /etc/kubernetes/deckhouse/extra-files/webhook-
config.yaml create --raw / -f - | jq .status
{
  "apiVersion": "authorization.k8s.io/v1",
  "kind": "SubjectAccessReview",
  "spec": {
    "resourceAttributes": {
      "namespace": "dev",
      "verb": "watch",
      "version": "v1",
      "resource": "pods"
    },
    "user": "user@example.com",
    "groups": [
      "developers"
    ]
  }
}
EOF
```

Example response if the user does not have access permissions:

```
{
  "allowed": false
}
```

A response with `"allowed": false` means the webhook is not blocking the request. If the webhook blocks the request, you get, for example, the following message:

```
{
  "allowed": false,
  "denied": true,
  "reason": "either you have no access to the namespace or the namespace does not
exist"
}
```

Getting a full permission report

With multitenancy mode enabled (`enableMultiTenancy`), the `SubjectAccessReport` resource of the `user-authz` module gives a ready-made report of everything a subject is allowed to do, instead of checking one verb on one resource at a time: which roles are granted through which bindings, which actions on which resources are allowed cluster-wide and in every namespace, and where each permission comes from.

Example of getting a report:

```
d8 k create -o yaml -f - <<EOF
apiVersion: authorization.deckhouse.io/v1alpha1
kind: SubjectAccessReport
metadata:
  name: what-can-jane-do
spec:
  subject:
    kind: User
    name: jane@example.com
EOF
```

The `spec.subject.kind` field accepts `User`, `Group`, and `ServiceAccount` (for the latter, `spec.subject.namespace` is required). If `spec.subject` is omitted, the report is generated for the caller.

A report about oneself is available to every authenticated user and requires no extra permissions. Building a report about **another** subject requires the `d8:user-authz:subject-access-checker` cluster role, which is not bound to anyone by default.

There is also a reverse query — the `WhoCan` resource — which answers “who can perform action X on resource Y?” and returns the list of users, groups, and ServiceAccounts. Example:

```
d8 k create -o yaml -f - <<EOF
apiVersion: authorization.deckhouse.io/v1alpha1
kind: WhoCan
metadata:
  name: who-can-create-networkpolicies
spec:
  resourceAttributes:
    namespace: my-namespace
    verb: create
    group: networking.k8s.io
    resource: networkpolicies
EOF
```

The answer is returned in the `status` field (it contains the `users`, `groups`, and `serviceAccounts` fields) right in the command output. The object is not stored anywhere.

The right to create `WhoCan` queries is granted by the `d8:user-authz:who-can-checker` cluster role. It is not bound to anyone by default: the result of a query reveals the access subjects in all namespaces, so grant it only to trusted administrators through a ClusterRoleBinding.

The managers of the `iam` and `security` subsystems can build reports about other subjects and create `WhoCan` queries as well. This right comes with the `d8:subsystem-capability:iam:inspect_access` capability of the `d8:subsystem:iam:manager` and `d8:subsystem:security:manager` roles, so the roles above them have it too (`d8:subsystem:iam:superadmin`, `d8:subsystem:security:superadmin`, `d8:system:manager`, and `d8:system:superadmin`). For details on both resources, see the `user-authz` module FAQ.

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Access for CI/CD

The following methods are available for authenticating CI/CD pipelines in the Kubernetes API:

- ServiceAccount — Kubernetes ServiceAccount token.
- Basic Auth — username and password via IdP.
- Token Exchange — exchange IdP token for Dex token.

ServiceAccount

The ServiceAccount token is used directly for API authentication. No external IdP is required. For ServiceAccount, you can create long-lived tokens (without TTL, with the possibility of revocation or rotation) and short-lived tokens.

When multiple pipelines share a single ServiceAccount, audit logs will not contain information about specific pipelines.

Prerequisites

To configure token-based authentication for ServiceAccount, the following requirements must be met:

- Cluster access with permissions to create ServiceAccounts and Secrets.
- For external access: apiserver.publishAPI of the `control-plane-manager` module, or direct API access via VPN.

Create ServiceAccount and a long-lived token

To create a ServiceAccount and token, use the command:

```
d8 k create ns ci-deploy || true

cat <<EOF | d8 k apply -f -
apiVersion: v1
kind: ServiceAccount
metadata:
  name: gitlab-runner-deploy
  namespace: ci-deploy
---
apiVersion: v1
kind: Secret
metadata:
  name: gitlab-runner-deploy-token
  namespace: ci-deploy
  annotations:
    kubernetes.io/service-account.name: gitlab-runner-deploy
type: kubernetes.io/service-account-token
EOF
```

> **i** The `kubernetes.io/service-account-token` Secret type is a legacy approach. The recommended method is the TokenRequest API (`d8 k create token ...`).

Grant permissions

For details on granting permissions, see Granting permissions to users and service accounts .

Assign the necessary permissions to the ServiceAccount.

For the basic role model, use ClusterAuthorizationRule:

```
cat <<EOF | d8 k apply -f -
apiVersion: deckhouse.io/v1
kind: ClusterAuthorizationRule
metadata:
  name: gitlab-runner-access
spec:
  subjects:
  - kind: ServiceAccount
    name: gitlab-runner-deploy
    namespace: ci-deploy
  accessLevel: Admin
  portForwarding: true
EOF
```

Available levels: `User`, `PrivilegedUser`, `Editor`, `Admin`, `ClusterEditor`, `ClusterAdmin`, `SuperAdmin`.

For the granular role model, grant the `d8:project:admin` role in all projects with a ClusterProjectRoleBinding. To grant access to a single namespace only, create a RoleBinding to the `d8:namespace:admin` role in it instead:

```
cat <<EOF | d8 k apply -f -
apiVersion: deckhouse.io/v1alpha3
kind: ClusterProjectRoleBinding
metadata:
  name: gitlab-runner-access
spec:
  subjects:
  - kind: ServiceAccount
    name: gitlab-runner-deploy
    namespace: ci-deploy
  roleRef:
    kind: ClusterRole
    name: d8:project:admin
EOF
```

Get API URL and CA certificate

When using publishAPI:

- When the API server is published via Ingress
- When the API server is published via Gateway API (`alb`)

When the API server is published via Ingress, use the following commands:

```
API_HOST=$(d8 k -n kube-system get ingress kubernetes-api -o
jsonpath='{.spec.rules[0].host}')
echo "API endpoint: https://${API_HOST}"
```

When the API server is published via Gateway API (the `alb` module), use the following commands:

```
API_HOST=$(d8 k -n kube-system get httproute kubernetes-api -o
jsonpath='{.spec.hostnames[0]}')
echo "API endpoint: https://${API_HOST}"
```

> **i** If the API certificate is signed by a public CA (Let’s Encrypt), the `--certificate-authority` parameter is not required.

For a private CA (self-signed, the default mode — shared between both publication methods):

```
d8 k -n kube-system get secret kubernetes-api-ca-key-pair -o jsonpath='{.data.tls\.crt}' |
base64 -d > /tmp/ca.crt
```

Create kubeconfig

Example of generating kubeconfig for a previously created ServiceAccount:

```
export CLUSTER_NAME=my-cluster
export USER_NAME=gitlab-runner-deploy
export CONTEXT_NAME=${CLUSTER_NAME}-${USER_NAME}
export FILE_NAME=kube.config

# For public CA, remove --certificate-authority and --embed-certs
d8 k config set-cluster $CLUSTER_NAME \
  --server=https://${API_HOST} \
  --certificate-authority=/tmp/ca.crt \
  --embed-certs=true \
  --kubeconfig=$FILE_NAME

d8 k config set-credentials $USER_NAME \
  --token=$(d8 k -n ci-deploy get secret gitlab-runner-deploy-token -o jsonpath='{.data.token}'
| base64 -d) \
  --kubeconfig=$FILE_NAME

d8 k config set-context $CONTEXT_NAME \
  --cluster=$CLUSTER_NAME --user=$USER_NAME \
  --kubeconfig=$FILE_NAME

d8 k config use-context $CONTEXT_NAME --kubeconfig=$FILE_NAME
```

Short-lived tokens (TokenRequest)

The TokenRequest API allows creating tokens with limited lifetime. When creating such a token, specify the name of the ServiceAccount that needs to be granted access in the command (in the example — `gitlab-runner-deploy`):

```
d8 k create token gitlab-runner-deploy -n ci-deploy --duration=1h
```

⚠ The `d8 k create token` command itself requires access to the Kubernetes API. If the CI job has no initial cluster access, it cannot execute TokenRequest from within the job.

Usage patterns in CI

Bootstrap token with minimal permissions. CI stores a long-lived kubeconfig/token that only has permission to create TokenRequest for a specific ServiceAccount. At the start of the job, the bootstrap token issues a short-lived token used for deployment.

External token broker. An operator, secret manager (Vault, External Secrets), or external service periodically issues short-lived tokens and places them in CI variables or secrets. The CI job only consumes the ready token.

ℹ The bootstrap token should have minimal permissions: only `create` on the `serviceaccounts/token` resource for a specific ServiceAccount/namespace. Do not use cluster-admin. Limit the TTL of issued tokens and promptly revoke bootstrap access if compromised.

Usage without kubeconfig file:

```
export KUBE_SERVER="https://${API_HOST}"
export KUBE_TOKEN=$(d8 k create token gitlab-runner-deploy -n ci-deploy --duration=1h)
d8 k --server=$KUBE_SERVER --token=$KUBE_TOKEN get ns
```

Basic Auth

Authentication via username and password through IdP (LDAP, OIDC).

⚠ The password is sent to DP and validated through basic-auth-proxy/Dex.

⚠ Only one DexProvider in the cluster can have `enableBasicAuth: true`.

Prerequisites

The following requirements must be met to configure Basic Auth:

- apiserver.publishAPI of the `control-plane-manager` module enabled.
- DexProvider configured for IdP.

Enable

Add `enableBasicAuth: true` to DexProvider. For DexProvider configuration examples, see user-authn module documentation.

Get API endpoint

To get the API endpoint, use the command:

```
API_HOST=$(d8 k -n d8-user-authn get ingress kubernetes-api -o
jsonpath='{.spec.rules[0].host}')
echo "https://${API_HOST}"
```

Verification

To check access, use the command:

```
curl -q -u "$K8S_USER:$K8S_PASSWORD" "https://${API_HOST}/version"
```

Possible errors:

- `401` — invalid credentials or Basic Auth not enabled.
- `403` — authentication succeeded but RBAC denies access.

Configure kubeconfig

Example of kubeconfig configuration for Basic Auth:

```
apiVersion: v1
kind: Config
clusters:
- name: my-cluster
  cluster:
    server: https://<API_HOST>
users:
- name: basic-auth-user
  user:
    username: "<USERNAME>"
    password: "<PASSWORD>"
contexts:
- name: default
  context:
    cluster: my-cluster
    user: basic-auth-user
current-context: default
```

Use in GitLab CI

Example of using Basic Auth in GitLab CI:

```
deploy:
  script:
    - d8 k --server="$K8S_SERVER" --username="$K8S_USER" --password="$K8S_PASSWORD"
get ns
```

Variables `K8S_SERVER`, `K8S_USER`, `K8S_PASSWORD` are set in the project CI/CD settings.

Token Exchange

The pipeline gets a token from its CI system, exchanges it at Dex for a token with `aud=kubernetes`, and uses it to access the API.

> **i** Recommended for GitLab CI and GitHub Actions.

DP/Dex receives no password. Dex trusts the CI system as a TokenExchangeProvider. It checks the signature, the issuer, the expiry and the audience of the token and the required claims, and names the pipeline in the cluster by a claim of the token.

Prerequisites

The following requirements must be met to configure Token Exchange:

- apiserver.publishAPI of the `control-plane-manager` module enabled.
- The CI system issues signed JWT ID tokens (GitLab CI `id_tokens`, GitHub Actions OIDC) and publishes its discovery document, or you have its public keys.

Create DexClient

To create DexClient, use the command:

```
cat <<EOF | d8 k apply -f -
apiVersion: deckhouse.io/v1
kind: DexClient
metadata:
  name: ci-token-exchange
  namespace: d8-user-authn
  annotations:
    dexclient.deckhouse.io/allow-access-to-kubernetes: "true"
spec: {}
EOF
```

The annotation `dexclient.deckhouse.io/allow-access-to-kubernetes` allows the client to request tokens with `aud=kubernetes`.

> ⚠ This grants cluster-wide access to the Kubernetes API. For this reason, adding the annotation or changing it to `"true"` requires the `create` permission on the `dexclients/allow-access-to-kubernetes` subresource of the `deckhouse.io` API group in the DexClient namespace. In the basic role model, this permission is granted at the `ClusterAdmin` level and above. In the granular model, it is granted by the `d8:subsystem:iam:manager` role and the roles that include it, such as `d8:system:manager`. A namespace-level role that permits creating a DexClient is not enough: the admission policy rejects the request with a message naming the annotation.
>
> The addition of the annotation is restricted regardless of the specified value, including `"false"`. This is required to ensure compatibility with previous DP versions where access has been granted when the annotation was present, regardless of its value.
>
> This restriction is not applicable to an object, which already has the annotation assigned. Deletion and recreation of DexClient is treated as another addition of the annotation, so a GitOps controller that recreates the object instead of patching it requires the same `create` permission on the `dexclients/allow-access-to-kubernetes` subresource.

Get client secret:

```
d8 k -n d8-user-authn get secret dex-client-ci-token-exchange -o jsonpath='{.data.clientSecret}' | base64 -d
```

client_id format: `dex-client-ci-token-exchange@d8-user-authn`.

Create TokenExchangeProvider

TokenExchangeProvider tells Dex which tokens to accept and which DexClient may exchange them. Example for GitLab CI:

```
cat <<EOF | d8 k apply -f -
apiVersion: deckhouse.io/v1alpha1
kind: TokenExchangeProvider
metadata:
  name: gitlab-ci
spec:
  issuer: https://gitlab.example.com
  keys:
    discovery: {}
  audiences:
  - exact: https://<DEX_HOST>/
  claimValidation:
  - claim: namespace_path
    equals: platform
  - claim: ref_protected
    equals: "true"
  identity:
    username:
      claim: sub
      prefix: "gitlab-ci:"
  clients:
  - dexClient:
      name: ci-token-exchange
      namespace: d8-user-authn
EOF
```

Parameters:

- `issuer`: URL of the GitLab instance, as in the `iss` claim of its ID tokens.
- `audiences`: Value of `aud` that the job sets in `id_tokens`. A token issued for another service is refused.
- `claimValidation`: Claims that a token must carry. In the example, only protected branches of projects in the `platform` group are accepted.
- `identity.username`: User name in the cluster, for example `gitlab-ci:project_path:platform/app:ref_type:branch:ref:main` for the `main` branch of `platform/app`.

Get the connector ID for the exchange request:

```
CONNECTOR_ID=$(d8 k get tokenexchangeprovider gitlab-ci -o jsonpath='{.status.connectorID}')
```

Store it as a CI variable. The ID changes if the object is deleted and created again, or if the provider gets its connector back after a `PrefixConflict`. In these cases, update the variable, otherwise Dex answers with 400 `Requested connector does not exist`.

Get Dex and API URLs

To get the Dex URL and API, use the following commands:

```
DEX_HOST=$(d8 k -n d8-user-authn get ingress dex -o jsonpath='{.spec.rules[0].host}')
API_HOST=$(d8 k -n d8-user-authn get ingress kubernetes-api -o
jsonpath='{.spec.rules[0].host}')
```

Grant RBAC

DP configures kube-apiserver to validate Dex tokens. The user name is the one TokenExchangeProvider sets in `identity.email` if it is set, and in `identity.username` otherwise; groups are taken from `identity.groups`.

For details on granting permissions, see Granting permissions to users and service accounts.

For the basic role model, use ClusterAuthorizationRule:

```
cat <<EOF | d8 k apply -f -
apiVersion: deckhouse.io/v1
kind: ClusterAuthorizationRule
metadata:
  name: ci-deployer
spec:
  subjects:
  - kind: User
    name: "gitlab-ci:project_path:platform/app:ref_type:branch:ref:main"
  accessLevel: Admin
EOF
```

For the granular role model, grant the `d8:project:admin` role in all projects with a ClusterProjectRoleBinding. To grant access to a single namespace only, create a RoleBinding to the `d8:namespace:admin` role in it instead:

```
cat <<EOF | d8 k apply -f -

EOF
```

Token exchange request

Example of a token exchange request:

```
RESPONSE=$(curl -q -s -X POST "https://${DEX_HOST}/token" \
  -u "${DEX_CLIENT_ID}:${DEX_CLIENT_SECRET}" \
  -H "Content-Type: application/x-www-form-urlencoded" \
  -d "grant_type=urn:ietf:params:oauth:grant-type:token-exchange" \
  -d "subject_token=${CI_TOKEN}" \
  -d "subject_token_type=urn:ietf:params:oauth:token-type:id_token" \
  -d "connector_id=${CONNECTOR_ID}" \
  -d "scope=openid email groups federated:id audience:server:client_id:kubernetes" \
  -d "requested_token_type=urn:ietf:params:oauth:token-type:id_token")

DEX_TOKEN=$(echo "$RESPONSE" | jq -r '.access_token')
```

Parameters:

- `subject_token`: ID token of the CI system. Access tokens are not accepted.
- `connector_id`: `status.connectorID` of TokenExchangeProvider.
- `scope`: Must include the following values:
  - `openid`: Required for an ID token.
  - `email`: kube-apiserver takes the user name from the `email` claim. Without it, the API answers 401.
  - `audience:server:client_id:kubernetes`: The token is issued for kube-apiserver.
  - `groups`: Required if RBAC grants rights to groups.
  - `federated:id`: Shows the TokenExchangeProvider of a token in `d8 k auth whoami` (the `user-authn.deckhouse.io/dex-provider` extra).

The Dex token lives as long as `idTokenTTL` of the `user-authn` module (10 minutes by default). Request a new one for a longer job.

GitLab CI

Example of a token request for GitLab CI:

```
deploy:
  id_tokens:
    GITLAB_OIDC_TOKEN:
      aud: https://<DEX_HOST>/
  script:
    - |
      RESPONSE=$(curl -q -s -X POST "https://${DEX_HOST}/token" \
        -u "${DEX_CLIENT_ID}:${DEX_CLIENT_SECRET}" \
        -H "Content-Type: application/x-www-form-urlencoded" \
        -d "grant_type=urn:ietf:params:oauth:grant-type:token-exchange" \
        -d "subject_token=${GITLAB_OIDC_TOKEN}" \
        -d "subject_token_type=urn:ietf:params:oauth:token-type:id_token" \
        -d "connector_id=${CONNECTOR_ID}" \
        -d "scope=openid email groups federated:id
audience:server:client_id:kubernetes" \
        -d "requested_token_type=urn:ietf:params:oauth:token-type:id_token")
      DEX_TOKEN=$(echo "$RESPONSE" | jq -r '.access_token')
      d8 k --server="${K8S_SERVER}" --token="${DEX_TOKEN}" auth whoami
```

GitHub Actions

For GitHub Actions, set the following in TokenExchangeProvider:

- `issuer`: `https://token.actions.githubusercontent.com`.
- `audiences`: Value that the workflow passes as `audience`.
- `claimValidation`: `repository_owner_id` and, if needed, `ref`. GitHub recommends checking the IDs, which never change. The name of a renamed or deleted organization can be taken by someone else.
- `identity.username`: `claim: sub` with a prefix, for example `github:`. The user name becomes `github:repo:my-org/app:ref:refs/heads/main`.

To request the token, add the `id-token: write` permission to the workflow:

```
permissions:
  id-token: write
steps:
  - run: |
      CI_TOKEN=$(curl -sS -H "Authorization: bearer
${ACTIONS_ID_TOKEN_REQUEST_TOKEN}" \
        "${ACTIONS_ID_TOKEN_REQUEST_URL}&audience=https://<DEX_HOST>/" | jq -r
'.value')
```

Exchange `CI_TOKEN` as in the token exchange request.

Migration from DexProvider

Earlier, a token was exchanged through a DexProvider of OIDC type, and the exchange request named it in `connector id`. This method is deprecated and off by default. A DexProvider exchanges tokens only with `spec.tokenExchange.enabled: true`. The module set this value during the upgrade in clusters that had a DexClient with the `dexclient.deckhouse.io/allow-access-to-kubernetes` annotation. The parameter can only be turned off. It will be removed after the next LTS release, together with this method. While a cluster exchanges tokens through a DexProvider, the `D8UserAuthnDexProviderTokenExchangeDeprecated` alert fires.

To migrate, follow these steps:

1. Create a TokenExchangeProvider with the `issuer` of the DexProvider and the audience your CI tokens carry.
2. Set `identity.username` to the claim the DexProvider took the user name from, for example `claim: user_email` for GitLab CI, with a prefix such as `gitlab-ci:`; give the groups a prefix too. The prefix is required. It sets the subjects of the provider apart from people and from the subjects of other providers.
3. Keep the checks of the DexProvider:
   - A DexProvider accepted only a token with `email_verified: true`, unless

`insecureSkipEmailVerified` was set. If the user name comes from an email, add `claimValidation: [{claim: email verified, equals: "true"}]`.
    - Move `allowedEmails`, `allowedEmailDomains` and `allowedGroups` to `allowedIdentities`. Dex applies them to the names with the prefixes added, such as `gitlab-ci:deployer@example.com`. Add the prefixes of `identity` to `allowedEmails` and `allowedGroups`. Move `allowedEmailDomains` as they are, because the domain is the part after the last `@`.
    - `allowedGroups` needs `identity.groups`. Without groups, every exchange is refused.
4. Before the switch, add the prefixed subjects to the ClusterAuthorizationRule, AuthorizationRule and RoleBinding objects that grant rights to the old names, for example `gitlab-ci:deployer@example.com` next to `deployer@example.com`.
5. In the exchange request, replace `connector_id` with `status.connectorID` of the new object.
6. After the switch, remove the old subjects from these objects.
7. Turn off token exchange through the DexProvider by setting `spec.tokenExchange.enabled: false`. It cannot be turned on again.

A TokenExchangeProvider accepts JWT ID tokens only. A pipeline that exchanged an access token, for example one of Keycloak, has to request an ID token of the issuer instead.

Diagnostics

> **i** Use `d8 k auth whoami` to verify which identity is being used.

`--token` flag may not work — kubeconfig with `auth-provider`, `exec`, or `tokenFile` overrides the token from the flag. Use `-v=8` for debugging:

```
d8 k --server="https://${API_HOST}" --token="${DEX_TOKEN}" auth whoami -v=8
```

The output shows which Authorization header is sent. For reliable token usage, use a minimal kubeconfig with only `server` and `token`, without `auth-provider`/`exec`.

TokenExchangeProvider is not ready — check the `Ready` condition of the object:

```
d8 k get tokenexchangeprovider gitlab-ci -o jsonpath='{.status.conditions}'
```

Dex 400 — one of the following:

- An unknown `subject_token_type`, or a wrong `connector_id` (`Requested connector does not exist`).
- The DexClient is not listed in `spec.clients` (`Connector not allowed for this client.`).
- `invalid_scope`: The DexClient has no `dexclient.deckhouse.io/allow-access-to-kubernetes` annotation, so it may not request `audience:server:client_id:kubernetes`. If the annotation is gone, check whether the admission-controller rejected the request that was supposed to add it, or whether a GitOps controller recreated the object without it. Adding the annotation requires the `create` permission on the `dexclients/allow-access-to-kubernetes` subresource of the `deckhouse.io` API group in the DexClient namespace.
- `unauthorized_client`: The client is a kubeconfig client or `kubernetes`, which may not exchange tokens.

Dex 401 — invalid client credentials, or the token is refused: an access token instead of an ID token, wrong signature or issuer, a `kid` of no pinned key, expired or valid for longer than `subjectTokenMaxLifetime`, another audience, a required claim does not match, or the names with the prefixes added are not in `allowedIdentities` (`User is not allowed.`). The Dex log names the reason.

API 401 — token validation failed. Check:

- `scope` contains `email` and `audience:server:client_id:kubernetes`.
- Time synchronization between CI runner and cluster.

API 403 — authentication succeeded but RBAC does not allow access for the user or group from the token, or TokenExchangeProvider was deleted or lost its connector (`PrefixConflict`). In this case, every token issued through it is refused if the `enableMultiTenancy` parameter of the `user-authz` module is enabled and the cluster runs Kubernetes 1.34 or later.

Decode token to check claims:

```
echo "${DEX_TOKEN}" | cut -d. -f2 | base64 -d 2>/dev/null | jq .
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Resource listing with access-based filtering

In Kubernetes, the `kubectl get <resource> -A` command requires cluster-wide permissions for the `list` operation. Otherwise, kube-apiserver returns the `403 Forbidden` error, even if the user has access to dozens of namespaces individually.

Deckhouse Platform (DP) extends kube-apiserver so that a user without cluster-wide permissions can explicitly request a response filtered down to what they can actually access, instead of a refusal.

The mechanism is strictly opt-in. For a client who does not request filtering, the behavior remains identical to the standard one used in Kubernetes.

Using via Deckhouse CLI

In DP, you can use the Deckhouse CLI tool to work with the filtered listing mechanism.

Resource filtering scopes

Using the `--scope` flag, you can define namespaces the resources will be returned from.

Value	What is returned
`accessible`	Objects from every namespace where the user's RBAC allows the given operation on the given resource
`projects`	Objects from namespaces belonging to any project, that is, namespaces with a non-empty value of the `projects.deckhouse.io/project` label
`project:<name>`	Objects from the namespaces of one specific project. The name must be a valid project name
`system`	Objects from system namespaces only: `default` and namespaces whose names start with `d8-` or `kube-`. This is a fixed list of namespaces defined by their names and independent of projects. Other namespaces that neither belong to a project nor match the list of system namespaces are not returned when setting either `system` or `projects` scope

The `projects` and `project:<name>` scopes require the `multitenancy-manager` module. While the module is disabled, requests with these scopes are rejected with the `400 Bad Request` error.

Examples

Use the `--scope` flag in the `d8 k get` command together with the `-A` flag (or `--all-namespaces`).

Obtaining objects from all namespaces available to the user:

```
d8 k get pods -A --scope=accessible
```

Obtaining objects from project namespaces only:

```
d8 k get pods -A --scope=projects
```

Obtaining objects from a specified project:

```
d8 k get pods -A --scope=project:my-project
```

The mechanism is applicable to custom resources as well:

```
d8 k get configauditreports -A --scope=accessible
```

The filtering can be applied to watch requests as well:

```
d8 k get pods -A --scope=accessible -w
```

Details:

- Deckhouse CLI rejects `--scope` without the `-A` flag and together with the `-n` (`--namespace`) flag: in a single namespace, the flag could only narrow that namespace's listing, usually to an empty one, instead of returning the `403 Forbidden` error. The HTTP API accepts the headers for a single namespace as well.
- If the `d8 k get <resource> -A` command without `--scope` fails with `403 Forbidden`, Deckhouse CLI suggests suitable `--scope` variants.
- Shell completion works for the `--scope` flag values, including the names of existing projects (`--scope=project:<TAB>`).

Example of an interface query for where the user may perform actions

With the multitenancy mode enabled (`enableMultiTenancy`), you can use the SelfScopedAccessReview resource to request information about the namespaces in which the user is allowed to perform actions. The query gives the user who creates it information on where actions are allowed for them within a filtering scope. One query replaces an access check per namespace. The namespaces are counted by the rule that filters a list sent with the same scope, so a section built on the answer opens exactly when its list has objects to return.

Any authenticated user can create the resource, and it answers only about the caller. A query with the `spec.user`, `spec.groups`, `spec.uid` or `spec.extra` fields is refused.

Example query from a Deckhouse web interface page that shows deployments of all projects, offers to create one and shows pod logs:

```
d8 k create -o yaml -f - <<EOF
apiVersion: authorization.deckhouse.io/v1alpha1
kind: SelfScopedAccessReview
spec:
  scope: projects
  requests:
  - group: apps
    resource: deployments
    verbs: [list, watch]
  - group: apps
    resource: deployments
    verbs: [create]
    includeNamespaces: true
  - group: ""
    resource: pods
    subresource: log
    verbs: [get]
    includeNamespaces: true
EOF
```

Example answer for a user who administers the `shop-dev` and `shop-stage` namespaces of a project and has read access without pod logs in `shop-prod`:

```
status:
  results:
  - allowed: true
    cluster: false
    count: 3
  - allowed: true
    cluster: false
    count: 2
    namespaces: [shop-dev, shop-stage]
  - allowed: true
    cluster: false
    count: 2
    namespaces: [shop-dev, shop-stage]
```

Example answer for a cluster administrator. The namespaces are neither counted nor listed, even with `includeNamespaces: true`:

```
status:
  results:
  - allowed: true
    cluster: true
  - allowed: true
    cluster: true
  - allowed: true
    cluster: true
```

Example answer for a user who can only read deployments in the `billing-prod` namespace of another project:

```
status:
  results:
  - allowed: true
    cluster: false
    count: 1
  - allowed: false
    cluster: false
    count: 0
    namespaces: []
  - allowed: false
    cluster: false
    count: 0
    namespaces: []
```

For details on the SelfScopedAccessReview resource (query), including how it works, the query and answer fields, errors and usage recommendations, refer to the `user-authz` module documentation.

Using from your own code (HTTP API)

The CLI is just a transport mechanism. The filtering is enabled by two HTTP request headers sent to kube-apiserver. To use the mechanism from you own service, a script, or any other client, set the headers yourself.

Header	Value	When required
`X-Deckhouse-Scope`	`accessible` | `projects` | `system` | `project`	Always (enables the mechanism)
`X-Deckhouse-Project`	Project name	Only together with `X-Deckhouse-Scope: project`

The headers only affect read operations (`list`, `get`, `watch`) of top-level namespaced resources without a subresource. They apply both on a cluster-scoped URL (a path without `namespaces/<name>`, which is produced when the `-A` flag is used) and on the URL of one namespace (`namespaces/<name>/...`). On the URL of one namespace, objects are returned only if that namespace

is in the resulting set of namespaces: while it is outside the set, `list` and `watch` return no objects, and `get` returns `404 Not Found`.

Mutating requests and requests to subresources ignore the headers, whatever their value. For reads of cluster-scoped resources, a valid header has no effect, while an invalid value is rejected with the `400 Bad Request` error, as for any other read.

Example of listing the pods available to a service account:

```
curl -H "Authorization: Bearer $TOKEN" \
     -H "X-Deckhouse-Scope: accessible" \
     https://<kube-apiserver>/api/v1/pods
```

Example of listing the Deployment objects of one project:

```
curl -H "Authorization: Bearer $TOKEN" \
     -H "X-Deckhouse-Scope: project" \
     -H "X-Deckhouse-Project: my-project" \
     https://<kube-apiserver>/apis/apps/v1/deployments
```

Response semantics:

Situation	Response
No headers	Standard Kubernetes behavior (the `403 Forbidden` error for a user without permissions)
Header present but RBAC denied the request	`200 OK` with a list of objects from accessible namespaces (the list can be empty)
Header present, and the user has cluster-wide permissions	`200 OK`. The filtering is applied by namespace classification only (for example, `system` keeps only `default`, `d8-*`, and `kube-*` namespaces)
Invalid header value: an unknown scope, `X-Deckhouse-Project` without `X-Deckhouse-Scope: project`, or a project name that is not a valid name	`400 Bad Request` for every user, before the permissions are checked
The `projects` or `project` scope while the `multitenancy-manager` module is disabled	`400 Bad Request`
`get` of an object outside the resulting set of namespaces	`404 Not Found`, as for an object that does not exist
RBAC denied the request, and `permission-browser` cannot answer now: it does not answer in time, is overloaded, or is unreachable	`503 Service Unavailable` with the `Retry-After` header; no objects are returned
RBAC denied the request, and the access boundary cannot be computed for another reason	`403 Forbidden` (fail-closed)

When using client-go, add the headers via `rest.Config.WrapTransport`.

How it works

1. **Kube-apiserver authorization filter.**

   If RBAC denied the request, the filter — instead of returning `403 Forbidden` immediately — checks three conditions:

   - The read operation (`list`, `get`, or `watch`) is underway.
   - The request is addressed to the main resource and not the subresource.
   - A filtering decorator is registered for this resource and the header is present.

   Only when all three conditions are met, the request is passed on, with a mark of filtering required at the storage layer.

2. **The storage layer** computes the final namespace set as the intersection of two independent sets:

   - **Classification**: Which namespaces match the `--scope` value. Determined by the `projects.deckhouse.io/project` label that the `multitenancy-manager` module assigns to

project namespaces. Resolved by a direct request to kube-apiserver and does not depend on the user.
- **Access boundary** (with RBAC floor in the mechanism's code): Which namespaces are actually available to the user for *this resource and this operation*. Computed with one `SelfScopedAccessReview` request to the `authorization.deckhouse.io` API (the `user-authz` module) for the exact resource, subresource, and verb, the same answer the web interface uses to decide what to show. Applied whenever RBAC denies the request. The boundary also includes the namespaces where a RoleBinding grants permissions to every authenticated user (the `system:authenticated` group), although the namespace list does not show them.

Only objects from namespaces in the final set make it into the response.

3. **Watch** (`-w`): Returns a filtered stream, and if the set of accessible namespaces changes "on the fly" (for example, permissions granted or revoked, or a namespace was moved to another project), it synthesizes `ADDED`/`DELETED` events for the affected objects without the client reconnecting.

   The set is refreshed every second. A synthesized `DELETED` event carries the last `resourceVersion` of the stream. If the set cannot be refreshed (for example, `permission-browser` does not respond), the stream keeps the previous set for up to 60 seconds, then sends an error and closes. The client reconnects and gets `503 Service Unavailable` while `permission-browser` cannot answer, or `403 Forbidden` while the set cannot be computed for another reason. If the `multitenancy-manager` module is disabled while a watch with the `projects` or `project` scope is open, the stream sends a `400 Bad Request` error and closes at once. If `permission-browser` answers that the user may now perform the request in the whole cluster, the stream sends `410 Gone` and closes, and the client lists again.

The mechanism supports all built-in namespaced Kubernetes resources and namespaced resources defined via CRD. Resources of aggregated APIs take part only when their `APIService` opts in, see below.

Aggregated APIs

A resource served by an aggregated API server (an `APIService` with `spec.service`) takes part in the mechanism only when its `APIService` lists it in the `scope.deckhouse.io/resources` annotation, a comma-separated list of resource names:

```
apiVersion: apiregistration.k8s.io/v1
kind: APIService
metadata:
  name: v1.example.deckhouse.io
  annotations:
    scope.deckhouse.io/resources: widgets,gadgets
```

Without the annotation a read with a scope that RBAC denied gets `403 Forbidden`, as before. Setting the annotation is a cluster administrator decision: the aggregated API server then receives scoped reads and must filter its answers itself.

How a scoped read of an opted-in resource works:

- kube-apiserver computes the resulting set of namespaces as for a built-in resource and sends it to the aggregated API server in the `X-Deckhouse-Scope-Namespaces` header, with `X-Deckhouse-Scope-Mode: filtered` (RBAC denied the read) or `narrowed` (RBAC allowed it, the set only narrows the answer). Copies of these headers sent by the client are removed. The aggregated API server must trust them only from a request authenticated with the front proxy client certificate of kube-apiserver.
- `get` of an object in a namespace outside the set is answered by kube-apiserver with `404 Not Found`, without a request to the aggregated API server.
- A set that does not fit the request header limit of the aggregated API server (1 MiB) is answered with `400 Bad Request`; use a narrower scope.
- Local `APIService` objects (built-in groups and CRDs) and the `authorization.deckhouse.io` API ignore the annotation.
- `permission-browser` follows the annotation through a watch on `APIService` objects, so adding or removing it takes effect within seconds.

A watch of an opted-in resource gets the set once, when it opens. kube-apiserver caps its `timeoutSeconds` at 5 minutes, recomputes the set every second while the stream is open, and ends the stream when the set changes, when the annotation is removed, or when the set cannot be recomputed for 60 seconds. It does not synthesize `ADDED` and `DELETED` events as for a built-in resource. Over HTTP, a JSON or protobuf stream ends with a `410 Gone` error event, so a client-go informer lists again and gets objects of the new set. A stream in another encoding (for example, CBOR),

a compressed stream, a stream with an event larger than 16 MiB, or one kube-apiserver cannot split into events is closed without that event. A WebSocket watch is closed without that event: a client that watches over WebSocket must list again after the connection closes.

Security model

- **Standard Kubernetes behavior without headers.** Controllers and operators relying on `403 Forbidden` as a signal continue normal operation.
- **Headers do not widen access permissions.** The access boundary is computed on the server based on the identity of a user who made the request. Even if a client inserts the headers manually they can't access objects out of what their RBAC allows. The check is made for each pair (`resource`, `verb`). Therefore, for example, a user with the `get secrets` permission in a namespace can't access pods in it.
- **Using the fail-closed model.** If the `authorization.deckhouse.io` API is not served (for example, if the `user-authz` module is disabled, or `permission-browser` does not serve `SelfScopedAccessReview` yet during an update), the access boundary cannot be computed — a denied user gets the standard `403 Forbidden` response. The same response is returned when `permission-browser` allows the operation in the whole cluster while kube-apiserver has denied it: the mechanism never answers with all namespaces. If `permission-browser` cannot answer now (it does not answer in time, answers `429 Too Many Requests` or a `5xx` error, or is unreachable), a scoped request gets `503 Service Unavailable` with the `Retry-After` header instead: the access is unknown rather than denied, and the client may retry. Neither response returns any objects.
- **Indistinguishable refusals.** Requests like `project:<someone else's>` and `project:<nonexistent>` result in identical empty responses and project existence is not disclosed.

Special case: namespaces

For the `namespaces` resource itself, filtering applies unconditionally, regardless of used flags or headers. The `d8 k get namespaces` command returns only the namespaces available to the user instead of `403 Forbidden`. Filtering of arbitrary resources via `--scope` is a generalization of the same mechanism, enabled explicitly.

If the `console` module older than 1.44.0 is enabled, the namespace list is not filtered: the access levels of ClusterAuthorizationRule and AuthorizationRule and the namespace roles keep the permission to list every namespace.

The same list is returned by the read-only accessiblenamespaces resource, which any authenticated user can request for themselves:

```
d8 k get accessiblenamespaces
```

This is handy for scripts and interfaces: there is no need to iterate over namespaces and check access to each one.

Special case: projects

A `Project` is cluster-scoped, but its visibility follows the same namespace boundary: a user sees a project when they can see any of its namespaces — the main one or an additional one. A namespace belongs to a project only when its `projects.deckhouse.io/project` label has a non-empty value; the project is never derived from the namespace name. A namespace without the label shows the virtual project that `multitenancy-manager` counts it in: `deckhouse` for `d8-*`, `kube-*`, `upmeter-*` and namespaces with the `heritage: deckhouse` or `heritage: upmeter` label, `default` for the rest. A user who may list namespaces in the whole cluster sees every project, both virtual ones included. Filtering applies unconditionally here as well, so `d8 k get projects` returns the accessible subset instead of `403 Forbidden`, and a `get` of a project unavailable for the user answers `NotFound`.

Because of that, access levels granted through a `ClusterAuthorizationRule` no longer carry a cluster-wide read of `projects`: the grant would let RBAC allow the listing before the filter could narrow it. As a result, `d8 k auth can-i list projects` answers `no` for such a user while the listing itself works and returns their projects. Writing projects is unaffected.

Monitoring

kube-apiserver exports the following metrics of the mechanism:

Metric	Meaning

Metric	Meaning
`apiserver_scopefilter_allowed_set_failures_total`	Requests answered with an error because the access boundary could not be computed, by the `operation` label (`list`, `get`, `watch`) and the `reason` label: `unavailable` (`permission-browser` cannot answer now, the request got `503 Service Unavailable`), `no_resolvers` (kube-apiserver started without the mechanism wired for aggregated APIs, the request got `403 Forbidden`) or `denied` (any other failure, the request got `403 Forbidden`)
`apiserver_scopefilter_cluster_disagreements_total`	Requests kube-apiserver denied while `permission-browser` allowed them in the whole cluster, answered with `403 Forbidden`
`apiserver_scopefilter_watch_refresh_failures_total`	Failed refreshes of the namespace set of an open watch, timeouts included
`apiserver_scopefilter_watch_closed_total`	Watches closed by the mechanism, by the `reason` label: `refresh_failures` (the set could not be refreshed for 60 seconds), `overflow` (the client did not read the events in time), `multitenancy_disabled` (the `projects` and `project` scopes are no longer served) or `access_changed` (the user may now perform the request in the whole cluster)
`apiserver_scopefilter_proxied_namespaces`	Size of the namespace set sent to an aggregated API server with a scoped read
`apiserver_scopefilter_proxied_watch_closed_total`	Scoped watches of an aggregated API ended so that the client reconnects with a new set, by the `reason` label: `set_changed` (the set changed or the read is no longer filtered), `opt_in_withdrawn` (the `APIService` was deleted or no longer lists the resource) or `refresh_failed` (the set could not be recomputed for 60 seconds)
`apiserver scopefilter_proxied_header_limit_rejections_total`	Scoped reads of an aggregated API answered with `400 Bad Request` because the set does not fit the header limit

Components involved

Component	Role
Deckhouse CLI	Supports the `--scope` flag and transforms its values into headers
kube-apiserver (DP patch)	Bypasses `403 Forbidden` and provides filtering at the storage layer
`user-authz` (`permission-browser`)	Defines the access boundary via `SelfScopedAccessReview`
`multitenancy-manager`	Provides namespace classification based on the `projects.deckhouse.io/project` label
`user-authz` (the `d8-user-authz-multitenancy-state` ConfigMap)	Tells kube-apiserver whether the `multitenancy-manager` module is enabled, in every edition

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with IaaS

Deckhouse Platform (DP) provides built-in tools for integrating with various cloud providers and virtualization systems. These tools let you:

- Automatically use cloud infrastructure to provision virtual machines and connect them to the cluster.
- Deploy clusters in cloud environments.
- Scale resources as needed.
- Automatically create base infrastructure resources (such as networks, routes, etc.), if supported by the provider.

The workflow for working with different cloud providers is generally the same, with only the preparation steps (such as creating a service account in the cloud) and configuration files differing.

Supported cloud providers:

- Amazon Web Services (AWS)
- Google Cloud Platform (GCP)
- Microsoft Azure
- OpenStack
- OVH Cloud
- Selectel Cloud
- VK Cloud
- Yandex Cloud

Integration is also possible with private clouds based on the following solutions:

- VK Cloud
- OpenStack
- Huawei Cloud

In addition to cloud providers, integration is supported with the following virtualization systems:

- Deckhouse Virtualization Platform (DVP)
- VMware Cloud Director
- VMware vSphere
- zVirt

It is also possible to configure hybrid clusters.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Public cloud providers

Deckhouse Platform (DP) can be deployed in various public clouds, enabling the use of scalable infrastructure and flexible integration with cloud services.

DP supports the following providers:

- Amazon Web Services (AWS)
- Google Cloud Platform (GCP)
- Microsoft Azure
- OpenStack
- OVH Cloud
- Selectel Cloud
- VK Cloud
- Yandex Cloud

This simplifies the choice of deployment environment and enables a unified approach to managing Kubernetes clusters across different cloud ecosystems.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Yandex Cloud

To allow Deckhouse Platform (DP) to manage resources in Yandex Cloud, you need to:

- Create a service account.
- Assign the required IAM roles to it.
- Generate an authorization key.
- Optionally reserve a public IP address.
- Ensure sufficient resource quotas in the cloud.

The steps below guide you through setting up the connection.

Preparing the environment

> The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

The `cloud-init` package must be installed on virtual machines (VM). After a VM is started, the following services associated with this package must be running:

- `cloud-config.service`
- `cloud-final.service`
- `cloud-init.service`

To verify that the services are running, use the following commands:

```
systemctl status cloud-config.service
systemctl status cloud-final.service
systemctl status cloud-init.service
```

> Starting with version 1.77, new clusters in Yandex Cloud use the Cilium CNI by default with pod traffic tunneling over VXLAN. In existing clusters, the CNI stays unchanged.
>
> Make sure all nodes run Linux kernel 5.8 or newer and that security groups allow UDP traffic between nodes. For the list of ports, see “Network interaction of the platform components”; for CNI settings, see “Internal network configuration”.

Creating a service account

To enable DP to manage Yandex Cloud resources, create a service account and assign it editing permissions. You can find detailed instructions on service account creation in the Yandex Cloud documentation.

To create the service account, run the following command:

```
yc iam service-account create --name deckhouse
```

The command will return information about the newly created service account:

```
id: <USER_ID>
folder_id: <FOLDER_ID>
created_at: "YYYY-MM-DDTHH:MM:SSZ"
name: deckhouse
```

⚠ Save the `userID` and `folderID` as they will be needed in the following steps.

Assigning IAM roles

To allow DP to work with cloud resources, assign the following roles to the service account:

```
yc resource-manager folder add-access-binding --id <FOLDER_ID> --role compute.editor --subject
serviceAccount:<USER_ID>
yc resource-manager folder add-access-binding --id <FOLDER_ID> --role vpc.admin --subject
serviceAccount:<USER_ID>
yc resource-manager folder add-access-binding --id <FOLDER_ID> --role load-balancer.editor --subject
serviceAccount:<USER_ID>
```

Generating an authorization key

Generate a JSON authorization file to use in your configuration:

```
yc iam key create --service-account-name deckhouse --output deckhouse-sa-key.json
```

The contents of the `deckhouse-sa-key.json` file are needed for the credentials Secret.

Credentials Secret

The service account key is stored in a separate Secret rather than in ModuleConfig. The provider reads it when starting the components that access the Yandex Cloud API.

The Secret is created during cluster installation together with the other resources of the initial configuration. If the provider is connected to a running cluster, the Secret is applied after the module creates the namespace. For the order of steps, see “Hybrid cluster with Yandex Cloud”. The Secret must meet the following requirements:

- The name is `d8-credentials` and the namespace is `d8-cloud-provider-yandex`.
- The type is `cloud-provider.deckhouse.io/credentials`.
- The `authScheme` field is set to `serviceAccount`.
- The `secret` field contains the service account key in JSON.

```
apiVersion: v1
kind: Secret
metadata:
  name: d8-credentials
  namespace: d8-cloud-provider-yandex
type: cloud-provider.deckhouse.io/credentials
stringData:
  authScheme: serviceAccount
  secret: |
    <SERVICE_ACCOUNT_JSON>
```

Replace `<SERVICE_ACCOUNT_JSON>` with the contents of the `deckhouse-sa-key.json` file.

To change the credentials, update the `secret` field:

```
d8 k -n d8-cloud-provider-yandex edit secret d8-credentials
```

In the “WithNATInstance layout”, the API key for monitoring the NAT instance is stored in a second Secret, `d8-credentials-exporter`, in the same namespace. Its `authScheme` field is set to `apiToken` and the key is placed in the `secret` field.

Instead of a ready key, the `secret` field can hold the `Auto` value. In that case, while provisioning the infrastructure, DP creates a service account named `<CLUSTER_PREFIX>-monitoring` in the folder, grants it the `monitoring.viewer` role, and generates an API key for it, which the metrics exporter then uses.

In clusters migrated to ModuleConfig, the service account key moves to the `d8-credentials` Secret from the `provider.serviceAccountJSON` parameter of the YandexClusterConfiguration resource. The

monitoring API key moves to the `d8-credentials-exporter` Secret from the `withNATInstance.exporterAPIKey` parameter.

Checking and increasing quotas

Make sure your cloud account has the required quotas for cluster deployment and scaling:

- vCPUs: 64
- SSD storage: 2000 GB
- Number of VMs: 25
- RAM: 256 GB

Increase quotas via the Yandex Cloud Console if necessary.

Reserving a public IP

If you are using the WithoutNAT or WithNATInstance deployment layout and need a fixed external IP address (for example, to use in `externalIPAddresses`, `natInstanceExternalAddress`, or a bastion host), run the following command:

```
yc vpc address create --external-ipv4 zone=ru-central1-a
```

Example output:

```
id: e9b4cfmmnc1mhgij75n7
folder_id: b1gog0h9k05lhqe5d88l
created_at: "2020-09-01T09:29:33Z"
external_ipv4_address:
  address: 178.154.226.159
  zone_id: ru-central1-a
  requirements: {}
reserved: true
```

After completing these steps, you will have all the information needed to configure the provider. For the order of steps, see “Configuration”.

Additional resources

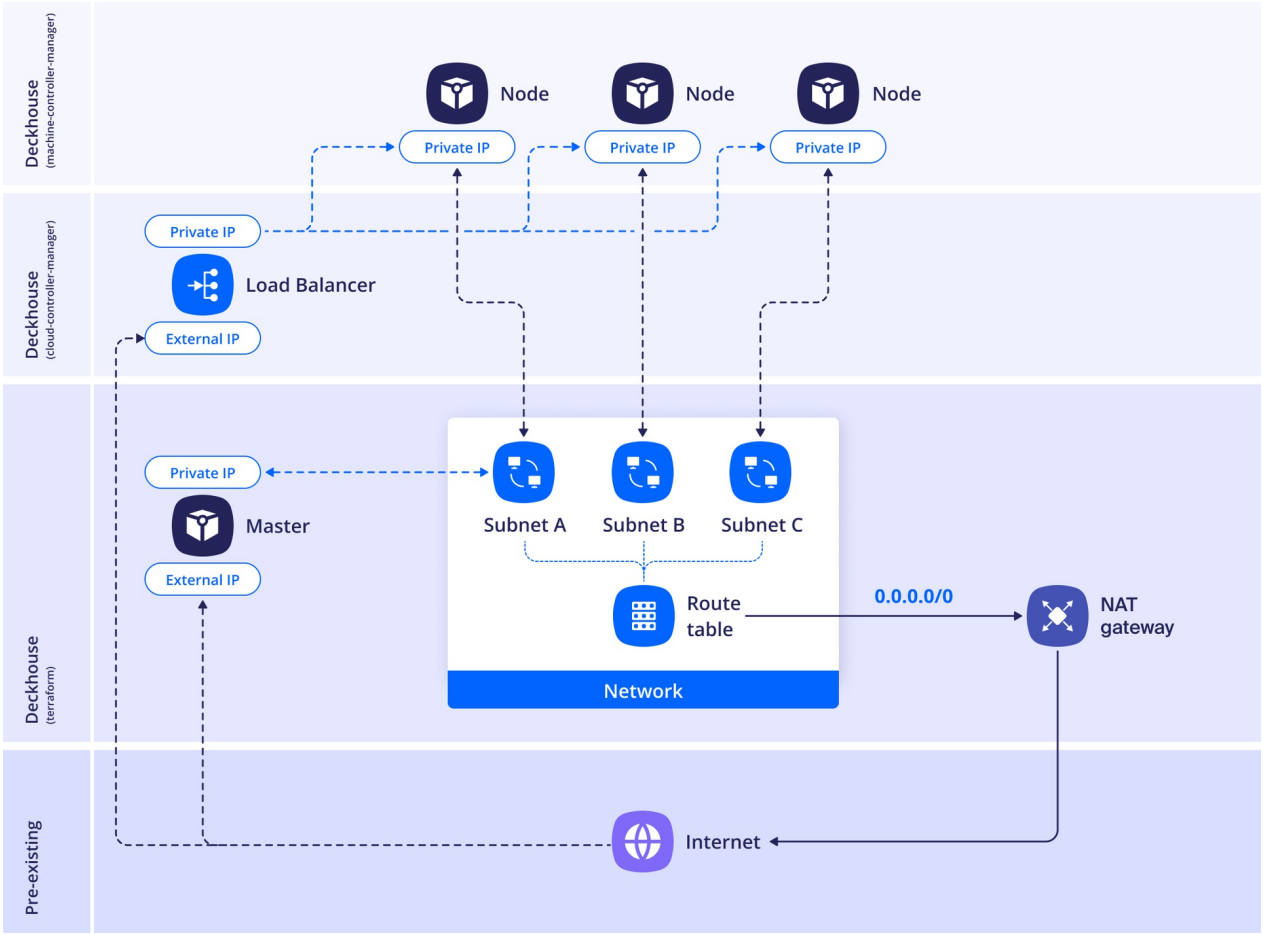
Layouts and configuration in Yandex Cloud



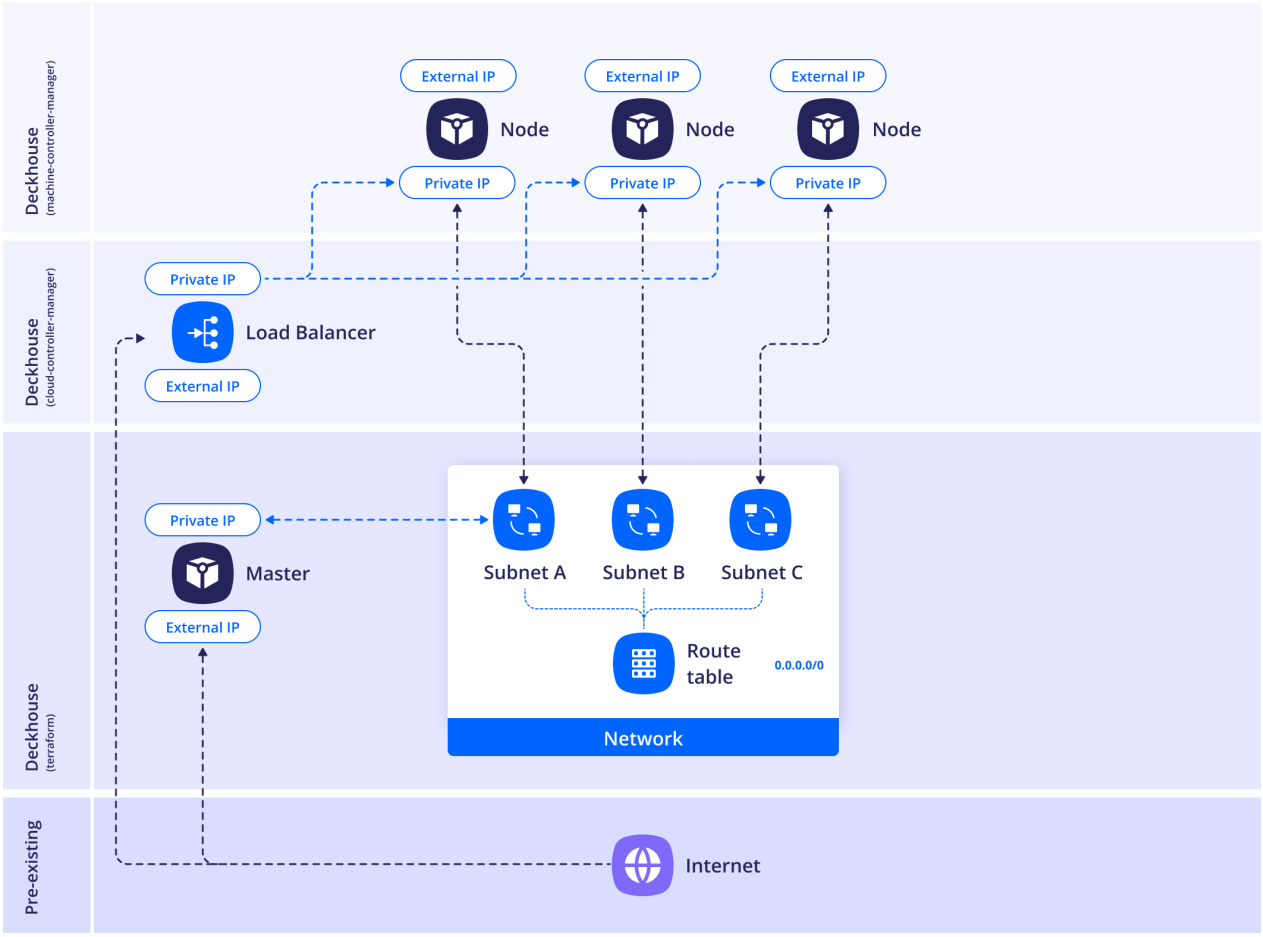
Layouts

This section describes the possible node placement layouts in Yandex Cloud infrastructure and the related configuration options. The layout is specified by the `layout` parameter in the ModuleConfig resource of the `cloud-provider-yandex` module. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

✖ In this layout, nodes will not have public IP addresses and will access the internet via a Yandex Cloud NAT Gateway. The NAT Gateway uses random public IP addresses from dedicated address ranges. Because of this, you cannot whitelist the IP addresses of cloud resources behind a specific NAT Gateway in third-party services.

⚠ Because nodes are created without public IP addresses in this layout, the master node must be accessible over SSH from the machine where `dhctl` is running: either directly over a private network or through a bastion host. If the master node is not directly accessible, run the installation with the `--ssh-bastion-host`, `--ssh-bastion-user`, and, if needed, `--ssh-bastion-port` parameters.



Example layout configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        cloudID: <CLOUD_ID>
        folderID: <FOLDER_ID>
    nodes:
      parameters:
        layout: Standard
        sshPublicKey: <SSH_PUBLIC_KEY>
        nodeNetworkCIDR: 192.168.12.0/24
        existingNetworkID: <EXISTING_NETWORK_ID>
        zones:
          - ru-central1-a
          - ru-central1-b
          - ru-central1-d
        labels:
          billing: prod
        dhcpOptions:
          domainName: test.local
          domainNameServers:
            - <DNS_SERVER_1>
            - <DNS_SERVER_2>
```

WithoutNAT

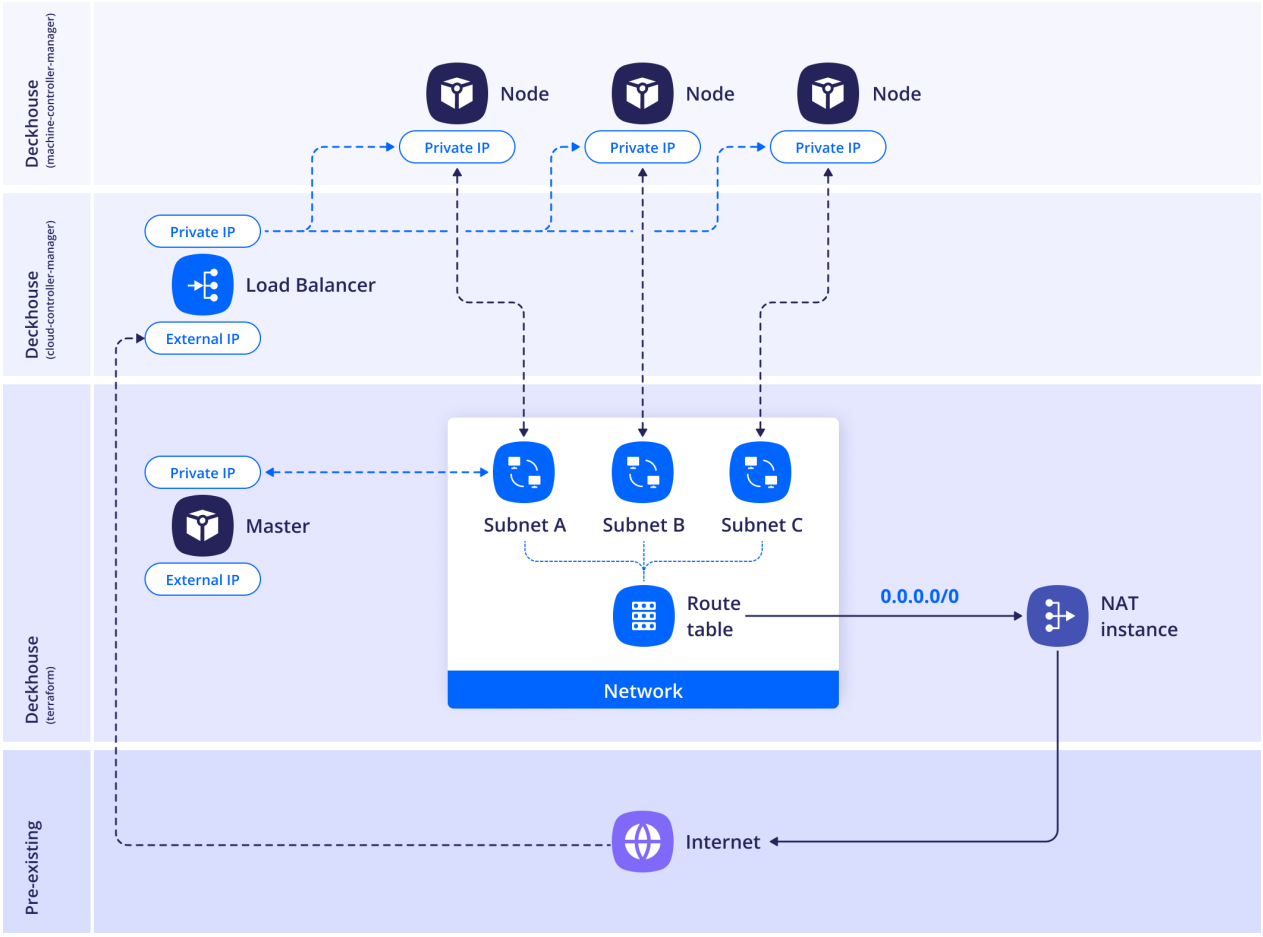
In this layout, no form of NAT is used, and each node is assigned a public IP address.

⚠ DP does not assign security groups to the nodes, so in this layout the nodes are accessible from the outside without restrictions. To restrict the traffic, use the rules of the default group as described in “Configuring security groups in Yandex Cloud”.

Example layout configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        cloudID: <CLOUD_ID>
        folderID: <FOLDER_ID>
    nodes:
      parameters:
        layout: WithoutNAT
        sshPublicKey: <SSH_PUBLIC_KEY>
        nodeNetworkCIDR: 192.168.12.0/24
        existingNetworkID: <EXISTING_NETWORK_ID>
        zones:
          - ru-central1-a
          - ru-central1-b
          - ru-central1-d
        externalIPAddresses:
          master:
            - Auto
            - Auto
            - Auto
          worker:
            - <ZONE_A_EXTERNAL_IP_WORKER_1>
            - Auto
        externalSubnetIDs:
          master:
            - <ZONE_A_SUBNET_ID>
            - <ZONE_B_SUBNET_ID>
            - <ZONE_D_SUBNET_ID>
          worker:
            - <ZONE_A_SUBNET_ID>
            - <ZONE_B_SUBNET_ID>
        dhcpOptions:
          domainName: test.local
          domainNameServers:
            - <DNS_SERVER_1>
            - <DNS_SERVER_2>
```

WithNATInstance



In this layout, a NAT instance is created in a separate subnet, and the route tables of the zone subnets are updated with a `0.0.0.0/0` route using the NAT instance as the next hop. The subnet is isolated to prevent routing loops and must not overlap with any other networks used in the cluster.

To place the NAT instance in an existing subnet, use the `withNATInstance.internalSubnetID` parameter. The instance will be created in the zone corresponding to this subnet.

If you need to create a new subnet, specify the `withNATInstance.internalSubnetCIDR` parameter. The NAT instance will be placed in this subnet.

Set one of the two parameters, `withNATInstance.internalSubnetID` or `withNATInstance.internalSubnetCIDR`.

If `withNATInstance.externalSubnetID` is also specified, the NAT instance will be connected to that subnet via a secondary network interface.

Example layout configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        cloudID: <CLOUD_ID>
        folderID: <FOLDER_ID>
    nodes:
      parameters:
        layout: WithNATInstance
        sshPublicKey: <SSH_PUBLIC_KEY>
        nodeNetworkCIDR: 192.168.12.0/24
        existingNetworkID: <EXISTING_NETWORK_ID>
        zones:
          - ru-central1-a
        withNATInstance:
          natInstanceExternalAddress: <NAT_INSTANCE_EXTERNAL_ADDRESS>
          internalSubnetID: <INTERNAL_SUBNET_ID>
          externalSubnetID: <EXTERNAL_SUBNET_ID>
        dhcpOptions:
          domainName: test.local
          domainNameServers:
            - <DNS_SERVER_1>
            - <DNS_SERVER_2>
```

> **i** In this example, master and worker nodes are created without public IP addresses and without additional external network interfaces. Outbound traffic from the cluster subnets goes through the NAT instance.
>
> The NAT instance is not automatically used by the `dhctl` installer as a bastion host or jump host. To install the cluster, the master node must be accessible over SSH from the machine where `dhctl` is running: either directly or through a bastion host.
>
> If the master node does not have a public IP address or is not directly accessible, run the installation with the `--ssh-bastion-host` and `--ssh-bastion-user` parameters.
>
> If you need to connect directly to a master node using a public IP address, specify the `externalIPAddresses` and `externalSubnetIDs` parameters in the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module. Note that the interface connected to the network specified in `externalSubnetIDs` will be used as the node's default gateway.

Configuration

The Yandex Cloud provider parameters are defined in four resources:

- The ModuleConfig of the `cloud-provider-yandex` module defines the layout, the network parameters, and the cloud and folder IDs.
- The `d8-credentials` Secret in the `d8-cloud-provider-yandex` namespace stores the service account key. Its format is described in "Credentials Secret".
- YandexInstanceClass describes the virtual machine parameters.
- NodeGroup describes the node groups and refers to an instance class. The master node group is described by the same resource with the `CloudPermanent` type.

To change the provider settings in a running cluster, edit the ModuleConfig:

```
d8 k edit mc cloud-provider-yandex
```

After changing the node parameters, run the following command:

```
dhctl converge
```

> **⚠** If the cluster was installed with the YandexClusterConfiguration schema, it must be migrated to the ModuleConfig-based configuration. Until the migration is complete, the `D8CloudProviderYandexCloudMigrationPending` alert fires and a Deckhouse Platform update can be blocked.
>
> For instructions, see "How to migrate a cloud provider to ModuleConfig-based configuration?".
>
> If the module settings had the `storageClass.default` parameter, set the default StorageClass with the global `defaultClusterStorageClass` parameter after the migration. The conversion does not carry this value over.

Configuration example

Below is a minimal configuration of a cluster with the Standard layout, one master node, and one group of worker nodes:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        cloudID: <CLOUD_ID>
        folderID: <FOLDER_ID>
```

```
    nodes:
      parameters:
        layout: Standard
        nodeNetworkCIDR: 10.241.32.0/20
        sshPublicKey: <SSH_PUBLIC_KEY>
        labels:
          billing: prod
---
apiVersion: deckhouse.io/v1
kind: YandexInstanceClass
metadata:
  name: master
spec:
  cores: 4
  memory: 8192
  imageID: <IMAGE_ID>
  etcdDiskSizeGB: 10
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: master
spec:
  nodeType: CloudPermanent
  cloudInstances:
    classReference:
      kind: YandexInstanceClass
      name: master
    minPerZone: 1
    maxPerZone: 1
---
apiVersion: deckhouse.io/v1
kind: YandexInstanceClass
metadata:
  name: worker
spec:
  cores: 4
  memory: 8192
  coreFraction: 50
  imageID: <IMAGE_ID>
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: YandexInstanceClass
      name: worker
    minPerZone: 1
    maxPerZone: 3
    zones:
      - ru-central1-a
```

Where:

- `CLOUD_ID` and `FOLDER_ID` are the Yandex Cloud cloud and folder identifiers, specified by the `cloudID` and `folderID` parameters in the `provider.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module. For instructions on obtaining these identifiers, see “Connecting and authorizing in Yandex Cloud”.
- `SSH_PUBLIC_KEY` is the public SSH key used to access nodes, specified by the `sshPublicKey`

parameter in the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module.
- `IMAGE ID` is the operating system image ID used to create virtual machines, specified by the `imageID` parameter of the YandexInstanceClass resource. If the parameter is not set, the image of the `master` node group instance class is used.

The YandexInstanceClass resource for the `master` node group must specify the `etcdDiskSizeGB` parameter, which defines the size of a separate disk for etcd. This parameter must not be specified for other node groups.

The rest of the parameters are described in the module settings and in the YandexInstanceClass resource description.

The service account key is not stored in ModuleConfig. It is defined in a separate Secret.

Network parameters and security

This section describes the settings related to addressing, routing, external traffic, and network security in a DP cluster deployed in Yandex Cloud.

Internal node addressing

The `nodeNetworkCIDR` parameter defines the IP address range that is split between availability zones and applied to the internal node interfaces. The parameter belongs to the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  settings:
    nodes:
      parameters:
        nodeNetworkCIDR: 192.168.12.0/24
```

Deckhouse Platform divides `nodeNetworkCIDR` into four equal parts and creates internal subnets for nodes in the corresponding availability zones. Each default zone has a fixed part of the range:

Zone	Part of the range
`ru-central1-a`	First
`ru-central1-b`	Second
`ru-central1-e`	Third
`ru-central1-d`	Fourth

You can list up to four zones in `zones`. If the parameter is not set, Deckhouse Platform uses all four zones in the table.

Instructions for using the `ru-central1-f` zone are provided in “Using the ru-central1-f zone”.

Nodes connect to the subnet in their zone. The range is divided this way in every layout. If `existingZoneToSubnetIDMap` is set, Deckhouse Platform uses the mapped subnets without creating new ones.

> **i** A subnet accepts only one route table, so two clusters with the `cni-simple-bridge` module cannot use the same subnets. To deploy such clusters in shared subnets, use the `cni-cilium` module.

Assigning external IP addresses and outgoing traffic

The `externalSubnetIDs` parameter belongs to the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module and is set per node group:

- the key is the node group name;

- the value is the list of Yandex Cloud subnet IDs that the external network interfaces of that group's nodes are attached to, in the order of the zones.

The parameter is required when you need to:

- assign a public IP address;
- define a default route for outgoing traffic from nodes;
- use the `Auto` value in the `externalIPAddresses` parameter.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  settings:
    nodes:
      parameters:
        externalSubnetIDs:
          worker:
            - <RU_CENTRAL1_A_SUBNET_ID>
            - <RU_CENTRAL1_B_SUBNET_ID>
            - <RU_CENTRAL1_D_SUBNET_ID>
```

The `externalIPAddresses` parameter in the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module specifies a list of external IP addresses for each node group in the order of their availability zones.

DNS and DHCP settings for internal networks

The `dhcpOptions` parameter sets the DHCP server configuration applied to all subnets created within the DP cluster in Yandex Cloud. The parameter belongs to the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module.

Available fields:

- `domainName`: The search domain set in the network configuration.
- `domainNameServers`: An array of IP addresses of DNS servers used as recursive resolvers.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  settings:
    nodes:
      parameters:
        dhcpOptions:
          domainName: test.local
          domainNameServers:
            - 192.168.0.2
            - 192.168.0.3
```

i The DNS servers listed in `domainNameServers` must resolve both external and internal domain zones used by the cluster. Otherwise, service disruptions may occur.

After updating `dhcpOptions`:

- force renew the DHCP lease on all VMs;
- restart the components running in the node network (`hostNetwork: true`), including `kube-dns`,

to refresh the `resolv.conf` contents.

You can apply changes using the following command:

```
netplan apply
```

or another method used in your system, for example `systemd-networkd` or `dhclient`.

Using pre-existing subnets

The `existingZoneToSubnetIDMap` parameter maps availability zones to pre-created subnets in Yandex Cloud. Set it when DP has to use existing subnets instead of creating new ones. The parameter belongs to the `nodes.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  settings:
    nodes:
      parameters:
        existingZoneToSubnetIDMap:
          ru-central1-a: e2lu8r1tbbtryhdpa9ro
          ru-central1-b: e2lu8r1tbbtryhdpa9ro
          ru-central1-d: e2lu8r1tbbtryhdpa9ro
```

i DP creates a route table but does not associate it with the subnets. Associate the table manually in the Yandex Cloud interface.

Additional external networks

The `additionalExternalNetworkIDs` parameter defines a list of additional external networks whose addresses DP treats as public. The parameter belongs to the `ccm.parameters` section of the ModuleConfig resource of the `cloud-provider-yandex` module.

This is useful when:

- There are external subnets not listed in `externalSubnetIDs` but that should be treated as external.
- You need precise control over how IP addresses are interpreted for load balancing, routing, and status export.
- You use custom network configurations (for example, external NAT gateways or manually reserved IPs).

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  enabled: true
  settings:
    ccm:
      parameters:
        additionalExternalNetworkIDs:
          - enp6t4sno
```

If this parameter is not set, DP will only use the subnets explicitly specified in the module settings (for example, via `externalSubnetIDs`) to determine whether an IP is public.

Configuring security groups in Yandex Cloud

For every cloud network, Yandex Cloud creates a default security group, including for the cluster network. That group allows any inbound and outbound traffic and applies to the virtual machine network interfaces that are not assigned another group.

You can restrict the cluster traffic with the rules of that group. Assigning another security group to the nodes is not possible, as neither the module settings nor the YandexInstanceClass resource have parameters for that.

⚠ Do not assign security groups to the nodes manually in the Yandex Cloud console. The `dhctl converge` command brings the virtual machines to the state described in the cluster configuration and may remove such an assignment.

✖ Do not delete the rules that allow any traffic until you have configured the other rules of the group. Otherwise, the group blocks the traffic between the nodes and the cluster components lose connection to each other.

Errors in the rules disrupt the cluster. Before configuring the rules in a production cluster, consult the security group usage details in Yandex Cloud.

If the cluster uses Cilium with pod traffic tunneling over VXLAN, allow UDP traffic between nodes on the ports listed in “Network interaction of the platform components”.

To configure the rules of the security group:

1. Identify the cloud network used by the DP cluster.

   The network name matches the `prefix` parameter of the ModuleConfig `global`. You can retrieve it using the following command:

   ```
   d8 k get mc global -o jsonpath='{.spec.settings.prefix}{"\n"}'
   ```

   If the value is empty, get it from the deprecated `cloud.prefix` parameter of ClusterConfiguration (the prefix has moved to the ModuleConfig `global`):

   ```
   d8 k get secrets -n kube-system d8-cluster-configuration -ojson | \
     jq -r '.data."cluster-configuration.yaml"' | base64 -d | grep prefix | cut -d: -f2
   ```

2. In the Yandex Cloud Console, go to the Virtual Private Cloud service and open the “Security Groups” section. You should see a security group marked `Default`.

3. Create rules according to the Yandex Cloud instructions.

4. Delete the rule that allows all **inbound** traffic (it is already deleted in the screenshot above) and save your changes.

Configuring access via bastion host

To connect to nodes located in private subnets (for example, when using the Standard or WithNATInstance layout), you can use a bastion host, an intermediary VM with a public IP address that provides SSH access to the nodes.

To configure access, follow these steps:

1. Bootstrap the base infrastructure. Before creating a bastion host, perform the initial installation phase of DP, which sets up the network infrastructure:

   ```
   dhctl bootstrap-phase base-infra --config config.yml
   ```

2. Create a bastion host in Yandex Cloud:

   ```
   yc compute instance create \
     --name bastion \
     --hostname bastion \
     --create-boot-disk image-family=ubuntu-2204-lts,image-folder-id=standard-
   images,size=20,type=network-hdd \
     --memory 2 \
     --cores 2 \
     --core-fraction 100 \
     --ssh-key ~/.ssh/<SSH_PUBLIC_KEY_FILE> \
     --zone ru-central1-a \
     --public-address 178.154.226.159
   ```

   Replace `<SSH_PUBLIC_KEY_FILE>` with the name of the public key, for example `id_rsa.pub` for

an RSA key or `id_ed25519.pub` for an ED25519 key.

Ensure the IP address specified in `--public-address` is accessible from your network and is correct.

3. Start the main DP bootstrap through the bastion host:

```
dhctl bootstrap --ssh-bastion-host=178.154.226.159 --ssh-bastion-user=yc-user \
  --ssh-user=ubuntu --ssh-agent-private-keys=/tmp/.ssh/<SSH_PRIVATE_KEY_FILE> --
config=/config.yml
```

Replace `<SSH PRIVATE KEY_FILE>` with the name of the private key, for example `id_rsa` for an RSA key or `id_ed25519` for an ED25519 key.

Where:

- `--ssh-bastion-user`: User for connecting to the bastion host.
- `--ssh-user`: User on the target cluster nodes.
- `--ssh-agent-private-keys`: Path to the private SSH key.
- `--config`: Path to the DP configuration file.

Replacing the OS image

The `imageID` parameter of YandexInstanceClass defines the image for `CloudEphemeral` nodes. With a ModuleConfig-based provider configuration, this parameter also defines the image for `CloudPermanent` nodes and master nodes.

With a YandexClusterConfiguration-based configuration, the image for `CloudPermanent` nodes and master nodes is set by `imageID` in `nodeGroups[].instanceClass` and `masterNodeGroup.instanceClass`, respectively.

The replacement procedure is described in “How do I replace the OS image in a cloud cluster?” .

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage and load balancing in Yandex Cloud

This section covers additional aspects of Deckhouse Platform (DP) integration with Yandex Cloud:

- Attaching cloud disks via CSI.
- Automatic StorageClass creation.
- Use of load balancers.
- Specifics of applying changes.
- Working with CloudStatic nodes and bastion hosts.

Storage (CSI and StorageClass)

DP integrates with Yandex Cloud block storage via the Container Storage Interface (CSI) component. This allows DP clusters to automatically provision and attach disks and use standard Kubernetes PersistentVolumeClaim resources for working with the storage.

DP automatically creates StorageClass resources for all supported Yandex Cloud disk types, enabling immediate storage usage without the need to define classes manually.

The following disk types are supported:

Disk type	StorageClass name	Notes
`network-hdd`	`network-hdd`	—
`network-ssd`	`network-ssd`	—
`network-ssd-nonreplicated`	`network-ssd-nonreplicated`	Size must be a multiple of 93 GB
`network-ssd-io-m3`	`network-ssd-io-m3`	Size must be a multiple of 93 GB

i The sizes of `network-ssd-nonreplicated` and `network-ssd-io-m3` disks must be multiples of 93 GB. Otherwise, volume provisioning will fail.

Excluding unnecessary StorageClasses

If certain disk types won't be used in the cluster, you can disable automatic creation of the corresponding StorageClass objects using the `settings.storage.parameters.excludedStorageClasses` parameter in the ModuleConfig resource:

```
settings:
  storage:
    parameters:
      excludedStorageClasses:
        - network-ssd-.*
        - network-hdd
```

In this example, DP will not create StorageClass resources for any `network-ssd` or `network-hdd` disks.

Creating additional StorageClasses and block size

The `settings.storage.parameters.provisionedStorageClasses` parameter lets you create additional StorageClasses or override the parameters of StorageClasses created by DP by default.

Use the `blockSize` parameter to set the block size for provisioned disks. The block size determines the maximum disk size. It is `8Ti` for `4Ki` and doubles with each next block size, up to `256Ti` for `128Ki`.

Example configuration of the `cloud-provider-yandex` module with an additional StorageClass configured with a block size of `64Ki`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-yandex
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        cloudID: <CLOUD_ID>
        folderID: <FOLDER_ID>
    nodes:
      parameters:
        layout: Standard
        nodeNetworkCIDR: 192.168.12.0/24
        sshPublicKey: <SSH_PUBLIC_KEY>
    storage:
      parameters:
        provisionedStorageClasses:
          - name: network-ssd-64k
            type: network-ssd
            blockSize: 64Ki
```

⚠ After a disk is created, its block size cannot be changed. Changing the `blockSize` parameter recreates the StorageClass, but does not change the block size of previously provisioned volumes.

Setting the default StorageClass

By default, DP determines the StorageClass using the `storageclass.kubernetes.io/is-default-class=true` annotation.

To explicitly set a different default StorageClass, use the global DP parameter `global.defaultClusterStorageClass`. You can modify it with the following command:

```
kubectl edit mc global
```

If `defaultClusterStorageClass` is not specified, DP determines the default StorageClass in the following order:

- A StorageClass with the annotation `storageclass.kubernetes.io/is-default-class='true'` (if it exists in the cluster).
- The first StorageClass in alphabetical order auto-created by the cloud provider.
- The default value of `defaultClusterStorageClass` is an empty string (`""`).

Resizing a PVC

You can increase the size of an existing PVC by changing the value of the `spec.resources.requests.storage` parameter, without stopping or recreating the pod that uses it.

After the value of `spec.resources.requests.storage` is changed, the CSI driver performs the following operations:

- increases the size of the disk in Yandex Cloud;
- updates the size of the associated PersistentVolume;
- expands the file system on the node to which the volume is attached.

During the operation, the pod continues running, and the mounted volume remains available to the application. After the resize operation is complete, the new file system size becomes available inside the container without restarting the pod.

ℹ Decreasing the size of a PVC is not supported.

To increase the size of a PVC, follow these steps:

1. Get the name of the StorageClass used by the PVC:

   ```
   d8 k -n <NAMESPACE> get pvc <PVC_NAME> \
     -o jsonpath='{.spec.storageClassName}{"\n"}'
   ```

   Where:

   - `<NAMESPACE>` — the namespace containing the PVC;
   - `<PVC_NAME>` — the name of the PVC to resize.

   For example:

   ```
   d8 k -n production get pvc application-data \
     -o jsonpath='{.spec.storageClassName}{"\n"}'
   ```

   Example output:

   ```
   network-ssd
   ```

   In this example, the `application-data` PVC uses the `network-ssd` StorageClass.

2. Make sure that the StorageClass allows volume expansion:

```
d8 k get storageclass <STORAGECLASS_NAME> \
  -o jsonpath='{.allowVolumeExpansion}{"\n"}'
```

Where `<STORAGECLASS_NAME>` is the name of the StorageClass obtained in the previous step.

For example:

```
d8 k get storageclass network-ssd \
  -o jsonpath='{.allowVolumeExpansion}{"\n"}'
```

Example output:

```
true
```

3. Check the current status and size of the PVC:

```
d8 k -n <NAMESPACE> get pvc <PVC_NAME>
```

For example:

```
d8 k -n production get pvc application-data
```

Example output:

```
NAME               STATUS   VOLUME                                     CAPACITY
ACCESS MODES   STORAGECLASS
application-data   Bound    pvc-65e92674-077c-4b4f-b65d-19e92f04e103   20Gi
RWO            network-ssd
```

Make sure that:

- the PVC is in the `Bound` state;
- the `CAPACITY` field shows the current PVC size;
- the `STORAGECLASS` field shows the StorageClass checked in the previous step.

4. Increase the PVC size:

```
d8 k -n <NAMESPACE> edit pvc <PVC_NAME>
```

For example:

```
d8 k -n production edit pvc application-data
```

Specify the new PVC size in the `spec.resources.requests.storage` field:

```
spec:
  resources:
    requests:
      storage: 30Gi
```

In this example, the PVC size is increased to `30Gi`.

Save the changes and close the editor.

> ⚠ For the `network-ssd-nonreplicated` and `network-ssd-io-m3` StorageClasses, the size must be a multiple of 93Gi.

5. Wait for the PVC resize operation to complete:

```
d8 k -n <NAMESPACE> get pvc <PVC_NAME> --watch
```

Where:

- `<NAMESPACE>` — the namespace containing the PVC;
- `<PVC_NAME>` — the name of the PVC being resized.

For example:

```
d8 k -n production get pvc application-data --watch
```

During the resize operation, the `CAPACITY` field may continue to show the previous size:

```
NAME               STATUS   VOLUME                                     CAPACITY
ACCESS MODES   STORAGECLASS
application-data   Bound    pvc-65e92674-077c-4b4f-b65d-19e92f04e103   20Gi
RWO            network-ssd
```

The operation is complete when the `CAPACITY` field shows the new PVC size:

```
NAME               STATUS   VOLUME                                     CAPACITY
ACCESS MODES   STORAGECLASS
application-data   Bound    pvc-65e92674-077c-4b4f-b65d-19e92f04e103   30Gi
RWO            network-ssd
```

6. Check the PVC events:

```
d8 k -n <NAMESPACE> describe pvc <PVC_NAME>
```

For example:

```
d8 k -n production describe pvc application-data
```

The following events may appear during the resize operation:

```
ExternalExpanding
Resizing
FileSystemResizeRequired
```

The following event indicates that the file system was successfully expanded:

```
FileSystemResizeSuccessful
```

For example:

```
Normal  FileSystemResizeSuccessful  kubelet  MountVolume.NodeExpandVolume
succeeded for volume "pvc-65e92674-077c-4b4f-b65d-19e92f04e103"
```

7. Check the file system size inside the pod:

```
d8 k -n <NAMESPACE> exec <POD_NAME> -- \
  df -hT <MOUNT_PATH>
```

Where:

- `<NAMESPACE>` — the namespace containing the pod;
- `<POD_NAME>` — the name of the pod using the PVC;
- `<MOUNT_PATH>` — the path inside the container where the PVC is mounted.

For example:

```
d8 k -n production exec application-0 -- \
  df -hT /data
```

Example output:

```
Filesystem   Type   Size    Used   Avail   Use%   Mounted on
/dev/vde     ext4   29.4G   22M    29.4G    1%    /data
```

> **i** The actual file system size may be slightly smaller than the PVC size due to file system metadata.

Load balancing

External LoadBalancer

DP automatically watches for Kubernetes Service objects of type LoadBalancer. When such a service is created, DP creates the following resources:

- **NetworkLoadBalancer**: A Yandex Cloud network load balancer.
- **TargetGroup**: A group of endpoints for traffic distribution.

These resources allow Kubernetes LoadBalancer services to receive traffic from the internet or internal networks, depending on the configuration.

For more details on the architecture, refer to the Kubernetes Cloud Controller Manager for Yandex Cloud documentation.

Internal LoadBalancer

To create an internal load balancer, you must explicitly specify the subnet where the load balancer listener should be created.

To do this, add the following annotation to the Service object:

```
metadata:
  annotations:
    yandex.cpi.flant.com/listener-subnet-id: <SUBNET_ID>
```

`SubnetID` refers to the ID of the subnet where the internal listener for the Yandex LoadBalancer will be created. This allows you to control the load balancer’s network exposure and limit it to internal addresses only.

> **i** The default behavior (external or internal LB) depends on the cluster configuration. To explicitly choose the type, use the `yandex.cpi.flant.com/loadbalancer-external` annotation.

Service annotations

Default values are configured in the cluster for placing load balancer resources (the network for the target group and the subnet for the Listener). These values are set automatically during cluster setup and can be overridden with annotations at the individual Service level.

The following annotations are supported by Yandex Cloud Controller Manager:

1. `yandex.cpi.flant.com/target-group-network-id` — specifies the NetworkID in which the target group for this Service will be created. Overrides the corresponding default value.
2. `yandex.cpi.flant.com/listener-subnet-id` — sets the SubnetID for the Listeners of the LB created for this Service. Overrides the corresponding default value.
3. `yandex.cpi.flant.com/listener-address-ipv4` — sets a predefined IPv4 address for the Listeners (supported for both internal and external LBs).
4. `yandex.cpi.flant.com/loadbalancer-external` — enables creation of an external LB for this Service (use it when you need to explicitly create an external load balancer). Overrides the default behavior.
5. `yandex.cpi.flant.com/target-group-name-prefix` — specifies the name prefix of the target group used by the LoadBalancer. The annotation on the Service identifies the target group but does not select nodes. To include nodes in the target group, set the same annotation value in `spec.nodeTemplate.annotations` in the NodeGroup. Yandex Cloud Controller Manager includes all suitable nodes carrying this annotation value, regardless of their NodeGroup. The target group name is formed as `<ANNOTATION_VALUE><YANDEX_CLOUD_CLUSTER_NAME><NETWORK_ID>`.

If separate target groups are created for the control plane or master nodes, add the label `node.kubernetes.io/exclude-from-external-load-balancers: ""` to the master nodes. This prevents the controller from automatically adding master nodes to new target groups for load balancers. If you create your own load balancer for master nodes and want YCC to also be able to place its load balancers on master nodes, pre-create a target group with a name matching the pattern `${CLUSTER-NAME}${VPC.ID}`.

Using a separate target group for a NodeGroup

By default, Yandex Cloud Controller Manager adds all suitable cluster nodes to the default target group. To assign nodes to a separate target group, use the `yandex.cpi.flant.com/target-group-name-prefix` annotation.

1. In the NodeGroup whose nodes should be included in a separate target group, specify the `yandex.cpi.flant.com/target-group-name-prefix` annotation in the `spec.nodeTemplate.annotations` parameter. For example:

   ```
   spec:
     nodeTemplate:
       annotations:
         yandex.cpi.flant.com/target-group-name-prefix: frontend-
   ```

   The annotation is propagated to the Node objects. Yandex Cloud Controller Manager adds all suitable nodes carrying the same annotation value to the target group, regardless of their NodeGroup.

2. In the Service object of the LoadBalancer type, specify the same annotation with the same value. For example:

   ```
   metadata:
     annotations:
       yandex.cpi.flant.com/target-group-name-prefix: frontend-
   ```

   The annotation on the Service identifies the target group used by the LoadBalancer but does not select nodes.

3. Make sure that the values of `yandex.cpi.flant.com/target-group-name-prefix` in the NodeGroup and Service match. In the example above, both resources use the `frontend-` value.

4. The target group will be created with a name generated according to the following pattern:

   ```
   <ANNOTATION_VALUE><YANDEX_CLOUD_CLUSTER_NAME><NETWORK_ID>
   ```

   For example, if the annotation value is `frontend-`, the cluster name is `my-cluster-`, and the network ID is `enp123456789`, the target group name will be:

   ```
   frontend-my-cluster-enp123456789
   ```

Configuration example:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: frontend
spec:
  nodeType: CloudEphemeral
  nodeTemplate:
    annotations:
      yandex.cpi.flant.com/target-group-name-prefix: frontend-
---
apiVersion: v1
kind: Service
metadata:
  name: nginx-frontend
  annotations:
    yandex.cpi.flant.com/target-group-name-prefix: frontend-
spec:
  type: LoadBalancer
```

⚠ Yandex Cloud does not allow a single target, identified by the (`SubnetID, IP`) pair, to belong to multiple target groups at the same time.

When the target group is changed, Yandex Cloud Controller Manager first removes the target from the current group and then adds it to the new one. This transition may cause a brief interruption in traffic handling.

Nodes with a dedicated target group prefix are excluded from the default target group. As a result, load balancers that use the default target group stop routing traffic to those nodes.

This automatic transition is performed only between target groups managed by Yandex Cloud Controller Manager. If a target already belongs to another target group that is not managed by Yandex Cloud Controller Manager, remove it from that group before using the annotation.

After the prefix is changed or removed, the previous target group may remain empty. If it is no longer used by any load balancers, delete it manually.

Target group health checks

Health check parameters (for LB target groups created by the controller):

1. `yandex.cpi.flant.com/healthcheck-interval-seconds` — how often to run the check, in seconds (default: 2).
2. `yandex.cpi.flant.com/healthcheck-timeout-seconds` — how long to wait for an endpoint response, in seconds. If no response is received within this time, the check is considered failed (default: 1).
3. `yandex.cpi.flant.com/healthcheck-unhealthy-threshold` — how many consecutive failed checks are required to mark an endpoint as unhealthy and exclude it from load balancing (default: 2).
4. `yandex.cpi.flant.com/healthcheck-healthy-threshold` — how many consecutive successful checks are required to return an endpoint to healthy status and include it back in load balancing (default: 2).

Applying changes

DP does not recreate existing Machine objects when configuration parameters change. Node recreation occurs only when:

- NodeGroup section parameters change.
- YandexInstanceClass parameters change.

This behavior helps prevent unnecessary operations and node idling, but it means you must manually recreate VMs if needed.

If you change the provider settings in the `cloud-provider-yandex` ModuleConfig (for example, the provider parameters, the layout, or the subnets), run the following command to apply the changes:

```
dhctl converge
```

This command reconciles the cluster state with the configuration defined in the resources.

Changing `networkType` does not recreate CloudEphemeral nodes

In clusters that use Machine Controller Manager (MCM), changing the `networkType` parameter in a YandexInstanceClass resource does not trigger automatic recreation of existing CloudEphemeral nodes. Although the MachineClass is updated, the network acceleration type of existing virtual machines in Yandex Cloud remains unchanged.

DP intentionally does not take the `networkType` parameter into account when determining whether CloudEphemeral nodes should be recreated in MCM. If it did, updating DP would recreate CloudEphemeral nodes in all clusters where `networkType` is specified, even if its value had not changed.

In Cluster API, the `networkType` parameter is taken into account when determining whether nodes should be recreated, so changing it automatically triggers node recreation. New CloudEphemeral NodeGroups in Yandex Cloud use Cluster API by default.

If you changed `networkType` in an MCM-based cluster and want the new value to apply to existing CloudEphemeral nodes, recreate them manually — instructions in the documentation.

Integrating manually created VMs

DP allows you to connect existing VMs in Yandex Cloud to the Kubernetes cluster as nodes. These nodes are called CloudStatic and they are not directly managed by the `node-manager` module but can still be used in the cluster.

To manually connect a VM as a CloudStatic node, follow these steps:

1. Retrieve the current `nodeNetworkCIDR` value from the cluster:

   ```
   d8 k get mc cloud-provider-yandex -o
   jsonpath='{.spec.settings.nodes.parameters.nodeNetworkCIDR}{"\n"}'
   ```

   Expected output:

   ```
   192.168.12.0/24
   ```

   Copy this value and use it in the VM metadata as `value`.

2. Set the `node-network-cidr` parameter in the VM metadata:

   ```
   key: node-network-cidr
   value: <NODE_NETWORK_CIDR>
   ```

   The `node-network-cidr` parameter must match the value of the `nodeNetworkCIDR` parameter in the ModuleConfig.

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with Yandex Cloud services

Deckhouse Platform (DP) supports native integration with several Yandex Cloud services. This allows for external monitoring, secure secret management, and automated data synchronization between the infrastructure and the cluster.

This section describes steps to configure the following integrations:

- Yandex Lockbox via External Secrets Operator
- Yandex Managed Service for Prometheus

Integration with Yandex Lockbox

DP supports integration with Yandex Lockbox using the External Secrets Operator (ESO). This allows Kubernetes secrets in the cluster to be automatically synchronized with Lockbox secrets.

To set up the integration:

1. Create a service account for External Secrets Operator:

   ```
   yc iam service-account create --name eso-service-account
   ```

2. Create an authorized key for the service account and save it to a file:

   ```
   yc iam key create --service-account-name eso-service-account --output authorized-key.json
   ```

3. Assign `lockbox.editor`, `lockbox.payloadViewer`, and `kms.keys.encrypterDecrypter` roles to the service account for accessing all secrets in the folder:

   ```
   folder_id=<folderID>
   yc resource-manager folder add-access-binding --id=${folder_id} --service-account-name
   eso-service-account --role lockbox.editor
   yc resource-manager folder add-access-binding --id=${folder_id} --service-account-name
   eso-service-account --role lockbox.payloadViewer
   yc resource-manager folder add-access-binding --id=${folder_id} --service-account-name
   eso-service-account --role kms.keys.encrypterDecrypter
   ```

   For fine-grained access control, refer to the Yandex Lockbox access documentation.

4. Install External Secrets Operator using the Helm chart as described in this guide.

   Note that you may need to specify additional parameters such as `nodeSelector`, `tolerations`, etc. To do this, use the `./external-secrets/values.yaml` file after extracting the Helm chart.

   Download and extract the chart using the following command:

   ```
   helm pull oci://cr.yandex/yc-marketplace/yandex-cloud/external-secrets/chart/external-secrets \
     --version 0.5.5 \
     --untar
   ```

   Install the chart:

   ```
   helm install -n external-secrets --create-namespace \
     --set-file auth.json=authorized-key.json \
     external-secrets ./external-secrets/
   ```

   Where:

   - `authorized-key.json`: The file created in step 2.

5. Create a SecretStore resource containing the `sa-creds` secret:

```
kubectl -n external-secrets apply -f - <<EOF

apiVersion: external-secrets.io/v1alpha1
kind: SecretStore
metadata:
  name: secret-store
spec:
  provider:
    yandexlockbox:
      auth:
        authorizedKeySecretRef:
          name: sa-creds
          key: key
EOF
```

Where:

- `sa-creds`: Name of the Secret containing the authorized key. The secret appears after the Helm chart is installed.
- `key`: Name of the key in the `.data` field of the secret.

6. Verify that External Secrets Operator is working:

   ```
   kubectl -n external-secrets get po
   ```

   Example output:

   ```
   NAME                                                READY   STATUS    RESTARTS
   AGE
   external-secrets-55f78c44cf-dbf6q                   1/1     Running   0
   77m
   external-secrets-cert-controller-78cbc7d9c8-rszhx   1/1     Running   0
   77m
   external-secrets-webhook-6d7b66758-s7v9c            1/1     Running   0
   77m
   ```

   Check the SecretStore status as well:

   ```
   kubectl -n external-secrets get secretstores.external-secrets.io
   ```

   Example output:

   ```
   NAME           AGE   STATUS
   secret-store   69m   Valid
   ```

7. Create a secret in Yandex Lockbox with the following parameters:

   - Name: `lockbox-secret`.
   - Key: Enter non-confidential ID `password`.
   - Value: Enter confidential data for storing `p@$$w0rd`.

8. Create an ExternalSecret pointing to the `lockbox-secret` in the `secret-store`:

```
kubectl -n external-secrets apply -f - <<EOF

apiVersion: external-secrets.io/v1alpha1
kind: ExternalSecret
metadata:
  name: external-secret
spec:
  refreshInterval: 1h
  secretStoreRef:
    name: secret-store
    kind: SecretStore
  target:
    name: k8s-secret
  data:
  - secretKey: password
    remoteRef:
      key: <SECRET_ID>
      property: password
EOF
```

Where:

- `target.name`: Name of the new secret. External Secret Operator will create this secret in the DP cluster and put the `lockbox-secret` Yandex Lockbox secret parameters into it.
- `data[].secretKey`: Name of the key in the `.data` field of the secret created by External Secret Operator.
- `data[].remoteRef.key`: ID of the `lockbox-secret` Yandex Lockbox secret created earlier (for example, `e6q28nvfmhu539******`).
- `data[].remoteRef.property`: Key for the `lockbox-secret` Yandex Lockbox secret.

9. Verify that the new `k8s-secret` key contains the `lockbox-secret` secret value:

```
kubectl -n external-secrets get secret k8s-secret -ojson | jq -r '.data.password' | base64 -d
```

The output will contain the `password` key value of the `lockbox-secret` secret created earlier:

```
p@$$w0rd
```

Integration with Yandex Managed Service for Prometheus

This integration lets you use Yandex Managed Service for Prometheus as an external storage for metrics (for example, for long-term retention).

To configure PrometheusRemoteWrite, follow these steps:

1. Create a service account with the `monitoring.editor` role.
2. Create an API key for the service account.
3. Create a PrometheusRemoteWrite resource:

```
kubectl apply -f - <<EOF

apiVersion: deckhouse.io/v1
kind: PrometheusRemoteWrite
metadata:
  name: yc-remote-write
spec:
  url: <REMOTE_WRITE_URL>
  bearerToken: <API_KEY>
EOF
```

Where:

- `<REMOTE_WRITE_URL>`: URL from the **Yandex Monitoring** -> **Prometheus** -> **Remote write** page.
- `<API KEY>`: API key from the previous step (for example, `AQVN1HHJReSrfo9jU3aopsXrJyfq_UHs********`).

You can specify additional parameters as described in the `prometheus` module documentation.

For more details on writing metrics, refer to the Yandex Cloud documentation.

To read metrics in Grafana:

1. Create a service account with the `monitoring.viewer` role.
2. Create an API key for the service account.
3. Create a GrafanaAdditionalDatasource resource:

```
apiVersion: deckhouse.io/v1
kind: GrafanaAdditionalDatasource
metadata:
  name: managed-prometheus
spec:
  type: prometheus
  access: Proxy
  url: <GRAFANA_READ_URL>
  basicAuth: false
  jsonData:
    timeInterval: 30s
    httpMethod: POST
    httpHeaderName1: Authorization
  secureJsonData:
    httpHeaderValue1: Bearer <API_KEY>
```

Where:

- `<GRAFANA_READ_URL>`: URL from the **Yandex Monitoring** -> **Prometheus** -> **Reading Grafana metrics** page.
- `<API KEY>`: API key from the previous step (for example, `AQVN1HHJReSrfo9jU3aopsXrJyfq_UHs********`).

You can specify additional parameters as described in the `prometheus` module documentation.

For more details on reading metrics with Grafana, refer to the Yandex Cloud documentation.

Additional resources

- Module `prometheus` custom resources

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in VK Cloud

To manage resources in VK Cloud using Deckhouse Platform, you must connect to the VK Cloud API.

The list of VK Cloud API services required for deployment is available in the Configuration section.

The user credentials required to access the VK Cloud API are provided in the OpenStack RC file (openrc file).

Instructions for downloading the openrc file via the standard web interface of VK Cloud and using it are available in the VK Cloud documentation.

If you’re using a cloud provider’s implementation of the VK Cloud API, the process for obtaining the openrc file may differ.

⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

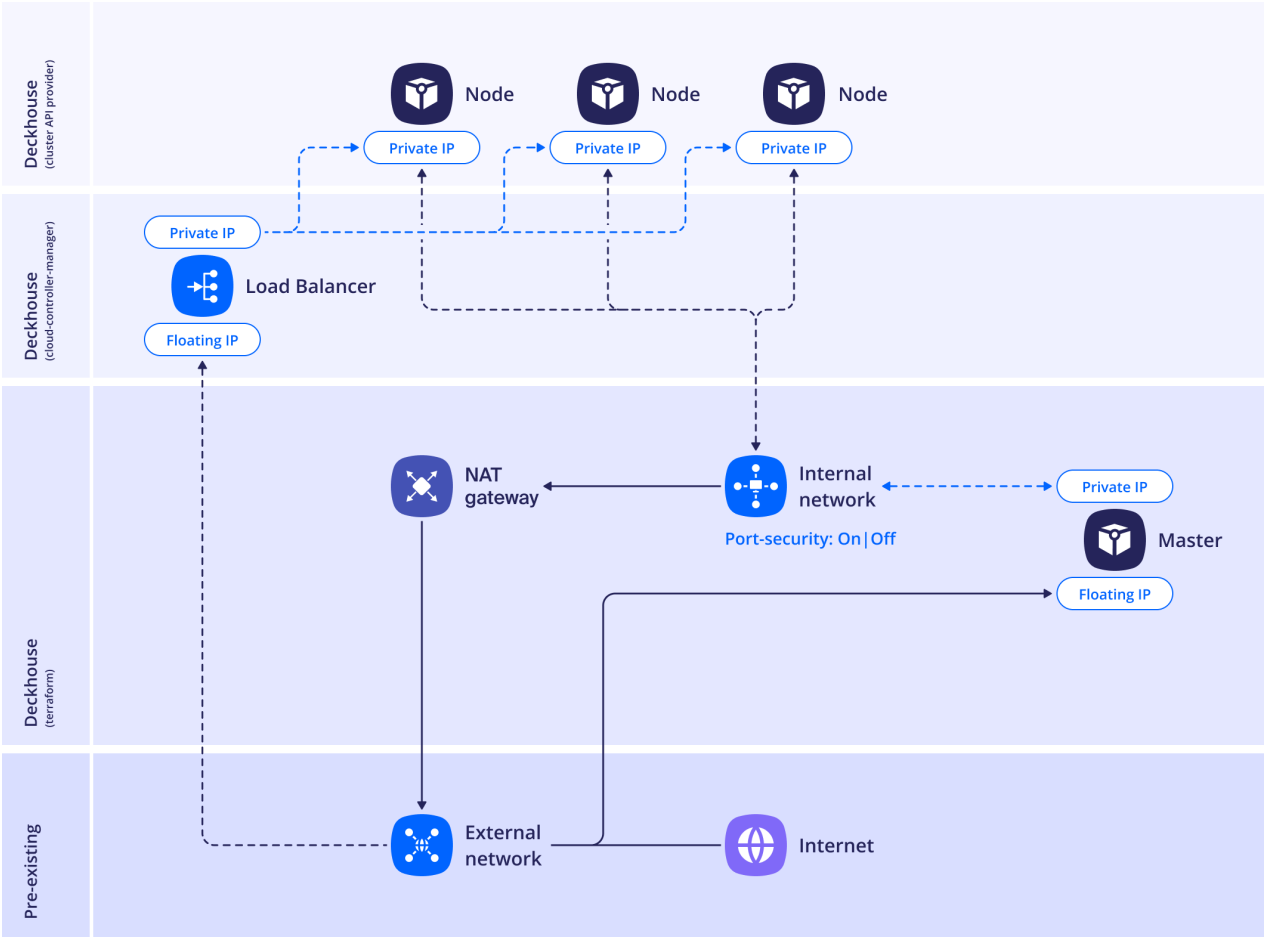
Layouts and configuration in VK Cloud

List of required OpenStack services

The following VK Cloud services must be available for Deckhouse Platform (DP) to operate:

Service	API Version
Identity (Keystone)	v3
Compute (Nova)	v2.1
Network (Neutron)	v2.0
Block Storage (Cinder)	v3
Load Balancing (Octavia) *	v2

* If you need to order a Load Balancer.



API endpoints and ports are listed in the official documentation.

Layouts

This section describes the possible node placement layouts in VK Cloud infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

In this scheme, an internal cluster network is created with a gateway to the public network; the nodes do not have public IP addresses. The floating IP is assigned to the master node.

If the provider does not support SecurityGroups, all applications running on nodes with Floating IPs assigned will be available at a public IP. For example, `kube-apiserver` on master nodes will be available on port `6443`. To avoid this, we recommend using the SimpleWithInternalNetwork or Standard layout with a bastion host.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

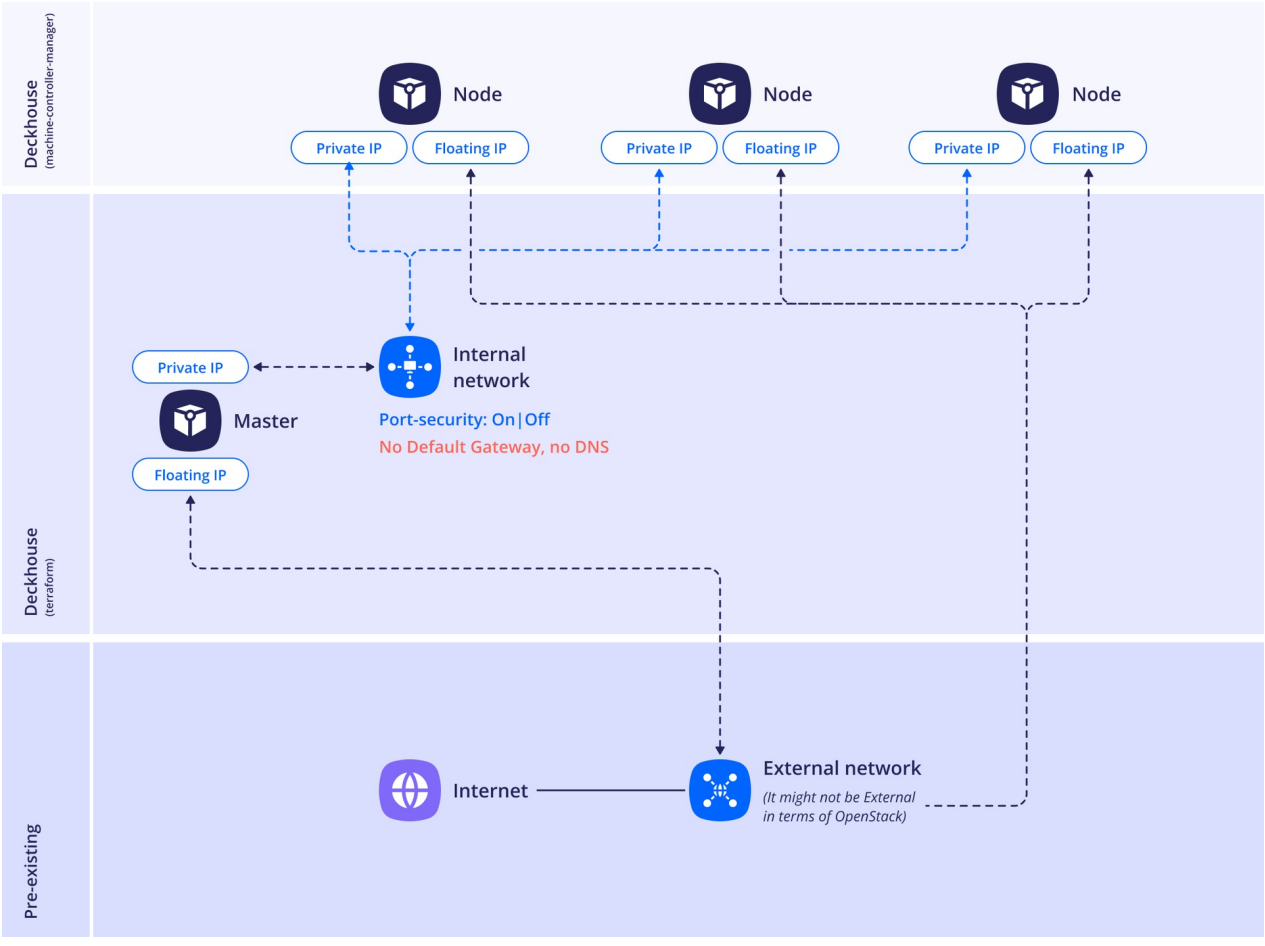
- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Standard
standard:
  internalNetworkCIDR: 192.168.199.0/24       # Required.
  internalNetworkDNSServers:                 # Required.
  - 8.8.8.8
  - 4.2.2.2
  internalNetworkSecurity: true|false         # Optional, true by default.
  externalNetworkName: shared                # Required.
  bastion:
    zone: ru2-b                             # Optional.
    volumeType: fast-ru-2b                   # Optional.
    instanceClass:
      flavorName: m1.large                   # Required.
      imageName: ubuntu-20-04-cloud-amd64      # Required.
      rootDiskSize: 50                      # Optional, 50 GB by default.
      additionalTags:
        severity: critical                   # Optional.
        environment: production              # Optional.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
    additionalTags:
      severity: critical
      environment: production
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    ru-1a: fast-ru-1a
    ru-1b: fast-ru-1b
    ru-1c: fast-ru-1c
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default. Determines if configuration drive is
    # required during vm bootstrap process. It's needed if there
    # is no DHCP in the network that is used as a default gateway.
    configDrive: false
    # Required, the gateway of this network will be used as the default gateway.
```



```
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                   # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  zones:
  - ru-1a
  - ru-1b
sshPublicKey: "<SSH_PUBLIC_KEY>"
tags:
  project: cms
  owner: default
provider:
  ...
```

StandardWithNoRouter

An internal cluster network is created that does not have access to the public network. All nodes (including master ones) have two interfaces: the first one to the public network, the second one to the internal network. This layout should be used if you want all nodes in the cluster to be directly accessible.

⚠

- This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.
- Using this strategy, make sure to explicitly specify the name of the internal network in `additionalNetworks` when creating an OpenStackInstanceClass in the cluster.

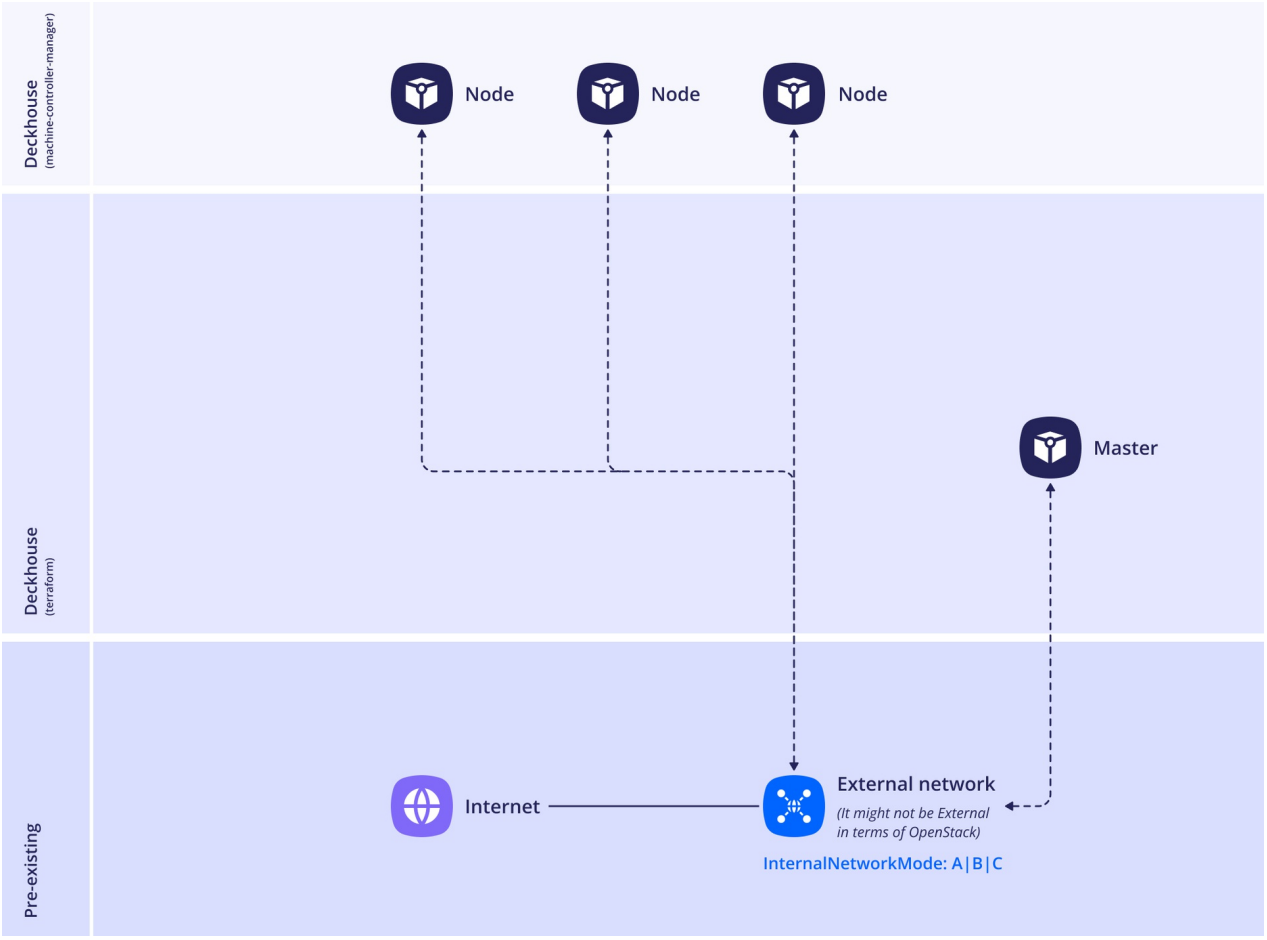
The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.



Example layout configuration:

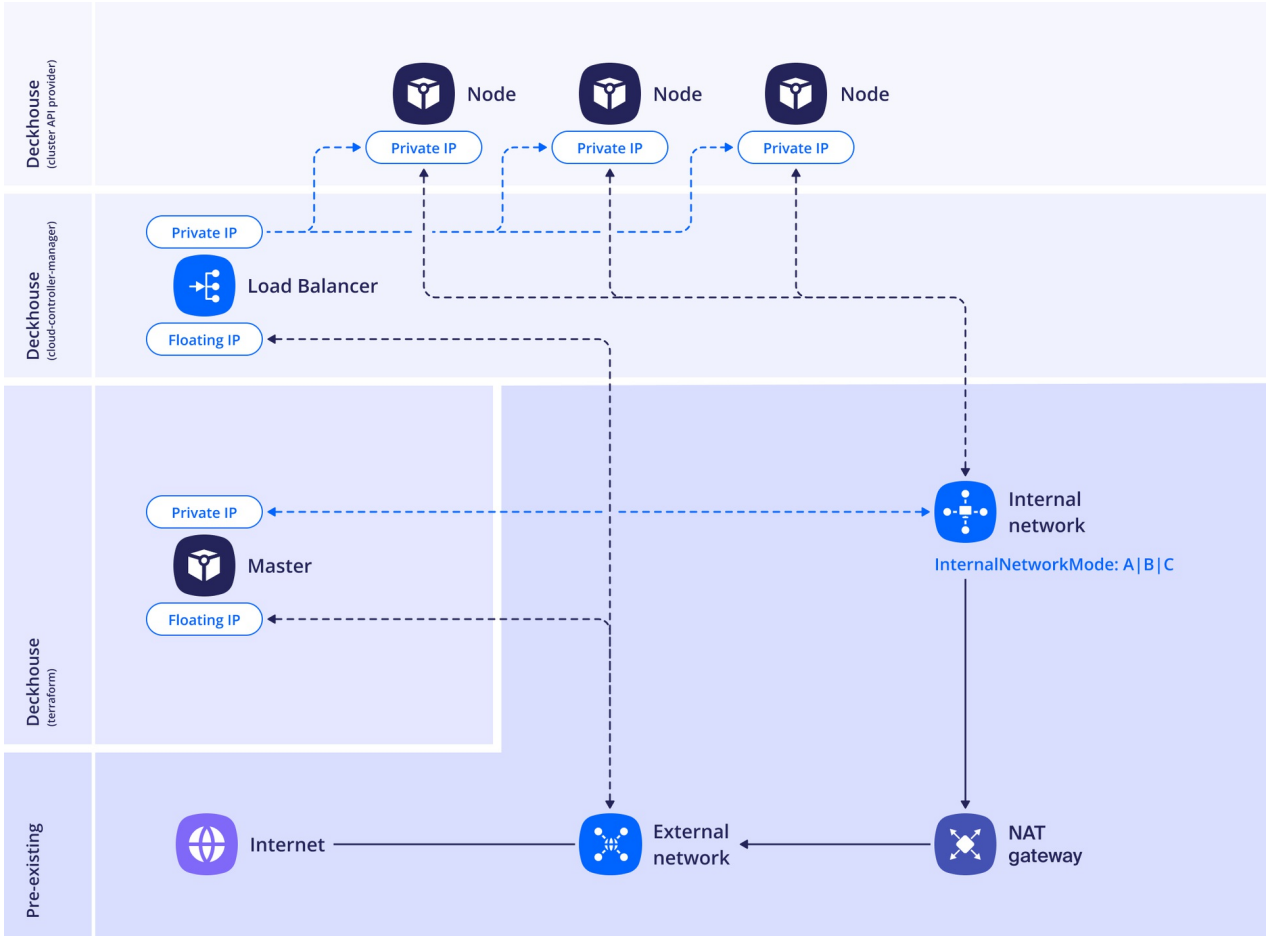
```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: StandardWithNoRouter
standardWithNoRouter:
  internalNetworkCIDR: 192.168.199.0/24        # Required.
  externalNetworkName: ext-net                # Required.
  # Optional, defines whether DHCP is enabled in specified external
  # network (true by default).
  externalNetworkDHCP: false
  internalNetworkSecurity: true|false          # Optional, true by default.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the gateway of the network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                      # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required if rootDiskSize is specified. Volume type map for node's root volume.
  volumeTypeMap:
    nova: ceph-ssd
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Simple

The master node and cluster nodes are connected to the existing network. This placement strategy can be useful if you need to merge a Kubernetes cluster with existing VMs.

⚠ This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:



- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Simple
simple:
  externalNetworkName: ext-net              # Required.
  externalNetworkDHCP: false                # Optional, true by default.
  # Optional, VXLAN by default, may also be DirectRouting
  # or DirectRoutingWithPortSecurityEnabled.
  podNetworkMode: VXLAN
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

SimpleWithInternalNetwork

The master node and cluster nodes are connected to the existing network. This layout can be useful if you need to merge a Kubernetes cluster with existing VMs.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: SimpleWithInternalNetwork
simpleWithInternalNetwork:
  # All cluster nodes have to be in the same subnet. Set either the subnet name
  # in internalSubnetName or its UUID in internalSubnetID.
  internalSubnetName: pivot-standard
  # Optional, DirectRoutingWithPortSecurityEnabled by default,
  # may also be DirectRouting or VXLAN.
  podNetworkMode: DirectRoutingWithPortSecurityEnabled
  # Optional. If set, it will be used for the load balancer default
  # configuration and ordering the master floating IP.
  externalNetworkName: ext-net
  # Optional, true by default.
  masterWithExternalFloatingIP: false
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Configuration

Integration with VK Cloud is performed using the OpenStackClusterConfiguration resource. It defines the configuration of the cloud cluster in VK Cloud and is used by the cloud provider when the cluster control plane is hosted in the cloud. The DP module responsible for the integration is automatically configured based on the selected layout.

To modify the configuration in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After changing node-related parameters, run the `dhctl converge` command to apply the changes.

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the VK Cloud cloud provider, the instance class is a custom resource called OpenStackInstanceClass, which contains the specific configuration of the VMs.

> **i** An OpenStack cluster is deployed in a single region (`provider.region`). Zones from other regions cannot be used. For details on configuring zones for CloudPermanent and CloudEphemeral nodes, see How do I create NodeGroups in availability zones? section.

If the instance class of the group sets the `rootDiskSize` parameter, the root disk is created in Cinder. In clouds where volume types are bound to availability zones, set the volume type for each zone in the `volumeTypeMap` parameter of the OpenStackInstanceClass resource. Otherwise, provisioning a node in a zone where the default volume type is unavailable fails with the `HTTP 400 Availability zone '…' is invalid` error.

> **⚠** When the module settings are changed, **existing Machine objects in the cluster are NOT recreated** (new Machine objects will use the updated parameters). The recreation only occurs if you modify the NodeGroup or the OpenStackInstanceClass parameters.

Configuration examples

The following are two simple configuration examples for the OpenStack cloud provider.

Example 1

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: test
spec:
  flavorName: m1.large
```

Example 2

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-openstack
spec:
  version: 1
  enabled: true
  settings:
    connection:
      authURL: https://test.tests.com:5000/v3/
      domainName: default
      tenantName: default
      username: jamie
      password: nein
      region: SomeRegion
    externalNetworkNames:
    - public
    internalNetworkNames:
    - kube
    instances:
      sshKeyPairName: my-ssh-keypair
      securityGroups:
      - default
      - allow-ssh-and-icmp
    zones:
    - zone-a
    - zone-b
    tags:
      project: cms
      owner: default
```

LoadBalancer configuration

⚠ To correctly determine the client IP address, use a LoadBalancer with Proxy Protocol support.

It is recommended to limit the list of nodes added to the load balancer pool using the `loadbalancer.openstack.org/node-selector` annotation.

Without a `node-selector` restriction, cloud-controller-manager may use all suitable cluster nodes as load balancer targets. As a result, adding or removing nodes that are not related to the workload served by the load balancer may trigger an update of the load balancer pool membership. In large or frequently changing clusters, such updates may occur regularly and, in some configurations, may cause brief disruptions to existing connections.

The `annotations` field of the corresponding inlet configuration in the IngressNginxController resource supports the following annotations:

- `loadbalancer.openstack.org/node-selector`: Selects the nodes that will be used as LoadBalancer targets.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id`: Instructs OpenStack CCM to use a pre-created Octavia load balancer.
- `loadbalancer.openstack.deckhouse.io/load-balancer-address`: Instructs OpenStack CCM to associate a pre-allocated floating IP with the load balancer it creates.

DP automatically adds the specified annotations to the generated Service object of type LoadBalancer.

When using the `loadbalancer.openstack.deckhouse.io/load-balancer-id` annotation, the load balancer must meet the following requirements:

- reside in the cluster subnet
- be in the `ACTIVE` state

If `loadbalancer.openstack.deckhouse.io/load-balancer-id` is used to reference a pre-created load balancer with a custom name, associate the floating IP with its VIP port before creating the cluster. In this case, do not specify the `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotation.

When using only `loadbalancer.openstack.deckhouse.io/load-balancer-address`, the floating IP must meet the following requirements:

- not be associated with any port
- reside in the floating network configured for OpenStack CCM

If the specified floating IP is unavailable, OpenStack CCM will not be able to assign an external IP address to the Service object.

Do not add the `loadbalancer.openstack.deckhouse.io/load-balancer-id` or `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotations to application Ingress resources. Specify them only in the IngressNginxController configuration. DP will add them to the generated Service object, which is processed by `openstack-cloud-controller-manager`.

IngressNginxController with a pre-created load balancer

In the example below:

- Ingress controller pods are scheduled on frontend nodes.
- `loadbalancer.openstack.org/node-selector` limits the load balancer target pool to those frontend nodes.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id` references a pre-created Octavia load balancer whose VIP port already has a floating IP associated with it.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-id: "df7c6f73-8c68-4a11-a3e2-6268a655ce9b"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

IngressNginxController with a pre-allocated floating IP

In the example below, OpenStack CCM creates a load balancer and associates the specified unassigned floating IP with it:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-address: "203.0.113.10"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Uploading an image to VK Cloud

1. Download the latest stable Ubuntu 18.04 image:

   ```
   curl -L https://cloud-images.ubuntu.com/bionic/current/bionic-server-cloudimg-amd64.img --output ~/ubuntu-18-04-cloud-amd64
   ```

2. Prepare an openrc file that contains credentials for accessing the VK Cloud API.

   > **i** The method of obtaining the openrc file may vary depending on the VK Cloud provider. If your provider offers the standard interface for VK Cloud, follow this guide to download the file.

3. Alternatively, install the OpenStack CLI tools following the instructions.

   You can also run a container, mounting both the openrc file and the downloaded Ubuntu image:

   ```
   docker run -ti --rm -v ~/ubuntu-18-04-cloud-amd64:/ubuntu-18-04-cloud-amd64 -v ~/.openrc:/openrc jmcvea/openstack-client
   ```

4. Initialize environment variables from the openrc file:

   ```
   source /openrc
   ```

5. List the available volume types:

   ```
   openstack volume type list
   ```

   Example output:

   ```
   +--------------------------------------+---------------+-----------+
   | ID                                   | Name          | Is Public |
   +--------------------------------------+---------------+-----------+
   | 8d39c9db-0293-48c0-8d44-015a2f6788ff | ko1-high-iops | True      |
   | bf800b7c-9ae0-4cda-b9c5-fae283b3e9fd | dp1-high-iops | True      |
   | 74101409-a462-4f03-872a-7de727a178b8 | ko1-ssd       | True      |
   | eadd8860-f5a4-45e1-ae27-8c58094257e0 | dp1-ssd       | True      |
   | 48372c05-c842-4f6e-89ca-09af3868b2c4 | ssd           | True      |
   | a75c3502-4de6-4876-a457-a6c4594c067a | ms1           | True      |
   | ebf5922e-42af-4f97-8f23-716340290de2 | dp1           | True      |
   | a6e853c1-78ad-4c18-93f9-2bba317a1d13 | ceph          | True      |
   +--------------------------------------+---------------+-----------+
   ```

6. Create an image and assign the volume type as a property (this is necessary if VK Cloud does not support local disks or they are unsuitable for workloads):

   ```
   openstack image create --private --disk-format qcow2 --container-format bare \
     --file /ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=dp1-high-iops ubuntu-18-04-cloud-amd64
   ```

7. Ensure the image has been created:

```
openstack image show ubuntu-18-04-cloud-amd64
```

Example output:

```
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| Field            | Value
|
+------------------+------------------------------------------------------------------------------

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the OpenStackInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the OpenStackClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Verifying security group support by the cloud provider

Run the `openstack security group list` command. If you don’t receive any errors, it means that security groups are supported.

Cinder CSI resilience during re-authentication in OpenStack

The Cinder CSI driver supports OpenStack re-authentication with service catalog refresh. This improves the reliability of

volume operations in `cinder-csi-plugin` pods that have been running for a long time without being restarted.

When a token expires or a `401 Unauthorized` response is received, the driver re-authenticates with OpenStack and updates the data used to access OpenStack API services. As a result, PersistentVolume operations, including volume attachment and detachment, continue without requiring CSI driver pods to be restarted.

This behavior is especially important for clusters where `cinder-csi-plugin` pods run for a long time without being restarted, while the OpenStack service catalog may change between the initial authentication and subsequent API requests.

Configuring online volume resize

When resizing a disk via the OpenStack API, Cinder does not pass updated size information to Nova. As a result, the disk size inside the guest OS remains unchanged.

To fix this, you must configure access to the Nova API in the `cinder.conf` file. For example:

```
[nova]
interface = admin
insecure = {{ keystone_service_internaluri_insecure | bool }}
auth_type = {{ cinder_keystone_auth_plugin }}
auth_url = {{ keystone_service_internaluri }}/v3
password = {{ nova_service_password }}
project_domain_id = default
project_name = service
region_name = {{ nova_service_region }}
user_domain_id = default
username = {{ nova_service_user_name }}
```

For more details, see the OpenStack-Ansible bug report.

Using rootDiskSize

Disks in VK Cloud

A node’s disk can be either local or network-attached. In VK Cloud terminology:

- A local disk is called an ephemeral disk.
- A network-attached disk is called a persistent disk (Cinder storage).

The ephemeral disk is deleted along with the VM, while the persistent disk remains in the cloud even after the VM is deleted.

- For master nodes, network-attached disks are preferred so the nodes could migrate between hypervisors.
- For ephemeral nodes, local disks are preferred for cost efficiency. However, not all cloud providers support local disks. If not supported, you have to use network-attached disks for ephemeral nodes.

Local disk (ephemeral)	Network-attached disk (persistent)
Deleted with the VM	Remains in cloud and can be reused
Less expensive	More expensive
Suitable for ephemeral nodes	Suitable for master nodes

rootDiskSize parameter

The OpenStackInstanceClass resource includes a `rootDiskSize` parameter. In VK Cloud, flavors may also define a disk size.

The resulting disk type depends on the combination of the following parameters:

	flavor disk size = 0	flavor disk size > 0
`rootDiskSize` not set	*Disk size must be specified*. VM creation will fail without it.	Local disk with size from the flavor.
`rootDiskSize` set	Network-attached disk with size that equals `rootDiskSize`.	Both network-attached (`rootDiskSize`) and local (from flavor). Avoid this setup, as the cloud provider may charge for both.

> **i** In Selectel Cloud, when creating nodes with CloudEphemeral type outside zone A, you must pre-create a flavor with the target disk size. In this case, you do not need to set the `rootDiskSize` parameter.

Recommendations for master nodes and bastion with network-attached disks

- Use a flavor with zero disk size.
- Set `rootDiskSize` in the OpenStackInstanceClass resource.
- Ensure the disk type is correct:

- If specified in the OS image, it will be used.
- If not specified, the type will be taken from `volumeTypeMap`.

Recommendations for ephemeral nodes with local disks

- Use a flavor with a defined disk size.
- Do not use the `rootDiskSize` parameter in OpenStackInstanceClass.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the cloud provider's default disk type will be used.

Checking the disk size in a flavor

Run the following command:

```
openstack flavor show m1.medium-50g -C disk
```

Example output:

```
+-------+-------+
| Field | Value |
+-------+-------+
| disk  | 50    |
+-------+-------+
```

Overriding the cloud provider's default disk type

If your cloud provider offers multiple volume types, you can specify the default type for an image by setting the `cinder_img_volume_type` property in the image metadata. Any VM created from that image will use the specified volume type.

You can also create a new VK Cloud image and upload it.

Example:

```
openstack volume type list
openstack image set ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=VOLUME_NAME
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Selectel Cloud

To manage resources in Selectel using Deckhouse Platform, you must connect to the Selectel API.

The list of Selectel API services required for deployment is available in the Configuration section.

The user credentials required to access the Selectel API are provided in the OpenStack RC file (openrc file).

Instructions for downloading the openrc file via the standard web interface of Selectel and using it are available in the Selectel documentation.

If you're using a cloud provider's implementation of the Selectel API, the process for obtaining the openrc file may differ.

> ⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

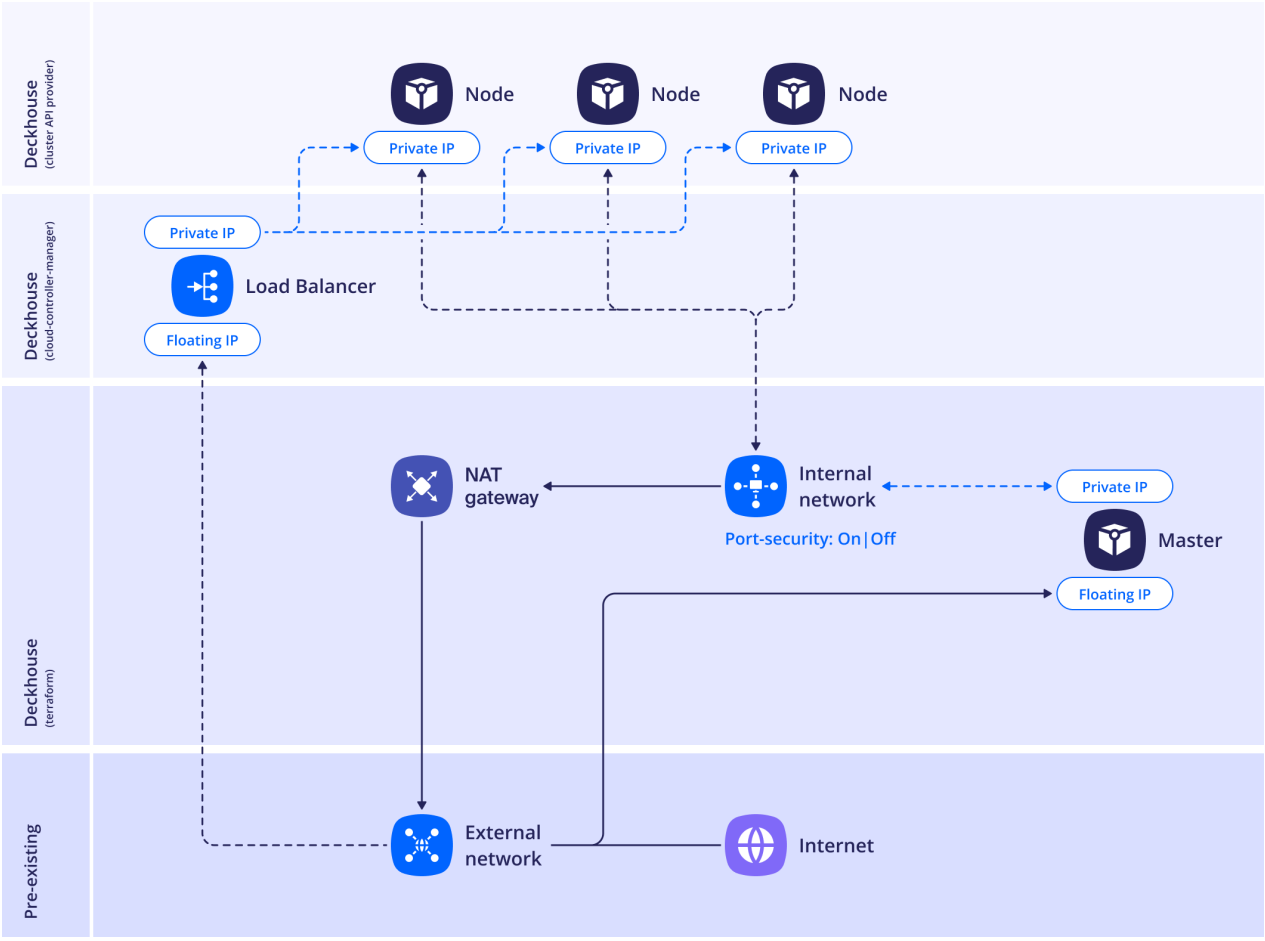
Layouts and configuration in Selectel Cloud

List of required OpenStack services

The following Selectel services must be available for Deckhouse Platform (DP) to operate:

Service	API Version
Identity (Keystone)	v3

Service	API Version
Compute (Nova)	v2.1
Network (Neutron)	v2.0
Block Storage (Cinder)	v3
Load Balancing (Octavia) *	v2



* If you need to order a Load Balancer.

Layouts

This section describes the possible node placement layouts in Selectel infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

In this scheme, an internal cluster network is created with a gateway to the public network; the nodes do not have public IP addresses. The floating IP is assigned to the master node.

⚠ If the provider does not support SecurityGroups, all applications running on nodes with Floating IPs assigned will be available at a public IP. For example, `kube-apiserver` on master nodes will be available on port `6443`. To avoid this, we recommend using the SimpleWithInternalNetwork or Standard layout with a bastion host.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000-32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.

- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Standard
standard:
  internalNetworkCIDR: 192.168.199.0/24       # Required.

  owner: default
provider:
  ...
```

StandardWithNoRouter

An internal cluster network is created that does not have access to the public network. All nodes (including master ones) have two interfaces: the first one to the public network, the second one to the internal network. This layout should be used if you want all nodes in the cluster to be directly accessible.

⚠

- This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.
- Using this strategy, make sure to explicitly specify the name of the internal network in `additionalNetworks` when creating an OpenStackInstanceClass in the cluster.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

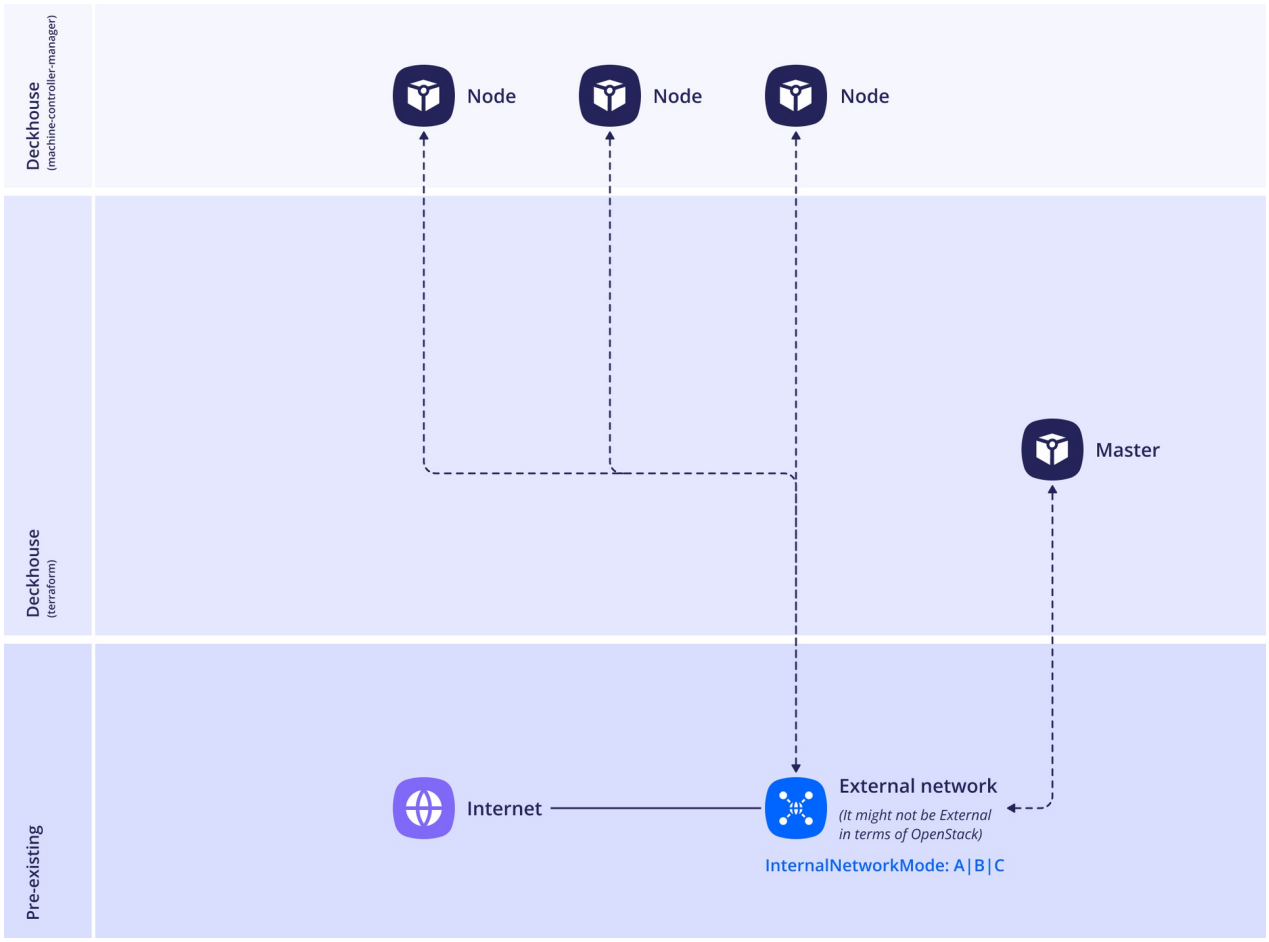
The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the

OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.



Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: StandardWithNoRouter
standardWithNoRouter:
  internalNetworkCIDR: 192.168.199.0/24        # Required.
  externalNetworkName: ext-net                # Required.
  # Optional, defines whether DHCP is enabled in specified external
  # network (true by default).
  externalNetworkDHCP: false
  internalNetworkSecurity: true|false          # Optional, true by default.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the gateway of the network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                      # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:

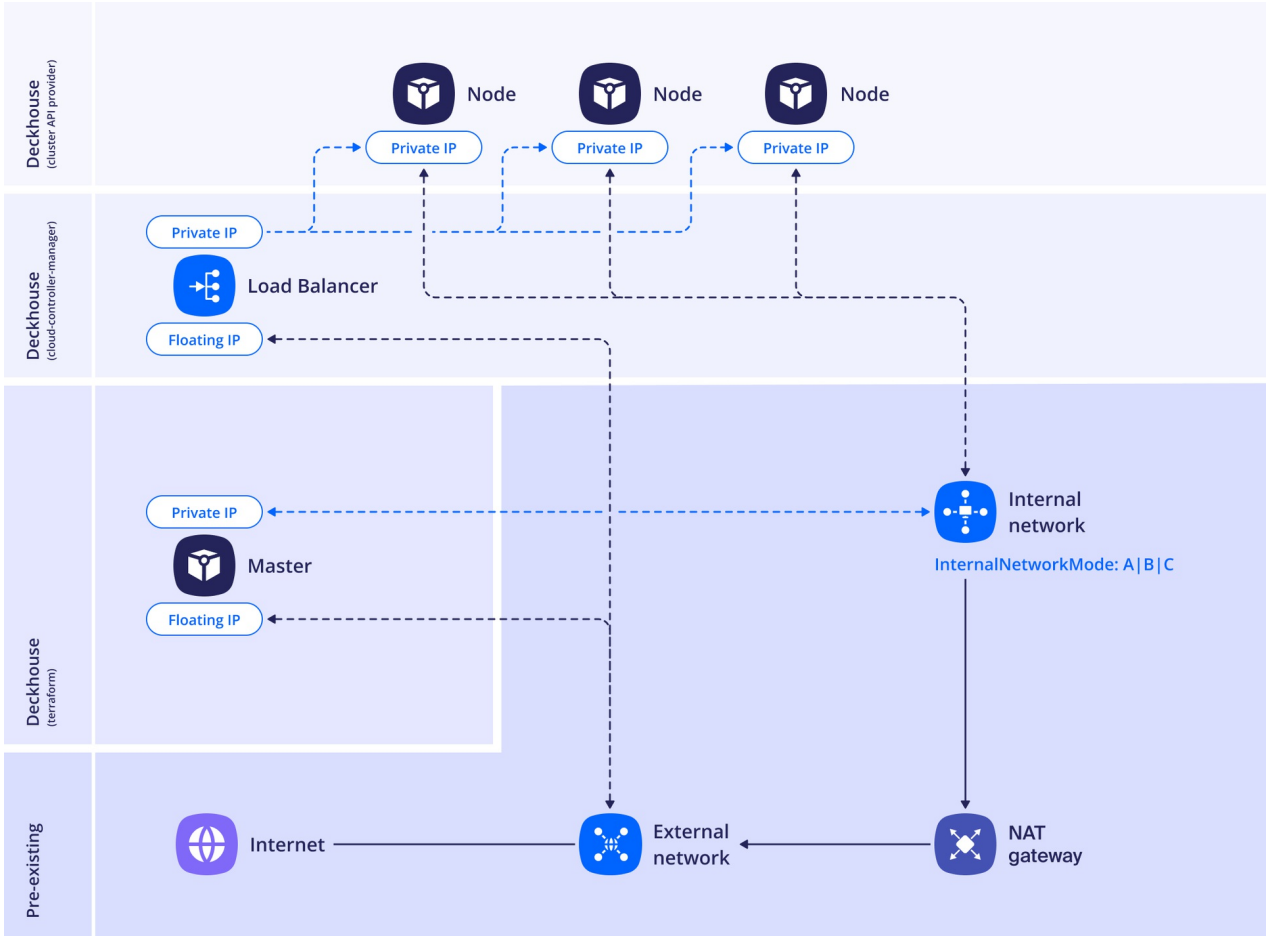
provider:
  ...
```

Simple

The master node and cluster nodes are connected to the existing network. This placement strategy can be useful if you need to merge a Kubernetes cluster with existing VMs.

⚠ This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:



- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Simple
simple:
  externalNetworkName: ext-net              # Required.
  externalNetworkDHCP: false                # Optional, true by default.
  # Optional, VXLAN by default, may also be DirectRouting
  # or DirectRoutingWithPortSecurityEnabled.
  podNetworkMode: VXLAN
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

SimpleWithInternalNetwork

The master node and cluster nodes are connected to the existing network. This layout can be useful if you need to merge a Kubernetes cluster with existing VMs.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: SimpleWithInternalNetwork
simpleWithInternalNetwork:
  # All cluster nodes have to be in the same subnet. Set either the subnet name
  # in internalSubnetName or its UUID in internalSubnetID.
  internalSubnetName: pivot-standard
  # Optional, DirectRoutingWithPortSecurityEnabled by default,
  # may also be DirectRouting or VXLAN.
  podNetworkMode: DirectRoutingWithPortSecurityEnabled
  # Optional. If set, it will be used for the load balancer default
  # configuration and ordering the master floating IP.
  externalNetworkName: ext-net
  # Optional, true by default.
  masterWithExternalFloatingIP: false
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Configuration

Integration with Selectel is performed using the OpenStackClusterConfiguration resource. It defines the configuration of the cloud cluster in Selectel and is used by the cloud provider when the cluster control plane is hosted in the cloud. The DP module responsible for the integration is automatically configured based on the selected layout.

To modify the configuration in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After changing node-related parameters, run the `dhctl converge` command to apply the changes.

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the Selectel cloud provider, the instance class is a custom resource called OpenStackInstanceClass, which contains the specific configuration of the VMs.

> **i** An OpenStack cluster is deployed in a single region (`provider.region`). Zones from other regions cannot be used. For details on configuring zones for CloudPermanent and CloudEphemeral nodes, see How do I create NodeGroups in availability zones? section.

If the instance class of the group sets the `rootDiskSize` parameter, the root disk is created in Cinder. In clouds where volume types are bound to availability zones, set the volume type for each zone in the `volumeTypeMap` parameter of the OpenStackInstanceClass resource. Otherwise, provisioning a node in a zone where the default volume type is unavailable fails with the `HTTP 400 Availability zone '…' is invalid` error.

> **⚠** When the module settings are changed, **existing Machine objects in the cluster are NOT recreated** (new Machine objects will use the updated parameters). The recreation only occurs if you modify the NodeGroup or the OpenStackInstanceClass parameters.

Configuration examples

The following are two simple configuration examples for the OpenStack cloud provider.

Example 1

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: test
spec:
  flavorName: m1.large
```

Example 2

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-openstack
spec:
  version: 1
  enabled: true
  settings:
    connection:
      authURL: https://test.tests.com:5000/v3/
      domainName: default
      tenantName: default
      username: jamie
      password: nein
      region: SomeRegion
    externalNetworkNames:
    - public
    internalNetworkNames:
    - kube
    instances:
      sshKeyPairName: my-ssh-keypair
      securityGroups:
      - default
      - allow-ssh-and-icmp
    zones:
    - zone-a
    - zone-b
    tags:
      project: cms
      owner: default
```

How to create preemptible nodes in Selectel

Selectel triggers preemption on the presence of the raw Nova tag `preemptible`. Set the `preemptible` parameter of the OpenStackInstanceClass to `true` — the tag is then attached to the instance automatically.

Example:

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: worker-preempt
spec:
  flavorName: SL1.4-8192
  imageName: Ubuntu 24.04 LTS 64-bit
  rootDiskSize: 30
  preemptible: true
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker-preempt
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: OpenStackInstanceClass
      name: worker-preempt
    minPerZone: 2
    maxPerZone: 4
    zones: [ru-3a]
```

Limitations:

- The `preemptible` tag is a Selectel-specific mechanism, and the CAPI provider template emits it only when the cluster's `connection.authURL` points at Selectel (`selcloud.ru` / `selectel`). On other OpenStack providers the tag is silently dropped: the node is still created, but as a regular (non-preemptible) VM.
- Supported only for CloudEphemeral NodeGroups running on the CAPI engine. If an OpenStackInstanceClass with `preemptible: true` is used by a NodeGroup running on the MCM engine, the field is silently ignored — no MCM MachineClass field maps to a raw Nova tag. Nodes are created as regular VMs.
- Both situations above raise the **OpenStackPreemptibleUnsupported** Prometheus alert (with `reason=mcm` or `reason=non-selectel`) so the operator learns about the silent drop instead of discovering it weeks later from an unchanged billing line. The alert description carries the exact commands to fix each case.
- The management engine is selected per NodeGroup. If the same OpenStackInstanceClass with `preemptible: true` is used simultaneously by NodeGroups running on CAPI and MCM, the MCM NodeGroup keeps firing the alert — use separate OpenStackInstanceClass resources for different engines when the preemptibility contract differs.

> ⚠ Changing the `preemptible` parameter in an existing OpenStackInstanceClass changes the OpenStackMachineTemplate and causes all nodes in the corresponding NodeGroup to be recreated.

If a preemptible instance is terminated without a `graceful shutdown`, the corresponding node transitions to the `NotReady` state. After the missing instance is detected, CAPO and MachineHealthCheck initiate the creation of a new Machine and virtual machine. Until recovery is complete, pods on the lost node may still appear in the Kubernetes API with the `Running` status even though they are no longer actually available.

LoadBalancer configuration

> ⚠ To correctly determine the client IP address, use a LoadBalancer with Proxy Protocol support.

It is recommended to limit the list of nodes added to the load balancer pool using the `loadbalancer.openstack.org/node-selector` annotation.

Without a `node-selector` restriction, cloud-controller-manager may use all suitable cluster nodes as load balancer targets. As a result, adding or removing nodes that are not related to the workload served by the load balancer may trigger an update of the load balancer pool membership. In large or frequently changing clusters, such updates may occur regularly and, in some configurations, may cause brief disruptions to existing connections.

The `annotations` field of the corresponding inlet configuration in the IngressNginxController resource supports the following annotations:

- `loadbalancer.openstack.org/node-selector`: Selects the nodes that will be used as LoadBalancer targets.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id`: Instructs OpenStack CCM to use a pre-created Octavia load balancer.
- `loadbalancer.openstack.deckhouse.io/load-balancer-address`: Instructs OpenStack CCM to associate a pre-allocated floating IP with the load balancer it creates.

DP automatically adds the specified annotations to the generated Service object of type LoadBalancer.

When using the `loadbalancer.openstack.deckhouse.io/load-balancer-id` annotation, the load balancer must meet the following requirements:

- reside in the cluster subnet
- be in the `ACTIVE` state

If `loadbalancer.openstack.deckhouse.io/load-balancer-id` is used to reference a pre-created load balancer with a custom name, associate the floating IP with its VIP port before creating the cluster. In this case, do not specify the `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotation.

When using only `loadbalancer.openstack.deckhouse.io/load-balancer-address`, the floating IP must meet the following requirements:

- not be associated with any port
- reside in the floating network configured for OpenStack CCM

If the specified floating IP is unavailable, OpenStack CCM will not be able to assign an external IP address to the Service object.

Do not add the `loadbalancer.openstack.deckhouse.io/load-balancer-id` or `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotations to application Ingress resources. Specify them only in the IngressNginxController configuration. DP will add them to the generated Service object, which is processed by `openstack-cloud-controller-manager`.

IngressNginxController with a pre-created load balancer

In the example below:

- Ingress controller pods are scheduled on frontend nodes.
- `loadbalancer.openstack.org/node-selector` limits the load balancer target pool to those frontend nodes.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id` references a pre-created Octavia load balancer whose VIP port already has a floating IP associated with it.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-id: "df7c6f73-8c68-4a11-a3e2-6268a655ce9b"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

IngressNginxController with a pre-allocated floating IP

In the example below, OpenStack CCM creates a load balancer and associates the specified unassigned floating IP with it:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-address: "203.0.113.10"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Uploading an image to Selectel

1. Download the latest stable Ubuntu 18.04 image:

   ```
   curl -L https://cloud-images.ubuntu.com/bionic/current/bionic-server-cloudimg-amd64.img --output ~/ubuntu-18-04-cloud-amd64
   ```

2. Prepare an openrc file that contains credentials for accessing the Selectel API.

   > **i** The method of obtaining the openrc file may vary depending on the Selectel provider. If your provider offers the standard interface for Selectel, follow this guide to download the file.

3. Alternatively, install the OpenStack CLI tools following the instructions.

   You can also run a container, mounting both the openrc file and the downloaded Ubuntu image:

   ```
   docker run -ti --rm -v ~/ubuntu-18-04-cloud-amd64:/ubuntu-18-04-cloud-amd64 -v ~/.openrc:/openrc jmcvea/openstack-client
   ```

4. Initialize environment variables from the openrc file:

   ```
   source /openrc
   ```

5. List the available volume types:

   ```
   openstack volume type list
   ```

   Example output:

   ```
   +--------------------------------------+---------------+-----------+
   | ID                                   | Name          | Is Public |
   +--------------------------------------+---------------+-----------+
   | 8d39c9db-0293-48c0-8d44-015a2f6788ff | ko1-high-iops | True      |
   | bf800b7c-9ae0-4cda-b9c5-fae283b3e9fd | dp1-high-iops | True      |
   | 74101409-a462-4f03-872a-7de727a178b8 | ko1-ssd       | True      |
   | eadd8860-f5a4-45e1-ae27-8c58094257e0 | dp1-ssd       | True      |
   | 48372c05-c842-4f6e-89ca-09af3868b2c4 | ssd           | True      |
   | a75c3502-4de6-4876-a457-a6c4594c067a | ms1           | True      |
   | ebf5922e-42af-4f97-8f23-716340290de2 | dp1           | True      |
   | a6e853c1-78ad-4c18-93f9-2bba317a1d13 | ceph          | True      |
   +--------------------------------------+---------------+-----------+
   ```

6. Create an image and assign the volume type as a property (this is necessary if Selectel does not support local disks or they are unsuitable for workloads):

   ```
   openstack image create --private --disk-format qcow2 --container-format bare \
     --file /ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=dp1-high-iops ubuntu-18-04-cloud-amd64
   ```

7. Ensure the image has been created:

```
openstack image show ubuntu-18-04-cloud-amd64
```

Example output:

```
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| Field            | Value
|
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------

```

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the OpenStackInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the OpenStackClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Verifying security group support by the cloud provider

Run the `openstack security group list` command. If you don’t receive any errors, it means that security groups are supported.

Cinder CSI resilience during re-authentication in OpenStack

The Cinder CSI driver supports OpenStack re-authentication with service catalog refresh. This improves the reliability of

volume operations in `cinder-csi-plugin` pods that have been running for a long time without being restarted.

When a token expires or a `401 Unauthorized` response is received, the driver re-authenticates with OpenStack and updates the data used to access OpenStack API services. As a result, PersistentVolume operations, including volume attachment and detachment, continue without requiring CSI driver pods to be restarted.

This behavior is especially important for clusters where `cinder-csi-plugin` pods run for a long time without being restarted, while the OpenStack service catalog may change between the initial authentication and subsequent API requests.

Configuring online volume resize

When resizing a disk via the OpenStack API, Cinder does not pass updated size information to Nova. As a result, the disk size inside the guest OS remains unchanged.

To fix this, you must configure access to the Nova API in the `cinder.conf` file. For example:

```
[nova]
interface = admin
insecure = {{ keystone_service_internaluri_insecure | bool }}
auth_type = {{ cinder_keystone_auth_plugin }}
auth_url = {{ keystone_service_internaluri }}/v3
password = {{ nova_service_password }}
project_domain_id = default
project_name = service
region_name = {{ nova_service_region }}
user_domain_id = default
username = {{ nova_service_user_name }}
```

For more details, see the OpenStack-Ansible bug report.

Using rootDiskSize

Disks in Selectel

A node’s disk can be either local or network-attached. In Selectel terminology:

- A local disk is called an ephemeral disk.
- A network-attached disk is called a persistent disk (Cinder storage).

The ephemeral disk is deleted along with the VM, while the persistent disk remains in the cloud even after the VM is deleted.

- For master nodes, network-attached disks are preferred so the nodes could migrate between hypervisors.
- For ephemeral nodes, local disks are preferred for cost efficiency. However, not all cloud providers support local disks. If not supported, you have to use network-attached disks for ephemeral nodes.

Local disk (ephemeral)	Network-attached disk (persistent)
Deleted with the VM	Remains in cloud and can be reused
Less expensive	More expensive
Suitable for ephemeral nodes	Suitable for master nodes

rootDiskSize parameter

The OpenStackInstanceClass resource includes a `rootDiskSize` parameter. In Selectel, flavors may also define a disk size.

The resulting disk type depends on the combination of the following parameters:

	flavor disk size = 0	flavor disk size > 0
`rootDiskSize` not set	*Disk size must be specified*. VM creation will fail without it.	Local disk with size from the flavor.
`rootDiskSize` set	Network-attached disk with size that equals `rootDiskSize`.	Both network-attached (`rootDiskSize`) and local (from flavor). Avoid this setup, as the cloud provider may charge for both.

Recommendations for master nodes and bastion with network-attached disks

- Use a flavor with zero disk size.
- Set `rootDiskSize` in the OpenStackInstanceClass resource.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the type will be taken from `volumeTypeMap`.

Recommendations for ephemeral nodes with local disks

- Use a flavor with a defined disk size.
- Do not use the `rootDiskSize` parameter in OpenStackInstanceClass.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the cloud provider's default disk type will be used.

Checking the disk size in a flavor

Run the following command:

```
openstack flavor show m1.medium-50g -C disk
```

Example output:

```
+-------+-------+
| Field | Value |
+-------+-------+
| disk  | 50    |
+-------+-------+
```

Overriding the cloud provider's default disk type

If your cloud provider offers multiple volume types, you can specify the default type for an image by setting the `cinder_img_volume_type` property in the image metadata. Any VM created from that image will use the specified volume type.

You can also create a new Selectel image and upload it.

Example:

```
openstack volume type list
openstack image set ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=VOLUME_NAME
```

Offline disk resizing

If you encounter the following error during volume resizing, reduce the number of replicas in the affected StatefulSet to 0, wait for the volume size to update, and then scale the replicas back to the original value.

```
Warning  VolumeResizeFailed     5s (x11 over 41s)  external-resizer cinder.csi.openstack.org
resize volume "pvc-555555-ab66-4f8d-947c-296520bae4c1" by resizer "cinder.csi.openstack.org" failed:
rpc error: code = Internal desc = Could not resize volume "bb5a275b-3f30-4916-9480-9efe4b6dfba5" to size 2:

9efe4b6dfba5/action], but got 406 instead
{"computeFault": {"message": "Version 3.42 is not supported by the API. Minimum is 3.0 and maximum is 3.27.", "code": 406}}
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in OVH Cloud

To manage resources in OVHcloud using Deckhouse Platform, you must connect to the OVHcloud API.

The list of OVHcloud API services required for deployment is available in the Configuration section.

The user credentials required to access the OVHcloud API are provided in the OpenStack RC file (openrc file).

Instructions for downloading the openrc file via the standard web interface of OVHcloud and using it are available in the OVHcloud documentation.

If you're using a cloud provider's implementation of the OVHcloud API, the process for obtaining the openrc file may differ.

> The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

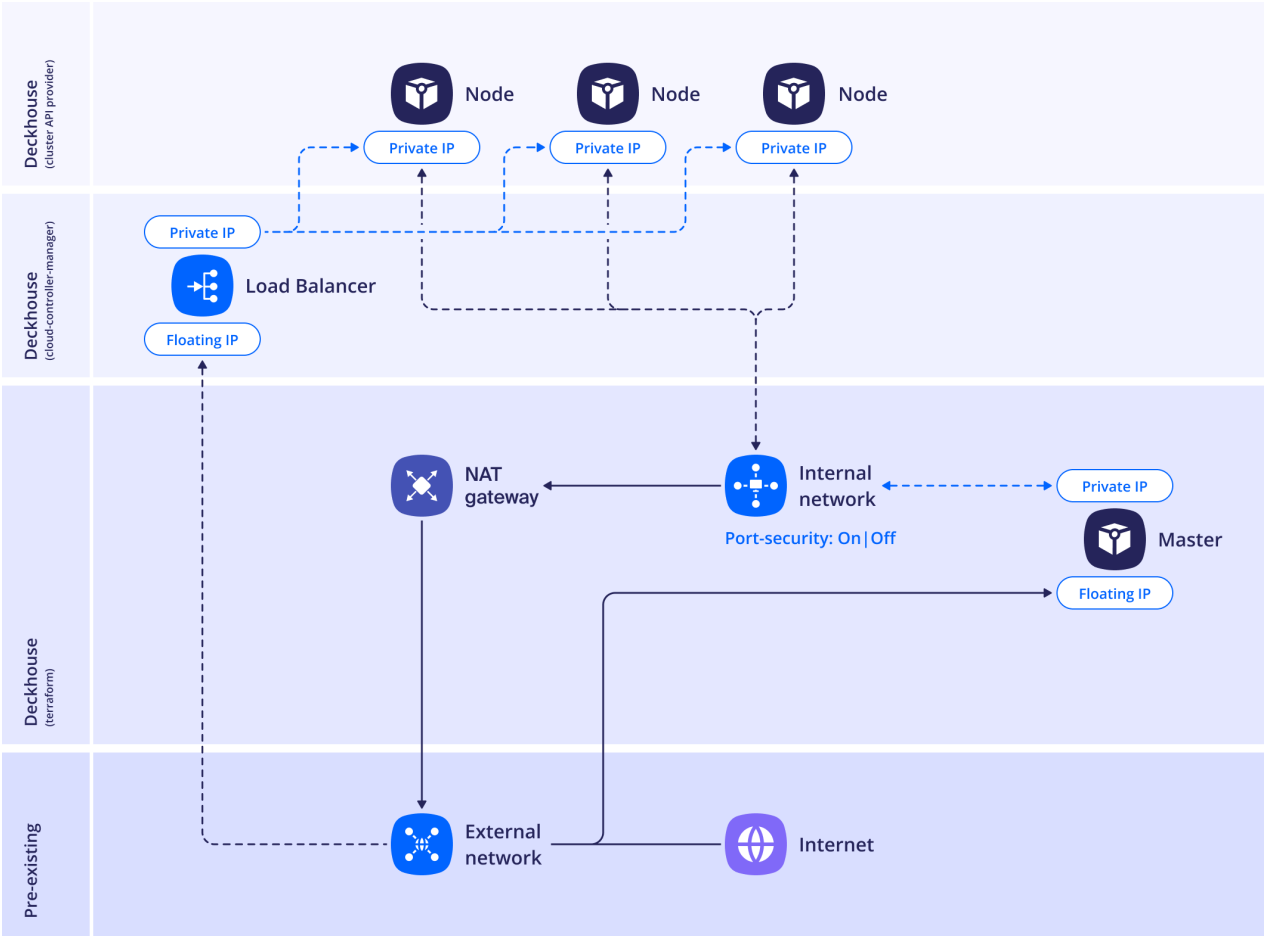
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in OVH Cloud

List of required OpenStack services

The following OVHcloud services must be available for Deckhouse Platform (DP) to operate:

Service	API Version
Identity (Keystone)	v3
Compute (Nova)	v2.1
Network (Neutron)	v2.0
Block Storage (Cinder)	v3
Load Balancing (Octavia) *	v2



* If you need to order a Load Balancer.

Layouts

This section describes the possible node placement layouts in OVHcloud infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

In this scheme, an internal cluster network is created with a gateway to the public network; the nodes do not have public IP addresses. The floating IP is assigned to the master node.

⚠ If the provider does not support SecurityGroups, all applications running on nodes with Floating IPs assigned will be available at a public IP. For example, `kube-apiserver` on master nodes will be available on port `6443`. To avoid this, we recommend using the SimpleWithInternalNetwork or Standard layout with a bastion host.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by

following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Standard
standard:
  internalNetworkCIDR: 192.168.199.0/24       # Required.
  internalNetworkDNSServers:                 # Required.
  - 8.8.8.8
  - 4.2.2.2
  internalNetworkSecurity: true|false         # Optional, true by default.
  externalNetworkName: shared                # Required.
  bastion:
    zone: ru2-b                             # Optional.
    volumeType: fast-ru-2b                   # Optional.
    instanceClass:
      flavorName: m1.large                   # Required.
      imageName: ubuntu-20-04-cloud-amd64      # Required.
      rootDiskSize: 50                      # Optional, 50 GB by default.
      additionalTags:
        severity: critical                   # Optional.
        environment: production              # Optional.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:

StandardWithNoRouter

An internal cluster network is created that does not have access to the public network. All nodes (including master ones) have two interfaces: the first one to the public network, the second one to the internal network. This layout should be used if you want all nodes in the cluster to be directly accessible.

⚠

- This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.
- Using this strategy, make sure to explicitly specify the name of the internal network in `additionalNetworks` when creating an OpenStackInstanceClass in the cluster.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

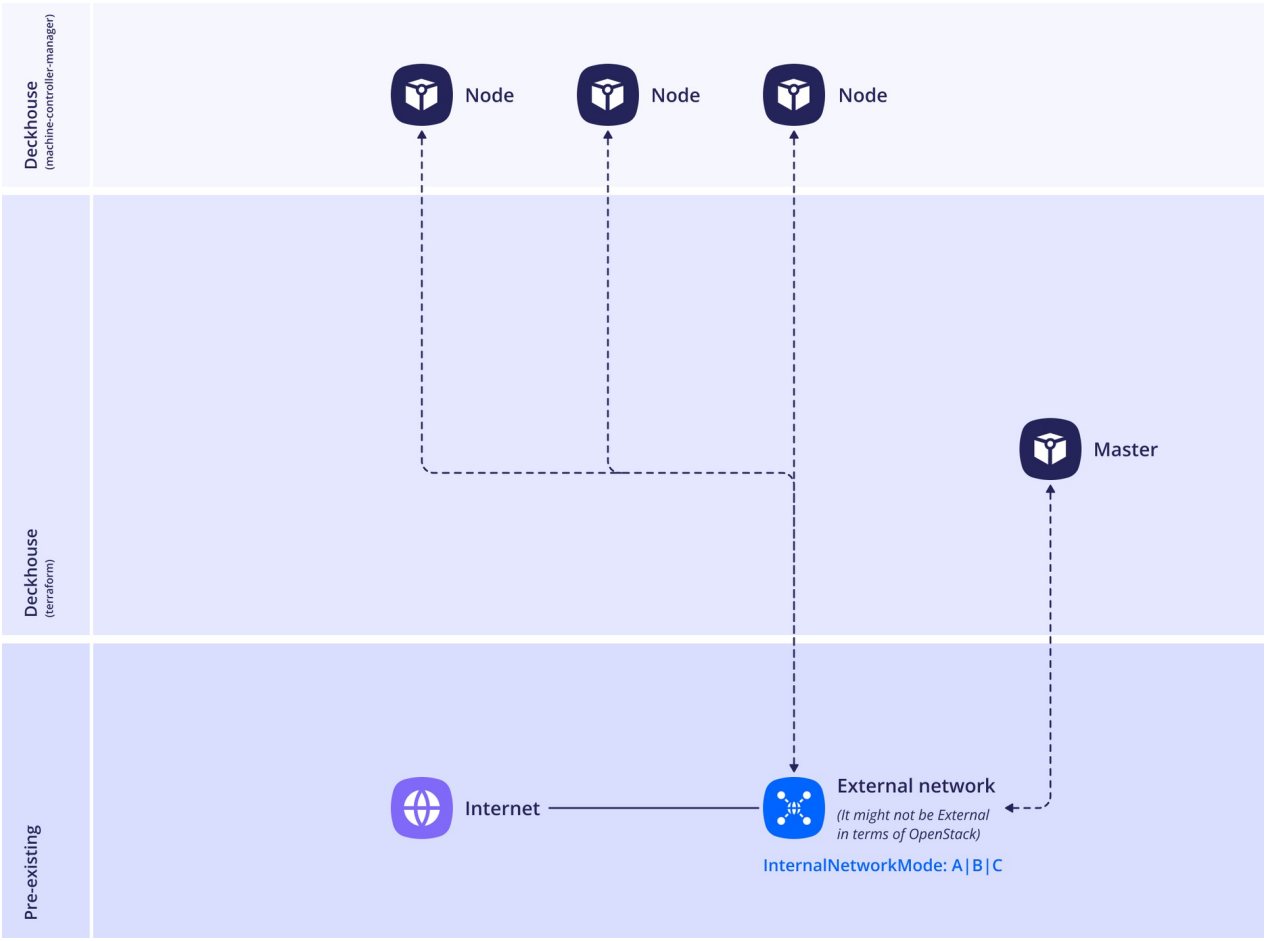
The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by

following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.



Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: StandardWithNoRouter
standardWithNoRouter:
  internalNetworkCIDR: 192.168.199.0/24        # Required.
  externalNetworkName: ext-net                # Required.
  # Optional, defines whether DHCP is enabled in specified external
  # network (true by default).
  externalNetworkDHCP: false
  internalNetworkSecurity: true|false          # Optional, true by default.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the gateway of the network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                      # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:

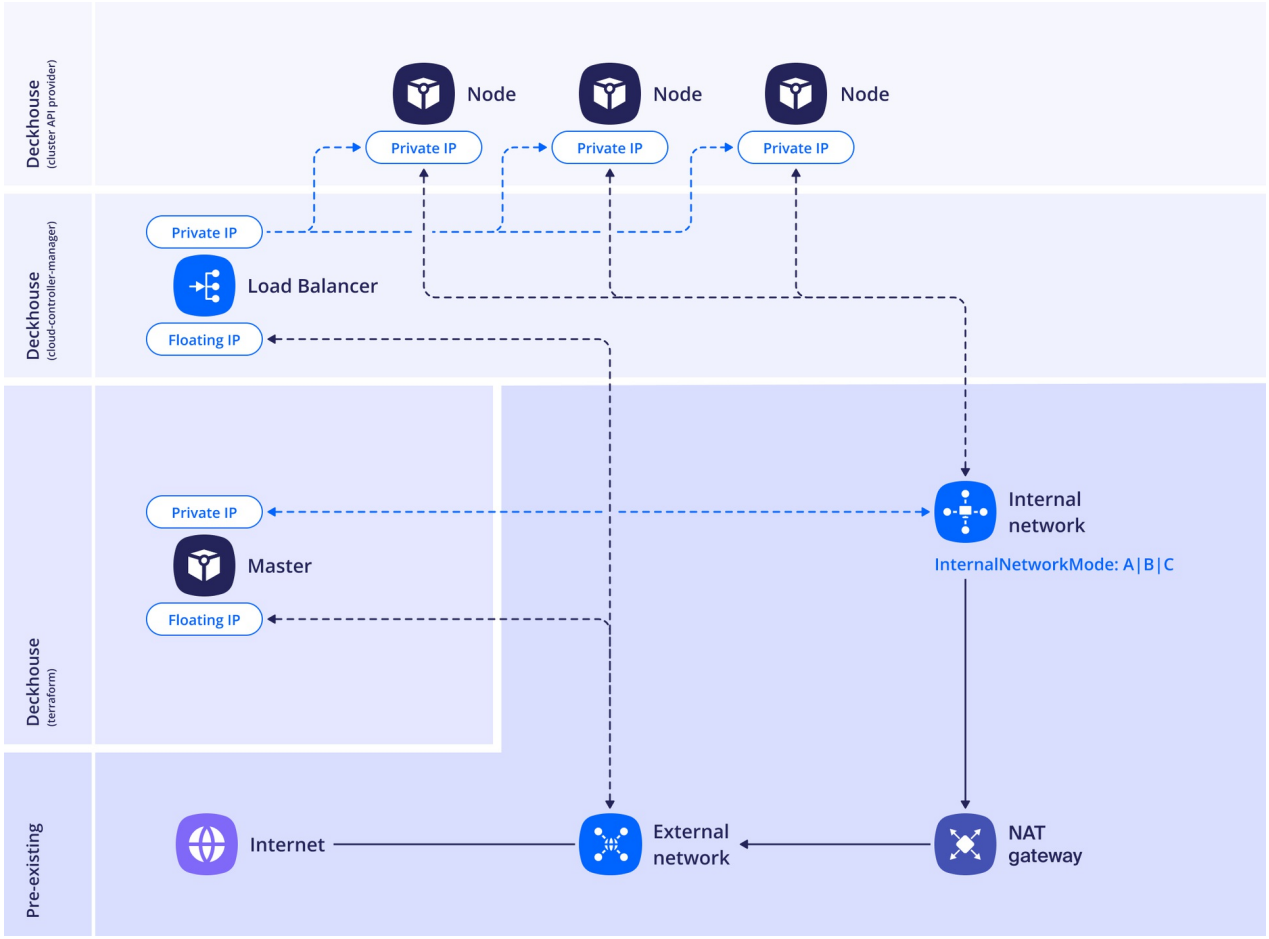
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required if rootDiskSize is specified. Volume type map for node's root volume.
  volumeTypeMap:
    nova: ceph-ssd
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Simple

The master node and cluster nodes are connected to the existing network. This placement strategy can be useful if you need to merge a Kubernetes cluster with existing VMs.

> ⚠ This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:



- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Simple
simple:
  externalNetworkName: ext-net              # Required.
  externalNetworkDHCP: false                # Optional, true by default.
  # Optional, VXLAN by default, may also be DirectRouting
  # or DirectRoutingWithPortSecurityEnabled.
  podNetworkMode: VXLAN
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

SimpleWithInternalNetwork

The master node and cluster nodes are connected to the existing network. This layout can be useful if you need to merge a Kubernetes cluster with existing VMs.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: SimpleWithInternalNetwork
simpleWithInternalNetwork:
  # All cluster nodes have to be in the same subnet. Set either the subnet name
  # in internalSubnetName or its UUID in internalSubnetID.
  internalSubnetName: pivot-standard
  # Optional, DirectRoutingWithPortSecurityEnabled by default,
  # may also be DirectRouting or VXLAN.
  podNetworkMode: DirectRoutingWithPortSecurityEnabled
  # Optional. If set, it will be used for the load balancer default
  # configuration and ordering the master floating IP.
  externalNetworkName: ext-net
  # Optional, true by default.
  masterWithExternalFloatingIP: false
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Configuration

Integration with OVHcloud is performed using the OpenStackClusterConfiguration resource. It defines the configuration of the cloud cluster in OVHcloud and is used by the cloud provider when the cluster control plane is hosted in the cloud. The DP module responsible for the integration is automatically configured based on the selected layout.

To modify the configuration in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After changing node-related parameters, run the `dhctl converge` command to apply the changes.

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the OVHcloud cloud provider, the instance class is a custom resource called OpenStackInstanceClass, which contains the specific configuration of the VMs.

> **i** An OpenStack cluster is deployed in a single region (`provider.region`). Zones from other regions cannot be used. For details on configuring zones for CloudPermanent and CloudEphemeral nodes, see How do I create NodeGroups in availability zones? section.

If the instance class of the group sets the `rootDiskSize` parameter, the root disk is created in Cinder. In clouds where volume types are bound to availability zones, set the volume type for each zone in the `volumeTypeMap` parameter of the OpenStackInstanceClass resource. Otherwise, provisioning a node in a zone where the default volume type is unavailable fails with the `HTTP 400 Availability zone '…' is invalid` error.

> **⚠** When the module settings are changed, **existing Machine objects in the cluster are NOT recreated** (new Machine objects will use the updated parameters). The recreation only occurs if you modify the NodeGroup or the OpenStackInstanceClass parameters.

Configuration examples

The following are two simple configuration examples for the OpenStack cloud provider.

Example 1

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: test
spec:
  flavorName: m1.large
```

Example 2

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-openstack
spec:
  version: 1
  enabled: true
  settings:
    connection:
      authURL: https://test.tests.com:5000/v3/
      domainName: default
      tenantName: default
      username: jamie
      password: nein
      region: SomeRegion
    externalNetworkNames:
    - public
    internalNetworkNames:
    - kube
    instances:
      sshKeyPairName: my-ssh-keypair
      securityGroups:
      - default
      - allow-ssh-and-icmp
    zones:
    - zone-a
    - zone-b
    tags:
      project: cms
      owner: default
```

LoadBalancer configuration

⚠ To correctly determine the client IP address, use a LoadBalancer with Proxy Protocol support.

It is recommended to limit the list of nodes added to the load balancer pool using the `loadbalancer.openstack.org/node-selector` annotation.

Without a `node-selector` restriction, cloud-controller-manager may use all suitable cluster nodes as load balancer targets. As a result, adding or removing nodes that are not related to the workload served by the load balancer may trigger an update of the load balancer pool membership. In large or frequently changing clusters, such updates may occur regularly and, in some configurations, may cause brief disruptions to existing connections.

The `annotations` field of the corresponding inlet configuration in the IngressNginxController resource supports the following annotations:

- `loadbalancer.openstack.org/node-selector`: Selects the nodes that will be used as LoadBalancer targets.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id`: Instructs OpenStack CCM to use a pre-created Octavia load balancer.
- `loadbalancer.openstack.deckhouse.io/load-balancer-address`: Instructs OpenStack CCM to associate a pre-allocated floating IP with the load balancer it creates.

DP automatically adds the specified annotations to the generated Service object of type LoadBalancer.

When using the `loadbalancer.openstack.deckhouse.io/load-balancer-id` annotation, the load balancer must meet the following requirements:

- reside in the cluster subnet
- be in the `ACTIVE` state

If `loadbalancer.openstack.deckhouse.io/load-balancer-id` is used to reference a pre-created load balancer with a custom name, associate the floating IP with its VIP port before creating the cluster. In this case, do not specify the `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotation.

When using only `loadbalancer.openstack.deckhouse.io/load-balancer-address`, the floating IP must meet the following requirements:

- not be associated with any port
- reside in the floating network configured for OpenStack CCM

If the specified floating IP is unavailable, OpenStack CCM will not be able to assign an external IP address to the Service object.

Do not add the `loadbalancer.openstack.deckhouse.io/load-balancer-id` or `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotations to application Ingress resources. Specify them only in the IngressNginxController configuration. DP will add them to the generated Service object, which is processed by `openstack-cloud-controller-manager`.

IngressNginxController with a pre-created load balancer

In the example below:

- Ingress controller pods are scheduled on frontend nodes.
- `loadbalancer.openstack.org/node-selector` limits the load balancer target pool to those frontend nodes.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id` references a pre-created Octavia load balancer whose VIP port already has a floating IP associated with it.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-id: "df7c6f73-8c68-4a11-a3e2-6268a655ce9b"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

IngressNginxController with a pre-allocated floating IP

In the example below, OpenStack CCM creates a load balancer and associates the specified unassigned floating IP with it:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-address: "203.0.113.10"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Uploading an image to OVHcloud

1. Download the latest stable Ubuntu 18.04 image:

   ```
   curl -L https://cloud-images.ubuntu.com/bionic/current/bionic-server-cloudimg-amd64.img --output ~/ubuntu-18-04-cloud-amd64
   ```

2. Prepare an openrc file that contains credentials for accessing the OVHcloud API.

   > **i** The method of obtaining the openrc file may vary depending on the OVHcloud provider. If your provider offers the standard interface for OVHcloud, follow this guide to download the file.

3. Alternatively, install the OpenStack CLI tools following the instructions.

   You can also run a container, mounting both the openrc file and the downloaded Ubuntu image:

   ```
   docker run -ti --rm -v ~/ubuntu-18-04-cloud-amd64:/ubuntu-18-04-cloud-amd64 -v ~/.openrc:/openrc jmcvea/openstack-client
   ```

4. Initialize environment variables from the openrc file:

   ```
   source /openrc
   ```

5. List the available volume types:

   ```
   openstack volume type list
   ```

   Example output:

   ```
   +--------------------------------------+---------------+-----------+
   | ID                                   | Name          | Is Public |
   +--------------------------------------+---------------+-----------+
   | 8d39c9db-0293-48c0-8d44-015a2f6788ff | ko1-high-iops | True      |
   | bf800b7c-9ae0-4cda-b9c5-fae283b3e9fd | dp1-high-iops | True      |
   | 74101409-a462-4f03-872a-7de727a178b8 | ko1-ssd       | True      |
   | eadd8860-f5a4-45e1-ae27-8c58094257e0 | dp1-ssd       | True      |
   | 48372c05-c842-4f6e-89ca-09af3868b2c4 | ssd           | True      |
   | a75c3502-4de6-4876-a457-a6c4594c067a | ms1           | True      |
   | ebf5922e-42af-4f97-8f23-716340290de2 | dp1           | True      |
   | a6e853c1-78ad-4c18-93f9-2bba317a1d13 | ceph          | True      |
   +--------------------------------------+---------------+-----------+
   ```

6. Create an image and assign the volume type as a property (this is necessary if OVHcloud does not support local disks or they are unsuitable for workloads):

   ```
   openstack image create --private --disk-format qcow2 --container-format bare \
     --file /ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=dp1-high-iops ubuntu-18-04-cloud-amd64
   ```

7. Ensure the image has been created:

```
openstack image show ubuntu-18-04-cloud-amd64
```

Example output:

```
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| Field            | Value
|
+------------------+------------------------------------------------------------------------------

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the OpenStackInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the OpenStackClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Verifying security group support by the cloud provider

Run the `openstack security group list` command. If you don’t receive any errors, it means that security groups are supported.

Cinder CSI resilience during re-authentication in OpenStack

The Cinder CSI driver supports OpenStack re-authentication with service catalog refresh. This improves the reliability of

volume operations in `cinder-csi-plugin` pods that have been running for a long time without being restarted.

When a token expires or a `401 Unauthorized` response is received, the driver re-authenticates with OpenStack and updates the data used to access OpenStack API services. As a result, PersistentVolume operations, including volume attachment and detachment, continue without requiring CSI driver pods to be restarted.

This behavior is especially important for clusters where `cinder-csi-plugin` pods run for a long time without being restarted, while the OpenStack service catalog may change between the initial authentication and subsequent API requests.

Configuring online volume resize

When resizing a disk via the OpenStack API, Cinder does not pass updated size information to Nova. As a result, the disk size inside the guest OS remains unchanged.

To fix this, you must configure access to the Nova API in the `cinder.conf` file. For example:

```
[nova]
interface = admin
insecure = {{ keystone_service_internaluri_insecure | bool }}
auth_type = {{ cinder_keystone_auth_plugin }}
auth_url = {{ keystone_service_internaluri }}/v3
password = {{ nova_service_password }}
project_domain_id = default
project_name = service
region_name = {{ nova_service_region }}
user_domain_id = default
username = {{ nova_service_user_name }}
```

For more details, see the OpenStack-Ansible bug report.

Using rootDiskSize

Disks in OVHcloud

A node’s disk can be either local or network-attached. In OVHcloud terminology:

- A local disk is called an ephemeral disk.
- A network-attached disk is called a persistent disk (Cinder storage).

The ephemeral disk is deleted along with the VM, while the persistent disk remains in the cloud even after the VM is deleted.

- For master nodes, network-attached disks are preferred so the nodes could migrate between hypervisors.
- For ephemeral nodes, local disks are preferred for cost efficiency. However, not all cloud providers support local disks. If not supported, you have to use network-attached disks for ephemeral nodes.

Local disk (ephemeral)	Network-attached disk (persistent)
Deleted with the VM	Remains in cloud and can be reused
Less expensive	More expensive
Suitable for ephemeral nodes	Suitable for master nodes

rootDiskSize parameter

The OpenStackInstanceClass resource includes a `rootDiskSize` parameter. In OVHcloud, flavors may also define a disk size.

The resulting disk type depends on the combination of the following parameters:

	flavor disk size = 0	flavor disk size > 0
`rootDiskSize` not set	*Disk size must be specified*. VM creation will fail without it.	Local disk with size from the flavor.
`rootDiskSize` set	Network-attached disk with size that equals `rootDiskSize`.	Both network-attached (`rootDiskSize`) and local (from flavor). Avoid this setup, as the cloud provider may charge for both.

> **i** In Selectel Cloud, when creating nodes with CloudEphemeral type outside zone A, you must pre-create a flavor with the target disk size. In this case, you do not need to set the `rootDiskSize` parameter.

Recommendations for master nodes and bastion with network-attached disks

- Use a flavor with zero disk size.
- Set `rootDiskSize` in the OpenStackInstanceClass resource.
- Ensure the disk type is correct:

- If specified in the OS image, it will be used.
- If not specified, the type will be taken from `volumeTypeMap`.

Recommendations for ephemeral nodes with local disks

- Use a flavor with a defined disk size.
- Do not use the `rootDiskSize` parameter in OpenStackInstanceClass.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the cloud provider's default disk type will be used.

Checking the disk size in a flavor

Run the following command:

```
openstack flavor show m1.medium-50g -C disk
```

Example output:

```
+-------+-------+
| Field | Value |
+-------+-------+
| disk  | 50    |
+-------+-------+
```

Overriding the cloud provider's default disk type

If your cloud provider offers multiple volume types, you can specify the default type for an image by setting the `cinder_img_volume_type` property in the image metadata. Any VM created from that image will use the specified volume type.

You can also create a new OVHcloud image and upload it.

Example:

```
openstack volume type list
openstack image set ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=VOLUME_NAME
```

Offline disk resizing

If you encounter the following error during volume resizing, reduce the number of replicas in the affected StatefulSet to 0, wait for the volume size to update, and then scale the replicas back to the original value.

```
Warning  VolumeResizeFailed     5s (x11 over 41s)  external-resizer cinder.csi.openstack.org
resize volume "pvc-555555-ab66-4f8d-947c-296520bae4c1" by resizer "cinder.csi.openstack.org" failed:

```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in OpenStack

To manage resources in OpenStack using Deckhouse Platform, you must connect to the OpenStack API.

The list of OpenStack API services required for deployment is available in the Configuration section.

The user credentials required to access the OpenStack API are provided in the OpenStack RC file (openrc file).

Instructions for downloading the openrc file via the standard web interface of OpenStack and using it are available in the OpenStack documentation.

If you're using a cloud provider's implementation of the OpenStack API, the process for obtaining the openrc file may differ.

> ⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

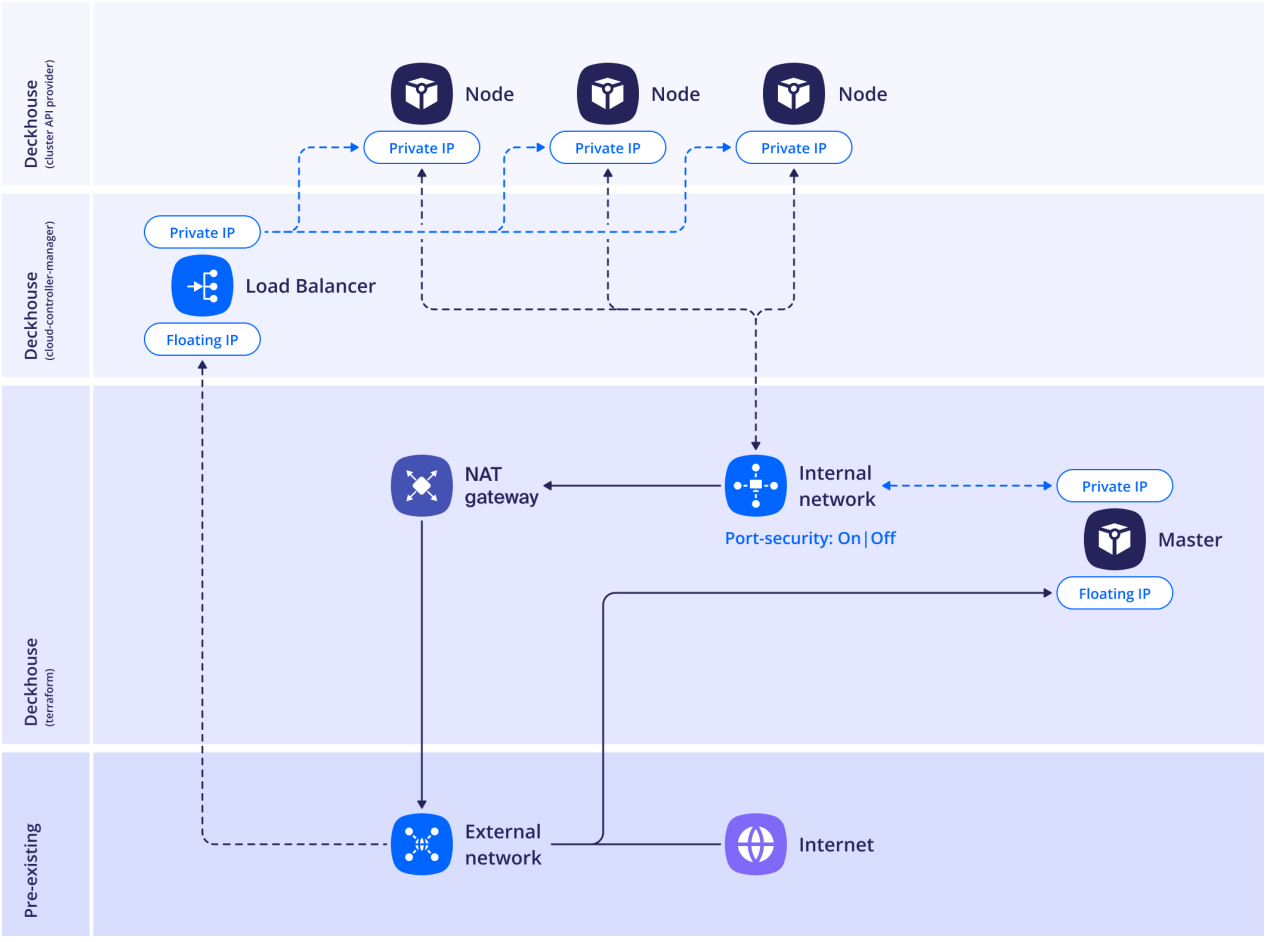
Layouts and configuration in OpenStack

List of required OpenStack services

The following OpenStack services must be available for Deckhouse Platform (DP) to operate:

Service	API Version
Identity (Keystone)	v3
Compute (Nova)	v2.1
Network (Neutron)	v2.0
Block Storage (Cinder)	v3
Load Balancing (Octavia) *	v2



* If you need to order a Load Balancer.

Layouts

This section describes the possible node placement layouts in OpenStack infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

In this scheme, an internal cluster network is created with a gateway to the public network; the nodes do not have public IP addresses. The floating IP is assigned to the master node.

> If the provider does not support SecurityGroups, all applications running on nodes with Floating IPs assigned will be available at a public IP. For example, `kube-apiserver` on master nodes will be available on port `6443`. To avoid this, we recommend using the SimpleWithInternalNetwork or Standard layout with a bastion host.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when

a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Standard
standard:
  internalNetworkCIDR: 192.168.199.0/24       # Required.
  internalNetworkDNSServers:                 # Required.
  - 8.8.8.8
  - 4.2.2.2
  internalNetworkSecurity: true|false         # Optional, true by default.
  externalNetworkName: shared                # Required.
  bastion:
    zone: ru2-b                             # Optional.
    volumeType: fast-ru-2b                   # Optional.
    instanceClass:
      flavorName: m1.large                   # Required.
      imageName: ubuntu-20-04-cloud-amd64     # Required.
      rootDiskSize: 50                      # Optional, 50 GB by default.
      additionalTags:
        severity: critical                   # Optional.
        environment: production              # Optional.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
    additionalTags:
      severity: critical
      environment: production
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    ru-1a: fast-ru-1a
    ru-1b: fast-ru-1b
    ru-1c: fast-ru-1c

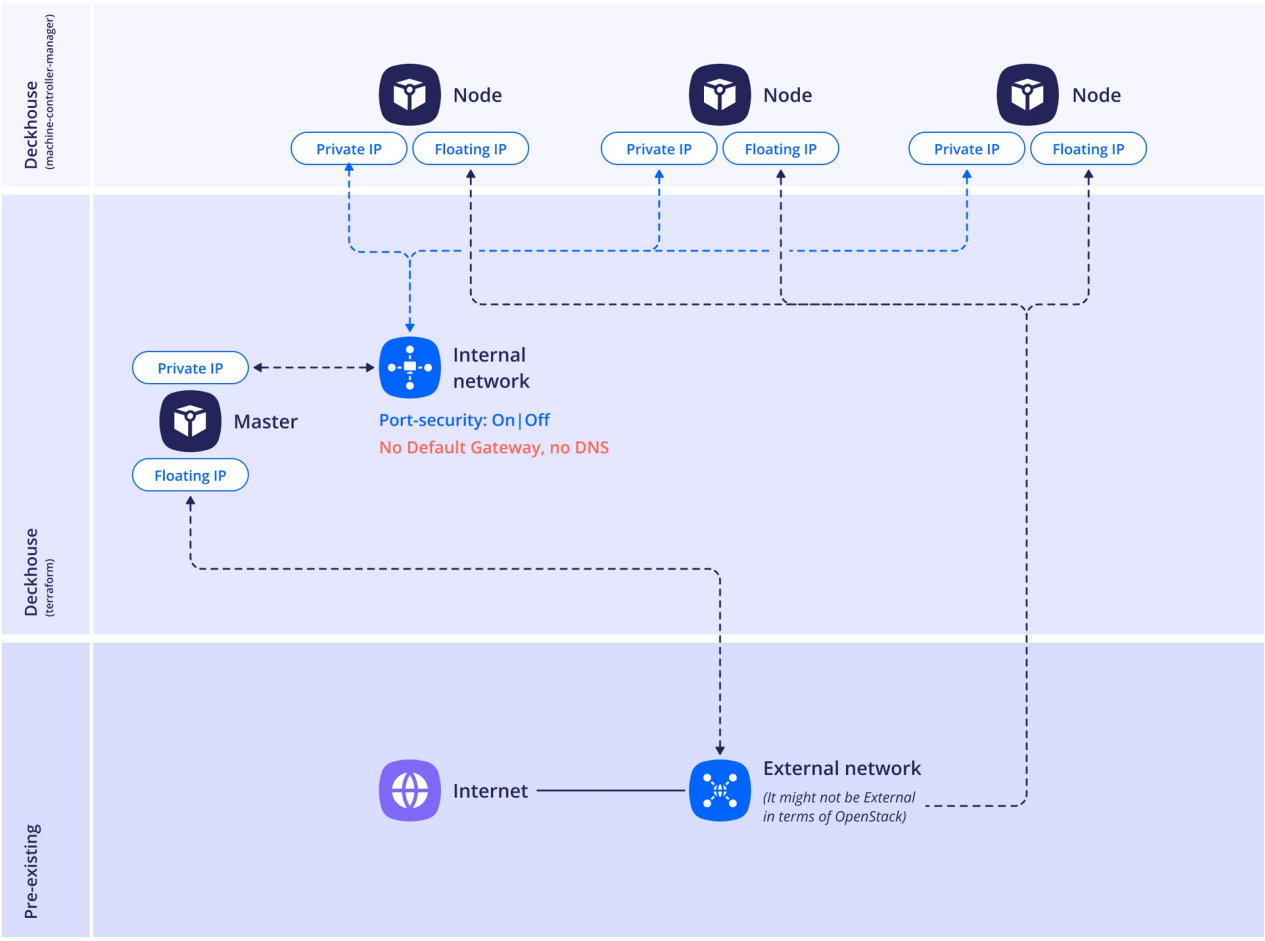
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default. Determines if configuration drive is
    # required during vm bootstrap process. It's needed if there
    # is no DHCP in the network that is used as a default gateway.
    configDrive: false
    # Required, the gateway of this network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
```



```
    mainNetwork: kube
    additionalNetworks:                  # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  zones:
  - ru-1a
  - ru-1b
sshPublicKey: "<SSH_PUBLIC_KEY>"
tags:
  project: cms
  owner: default
provider:
  ...
```

StandardWithNoRouter

An internal cluster network is created that does not have access to the public network. All nodes (including master ones) have two interfaces: the first one to the public network, the second one to the internal network. This layout should be used if you want all nodes in the cluster to be directly accessible.

⚠

- This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.
- Using this strategy, make sure to explicitly specify the name of the internal network in `additionalNetworks` when creating an OpenStackInstanceClass in the cluster.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when

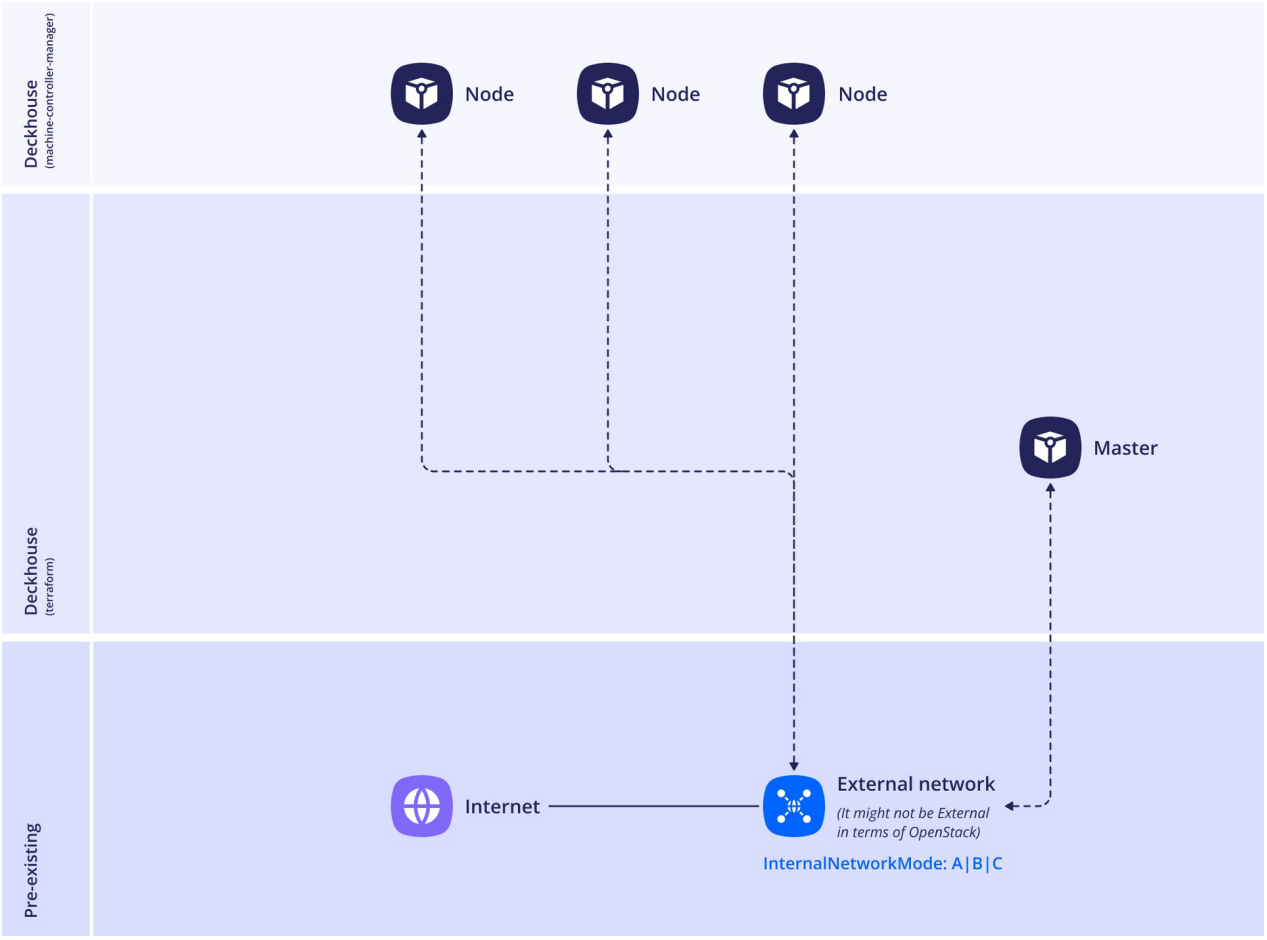
a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.



Example layout configuration:

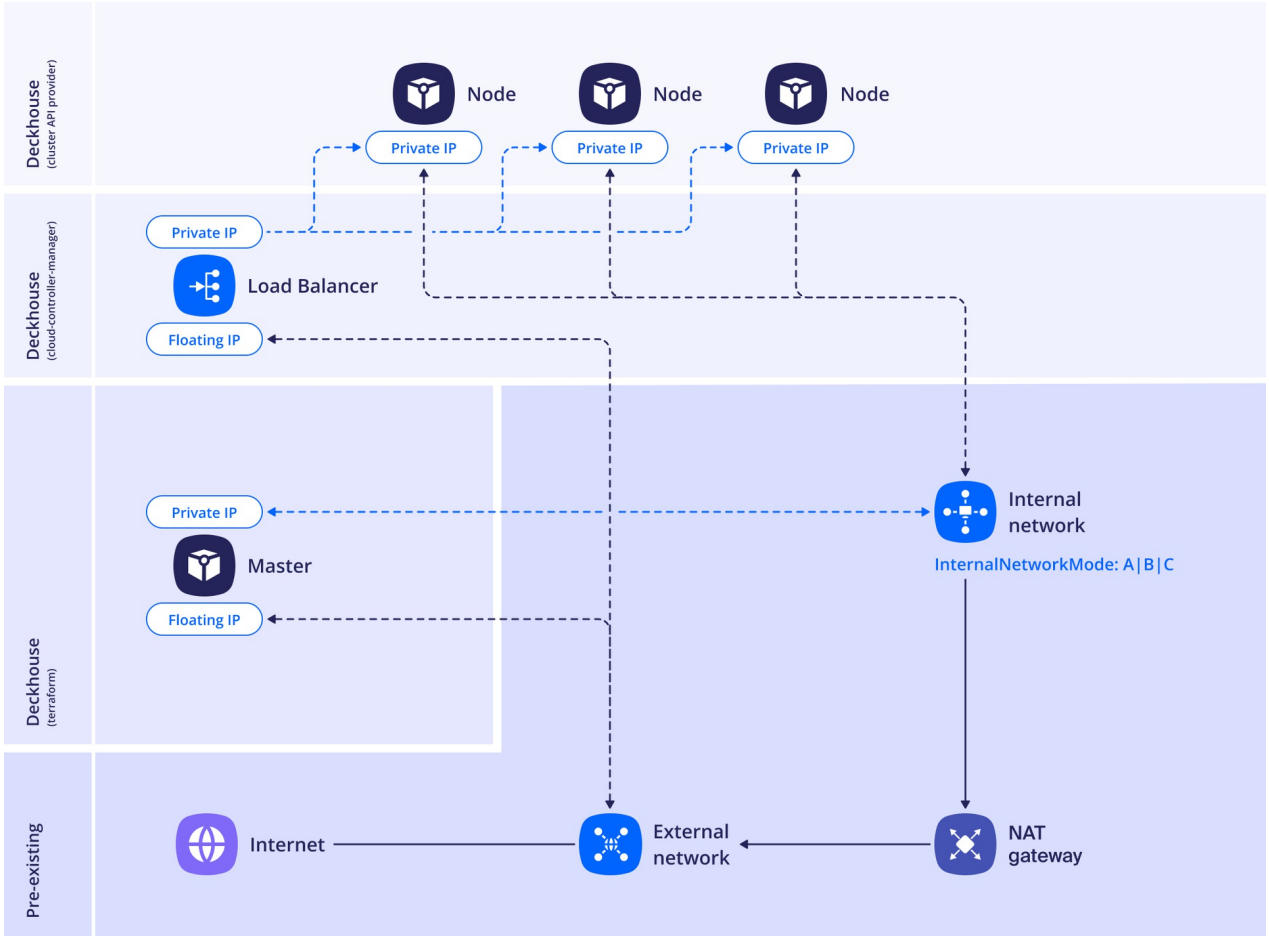
```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: StandardWithNoRouter
standardWithNoRouter:
  internalNetworkCIDR: 192.168.199.0/24        # Required.
  externalNetworkName: ext-net                # Required.
  # Optional, defines whether DHCP is enabled in specified external
  # network (true by default).
  externalNetworkDHCP: false
  internalNetworkSecurity: true|false          # Optional, true by default.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the gateway of the network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                      # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required if rootDiskSize is specified. Volume type map for node's root volume.
  volumeTypeMap:
    nova: ceph-ssd
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Simple

The master node and cluster nodes are connected to the existing network. This placement strategy can be useful if you need to merge a Kubernetes cluster with existing VMs.

⚠ This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:



- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Simple
simple:
  externalNetworkName: ext-net              # Required.
  externalNetworkDHCP: false                # Optional, true by default.
  # Optional, VXLAN by default, may also be DirectRouting
  # or DirectRoutingWithPortSecurityEnabled.
  podNetworkMode: VXLAN
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

SimpleWithInternalNetwork

The master node and cluster nodes are connected to the existing network. This layout can be useful if you need to merge a Kubernetes cluster with existing VMs.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: SimpleWithInternalNetwork
simpleWithInternalNetwork:
  # All cluster nodes have to be in the same subnet. Set either the subnet name
  # in internalSubnetName or its UUID in internalSubnetID.
  internalSubnetName: pivot-standard
  # Optional, DirectRoutingWithPortSecurityEnabled by default,
  # may also be DirectRouting or VXLAN.
  podNetworkMode: DirectRoutingWithPortSecurityEnabled
  # Optional. If set, it will be used for the load balancer default
  # configuration and ordering the master floating IP.
  externalNetworkName: ext-net
  # Optional, true by default.
  masterWithExternalFloatingIP: false
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Configuration

Integration with OpenStack is performed using the OpenStackClusterConfiguration resource. It defines the configuration of the cloud cluster in OpenStack and is used by the cloud provider when the cluster control plane is hosted in the cloud. The DP module responsible for the integration is automatically configured based on the selected layout.

To modify the configuration in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After changing node-related parameters, run the `dhctl converge` command to apply the changes.

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the OpenStack cloud provider, the instance class is a custom resource called OpenStackInstanceClass, which contains the specific configuration of the VMs.

> **i** An OpenStack cluster is deployed in a single region (`provider.region`). Zones from other regions cannot be used. For details on configuring zones for CloudPermanent and CloudEphemeral nodes, see How do I create NodeGroups in availability zones? section.

If the instance class of the group sets the `rootDiskSize` parameter, the root disk is created in Cinder. In clouds where volume types are bound to availability zones, set the volume type for each zone in the `volumeTypeMap` parameter of the OpenStackInstanceClass resource. Otherwise, provisioning a node in a zone where the default volume type is unavailable fails with the `HTTP 400 Availability zone '…' is invalid` error.

> **⚠** When the module settings are changed, **existing Machine objects in the cluster are NOT recreated** (new Machine objects will use the updated parameters). The recreation only occurs if you modify the NodeGroup or the OpenStackInstanceClass parameters.

Configuration examples

The following are two simple configuration examples for the OpenStack cloud provider.

Example 1

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: test
spec:
  flavorName: m1.large
```

Example 2

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-openstack
spec:
  version: 1
  enabled: true
  settings:
    connection:
      authURL: https://test.tests.com:5000/v3/
      domainName: default
      tenantName: default
      username: jamie
      password: nein
      region: SomeRegion
    externalNetworkNames:
    - public
    internalNetworkNames:
    - kube
    instances:
      sshKeyPairName: my-ssh-keypair
      securityGroups:
      - default
      - allow-ssh-and-icmp
    zones:
    - zone-a
    - zone-b
    tags:
      project: cms
      owner: default
```

LoadBalancer configuration

⚠ To correctly determine the client IP address, use a LoadBalancer with Proxy Protocol support.

It is recommended to limit the list of nodes added to the load balancer pool using the `loadbalancer.openstack.org/node-selector` annotation.

Without a `node-selector` restriction, cloud-controller-manager may use all suitable cluster nodes as load balancer targets. As a result, adding or removing nodes that are not related to the workload served by the load balancer may trigger an update of the load balancer pool membership. In large or frequently changing clusters, such updates may occur regularly and, in some configurations, may cause brief disruptions to existing connections.

The `annotations` field of the corresponding inlet configuration in the IngressNginxController resource supports the following annotations:

- `loadbalancer.openstack.org/node-selector`: Selects the nodes that will be used as LoadBalancer targets.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id`: Instructs OpenStack CCM to use a pre-created Octavia load balancer.
- `loadbalancer.openstack.deckhouse.io/load-balancer-address`: Instructs OpenStack CCM to associate a pre-allocated floating IP with the load balancer it creates.

DP automatically adds the specified annotations to the generated Service object of type LoadBalancer.

When using the `loadbalancer.openstack.deckhouse.io/load-balancer-id` annotation, the load balancer must meet the following requirements:

- reside in the cluster subnet
- be in the `ACTIVE` state

If `loadbalancer.openstack.deckhouse.io/load-balancer-id` is used to reference a pre-created load balancer with a custom name, associate the floating IP with its VIP port before creating the cluster. In this case, do not specify the `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotation.

When using only `loadbalancer.openstack.deckhouse.io/load-balancer-address`, the floating IP must meet the following requirements:

- not be associated with any port
- reside in the floating network configured for OpenStack CCM

If the specified floating IP is unavailable, OpenStack CCM will not be able to assign an external IP address to the Service object.

Do not add the `loadbalancer.openstack.deckhouse.io/load-balancer-id` or `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotations to application Ingress resources. Specify them only in the IngressNginxController configuration. DP will add them to the generated Service object, which is processed by `openstack-cloud-controller-manager`.

IngressNginxController with a pre-created load balancer

In the example below:

- Ingress controller pods are scheduled on frontend nodes.
- `loadbalancer.openstack.org/node-selector` limits the load balancer target pool to those frontend nodes.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id` references a pre-created Octavia load balancer whose VIP port already has a floating IP associated with it.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-id: "df7c6f73-8c68-4a11-a3e2-6268a655ce9b"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

IngressNginxController with a pre-allocated floating IP

In the example below, OpenStack CCM creates a load balancer and associates the specified unassigned floating IP with it:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-address: "203.0.113.10"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Uploading an image to OpenStack

1. Download the latest stable Ubuntu 18.04 image:

   ```
   curl -L https://cloud-images.ubuntu.com/bionic/current/bionic-server-cloudimg-amd64.img --output ~/ubuntu-18-04-cloud-amd64
   ```

2. Prepare an openrc file that contains credentials for accessing the OpenStack API.

   > **i** The method of obtaining the openrc file may vary depending on the OpenStack provider. If your provider offers the standard interface for OpenStack, follow this guide to download the file.

3. Alternatively, install the OpenStack CLI tools following the instructions.

   You can also run a container, mounting both the openrc file and the downloaded Ubuntu image:

   ```
   docker run -ti --rm -v ~/ubuntu-18-04-cloud-amd64:/ubuntu-18-04-cloud-amd64 -v ~/.openrc:/openrc jmcvea/openstack-client
   ```

4. Initialize environment variables from the openrc file:

   ```
   source /openrc
   ```

5. List the available volume types:

   ```
   openstack volume type list
   ```

   Example output:

   ```
   +--------------------------------------+---------------+-----------+
   | ID                                   | Name          | Is Public |
   +--------------------------------------+---------------+-----------+
   | 8d39c9db-0293-48c0-8d44-015a2f6788ff | ko1-high-iops | True      |
   | bf800b7c-9ae0-4cda-b9c5-fae283b3e9fd | dp1-high-iops | True      |
   | 74101409-a462-4f03-872a-7de727a178b8 | ko1-ssd       | True      |
   | eadd8860-f5a4-45e1-ae27-8c58094257e0 | dp1-ssd       | True      |
   | 48372c05-c842-4f6e-89ca-09af3868b2c4 | ssd           | True      |
   | a75c3502-4de6-4876-a457-a6c4594c067a | ms1           | True      |
   | ebf5922e-42af-4f97-8f23-716340290de2 | dp1           | True      |
   | a6e853c1-78ad-4c18-93f9-2bba317a1d13 | ceph          | True      |
   +--------------------------------------+---------------+-----------+
   ```

6. Create an image and assign the volume type as a property (this is necessary if OpenStack does not support local disks or they are unsuitable for workloads):

   ```
   openstack image create --private --disk-format qcow2 --container-format bare \
     --file /ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=dp1-high-iops ubuntu-18-04-cloud-amd64
   ```

7. Ensure the image has been created:

```
openstack image show ubuntu-18-04-cloud-amd64
```

Example output:

```
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| Field            | Value
|
+------------------+------------------------------------------------------------------------------

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the OpenStackInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the OpenStackClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Verifying security group support by the cloud provider

Run the `openstack security group list` command. If you don’t receive any errors, it means that security groups are supported.

Cinder CSI resilience during re-authentication in OpenStack

The Cinder CSI driver supports OpenStack re-authentication with service catalog refresh. This improves the reliability of

volume operations in `cinder-csi-plugin` pods that have been running for a long time without being restarted.

When a token expires or a `401 Unauthorized` response is received, the driver re-authenticates with OpenStack and updates the data used to access OpenStack API services. As a result, PersistentVolume operations, including volume attachment and detachment, continue without requiring CSI driver pods to be restarted.

This behavior is especially important for clusters where `cinder-csi-plugin` pods run for a long time without being restarted, while the OpenStack service catalog may change between the initial authentication and subsequent API requests.

Configuring online volume resize

When resizing a disk via the OpenStack API, Cinder does not pass updated size information to Nova. As a result, the disk size inside the guest OS remains unchanged.

To fix this, you must configure access to the Nova API in the `cinder.conf` file. For example:

```
[nova]
interface = admin
insecure = {{ keystone_service_internaluri_insecure | bool }}
auth_type = {{ cinder_keystone_auth_plugin }}
auth_url = {{ keystone_service_internaluri }}/v3
password = {{ nova_service_password }}
project_domain_id = default
project_name = service
region_name = {{ nova_service_region }}
user_domain_id = default
username = {{ nova_service_user_name }}
```

For more details, see the OpenStack-Ansible bug report.

Using rootDiskSize

Disks in OpenStack

A node’s disk can be either local or network-attached. In OpenStack terminology:

- A local disk is called an ephemeral disk.
- A network-attached disk is called a persistent disk (Cinder storage).

The ephemeral disk is deleted along with the VM, while the persistent disk remains in the cloud even after the VM is deleted.

- For master nodes, network-attached disks are preferred so the nodes could migrate between hypervisors.
- For ephemeral nodes, local disks are preferred for cost efficiency. However, not all cloud providers support local disks. If not supported, you have to use network-attached disks for ephemeral nodes.

Local disk (ephemeral)	Network-attached disk (persistent)
Deleted with the VM	Remains in cloud and can be reused
Less expensive	More expensive
Suitable for ephemeral nodes	Suitable for master nodes

rootDiskSize parameter

The OpenStackInstanceClass resource includes a `rootDiskSize` parameter. In OpenStack, flavors may also define a disk size.

The resulting disk type depends on the combination of the following parameters:

	flavor disk size = 0	flavor disk size > 0
`rootDiskSize` not set	*Disk size must be specified*. VM creation will fail without it.	Local disk with size from the flavor.
`rootDiskSize` set	Network-attached disk with size that equals `rootDiskSize`.	Both network-attached (`rootDiskSize`) and local (from flavor). Avoid this setup, as the cloud provider may charge for both.

> **i** In Selectel Cloud, when creating nodes with CloudEphemeral type outside zone A, you must pre-create a flavor with the target disk size. In this case, you do not need to set the `rootDiskSize` parameter.

Recommendations for master nodes and bastion with network-attached disks

- Use a flavor with zero disk size.
- Set `rootDiskSize` in the OpenStackInstanceClass resource.
- Ensure the disk type is correct:

- If specified in the OS image, it will be used.
- If not specified, the type will be taken from `volumeTypeMap`.

Recommendations for ephemeral nodes with local disks

- Use a flavor with a defined disk size.
- Do not use the `rootDiskSize` parameter in OpenStackInstanceClass.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the cloud provider's default disk type will be used.

Checking the disk size in a flavor

Run the following command:

```
openstack flavor show m1.medium-50g -C disk
```

Example output:

```
+-------+-------+
| Field | Value |
+-------+-------+
| disk  | 50    |
+-------+-------+
```

Overriding the cloud provider's default disk type

If your cloud provider offers multiple volume types, you can specify the default type for an image by setting the `cinder_img_volume_type` property in the image metadata. Any VM created from that image will use the specified volume type.

You can also create a new OpenStack image and upload it.

Example:

```
openstack volume type list
openstack image set ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=VOLUME_NAME
```

Offline disk resizing

If you encounter the following error during volume resizing, reduce the number of replicas in the affected StatefulSet to 0, wait for the volume size to update, and then scale the replicas back to the original value.

```
Warning  VolumeResizeFailed     5s (x11 over 41s)  external-resizer cinder.csi.openstack.org
resize volume "pvc-555555-ab66-4f8d-947c-296520bae4c1" by resizer "cinder.csi.openstack.org" failed:

{"computeFault": {"message": "Version 3.42 is not supported by the API. Minimum is 3.0 and maximum is 3.27.", "code": 406}}
```

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Amazon Web Services

Requirements

The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

Before you begin, you must prepare the cloud environment and provide access to AWS resources for Deckhouse Platform (DP) components that interact with the AWS API.

The `cloud-init` package must be installed on all virtual machines that will be part of the cluster. After booting up, make sure the following services are running:

- `cloud-config.service`
- `cloud-final.service`
- `cloud-init.service`

These services are required for correct EC2 instance initialization and for integration with DP infrastructure modules such as `cloud-provider-aws` and `machine-controller-manager`.

Accessing the AWS API

To access the AWS API, an IAM user with the required permissions is needed. You must create a JSON policy specification granting access to EC2, ELB, IAM, KMS, and other AWS services.

Example JSON policy with the required permission configuration:

```
{
    "Version": "2012-10-17",
    "Statement": [
        {
            "Sid": "VisualEditor0",
            "Effect": "Allow",
            "Action": [
                "autoscaling:DescribeAutoScalingGroups",
                "autoscaling:DescribeLaunchConfigurations",
                "autoscaling:DescribeTags",
                "ec2:AllocateAddress",
                "ec2:AssociateAddress",
                "ec2:AssociateRouteTable",
                "ec2:AttachInternetGateway",
                "ec2:AttachVolume",
                "ec2:AuthorizeSecurityGroupEgress",
                "ec2:AuthorizeSecurityGroupIngress",
                "ec2:CreateInternetGateway",
                "ec2:CreateKeyPair",
                "ec2:CreateNATGateway",
                "ec2:CreateRoute",
                "ec2:CreateRouteTable",
                "ec2:CreateSecurityGroup",
                "ec2:CreateSubnet",
                "ec2:CreateTags",
                "ec2:CreateVolume",
                "ec2:CreateVpc",
                "ec2:DeleteInternetGateway",
                "ec2:DeleteKeyPair",
                "ec2:DeleteNATGateway",
                "ec2:DeleteRoute",
                "ec2:DeleteRouteTable",
                "ec2:DeleteSecurityGroup",
                "ec2:DeleteSubnet",
                "ec2:DeleteTags",

                "iam:TagRole",
                "kms:DescribeKey",
                "sts:GetCallerIdentity"
            ],
            "Resource": "*"
        }
    ]
}
```

Configuring IAM via the AWS web console

1. Create policies:
   - Go to **Identity and Access Management (IAM)** → **Policies**.
   - Click **Create policy**.
   - Switch to the **JSON** tab and paste the prepared JSON specification.
   - Click **Next: Tags**, then **Next: Review**.
   - Provide a name for the policy, for example, D8CloudProviderAWS.
   - Click **Create policy**.
2. Create a user:
   - Go to **IAM** → **Users**.
   - Click **Add users**.
   - Enter a username, for example, deckhouse.
   - Under **Select AWS credential type**, choose **Access key** → **Programmatic access**.
   - Click **Next: Permissions**.
3. Attach policies to the user:
   - Choose **Attach existing policies directly**.
   - Enter the name of the policy created earlier in the filter field and check the box next to it.
   - Click **Next: Tags**, then **Next: Review**.
   - Click **Create user**.

> Save the generated `Access key ID` and `Secret access key`. You will need these to configure DP.

Ensure that your account (and the created user) has access to the required regions. To verify this, select the region from the dropdown menu in the upper-right corner. If the region switches successfully, access is available. If not, you may see a message like this:

Click **Continue** to enable the region.

Configuring IAM via AWS CLI

You can also configure IAM using the command-line interface. Follow these steps:

1. Save the JSON specification to a file named `policy.json`:

   ```
   cat > policy.json << EOF
   <Policy JSON spec>
   EOF
   ```

2. Create a new policy named `D8CloudProviderAWS` with the `ARN` details using the specification from the `policy.json`:

   ```
   aws iam create-policy --policy-name D8CloudProviderAWS --policy-document file://policy.json
   ```

   Example output:

```
{
   "Policy": {
      "PolicyName": "D8CloudProviderAWS",
      "PolicyId": "AAA",
      "Arn": "arn:aws:iam::123:policy/D8CloudProviderAWS",
      "Path": "/",
      "DefaultVersionId": "v1",
      "AttachmentCount": 0,
      "PermissionsBoundaryUsageCount": 0,
      "IsAttachable": true,
      "CreateDate": "2020-08-27T02:52:06+00:00",
      "UpdateDate": "2020-08-27T02:52:06+00:00"
   }
}
```

3. Create a new user:

   ```
   aws iam create-user --user-name deckhouse
   ```

   Example output:

   ```
   {
      "User": {
         "Path": "/",
         "UserName": "deckhouse",
         "UserId": "AAAXXX",
         "Arn": "arn:aws:iam::123:user/deckhouse",
         "CreateDate": "2020-08-27T03:05:42+00:00"
      }
   }
   ```

4. Grant access to the API and save `AccessKeyId` and `SecretAccessKey`:

   ```
   aws iam create-access-key --user-name deckhouse
   ```

   Example output:

   ```
   {
      "AccessKey": {
         "UserName": "deckhouse",
         "AccessKeyId": "XXXYYY",
         "Status": "Active",
         "SecretAccessKey": "ZZZzzz",
         "CreateDate": "2020-08-27T03:06:22+00:00"
      }
   }
   ```

5. Attach the policy to the user combining `User` and `Policy`:

   ```
   aws iam attach-user-policy --user-name username --policy-arn arn:aws:iam::123:policy/D8CloudProviderAWS
   ```

Configuring IAM via Terraform

Example Terraform resource configuration:

```
resource "aws_iam_user" "user" {
  name = "deckhouse"
}

resource "aws_iam_access_key" "user" {
  user = aws_iam_user.user.name
}

resource "aws_iam_policy" "policy" {
  name       = "D8CloudProviderAWS"
  path       = "/"
  description = "Deckhouse policy"

  policy = <<EOF
<JSON policy specification>
EOF
}

resource "aws_iam_user_policy_attachment" "policy-attachment" {
  user      = aws_iam_user.user.name
  policy_arn = aws_iam_policy.policy.arn
}
```

Using a custom IAM role for nodes (iamNodeRole)

The `iamNodeRole` parameter in the AWSClusterConfiguration resource lets you override the default IAM role that DP assigns to all EC2 instances of the cluster nodes.

By default, DP creates and assigns an IAM role named `<prefix>-node`, where `<prefix>` is the value of the `global` ModuleConfig `prefix` parameter. This role includes the minimum permissions required for node operation.

You can specify the IAM role name in the `iamNodeRole` parameter if you want to:

- Use a pre-created IAM role managed manually.
- Grant additional permissions to nodes (for example, access to specific AWS services).

> **i** The specified role must include all permissions required by DP. Without them, the nodes will not function properly. In particular, it must include the same permissions as the default `<prefix>-node` role, even if they are assigned manually.

For more information on IAM roles for AWS EC2, refer to the AWS documentation.

Additional resources

- Module `cloud-provider-aws` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

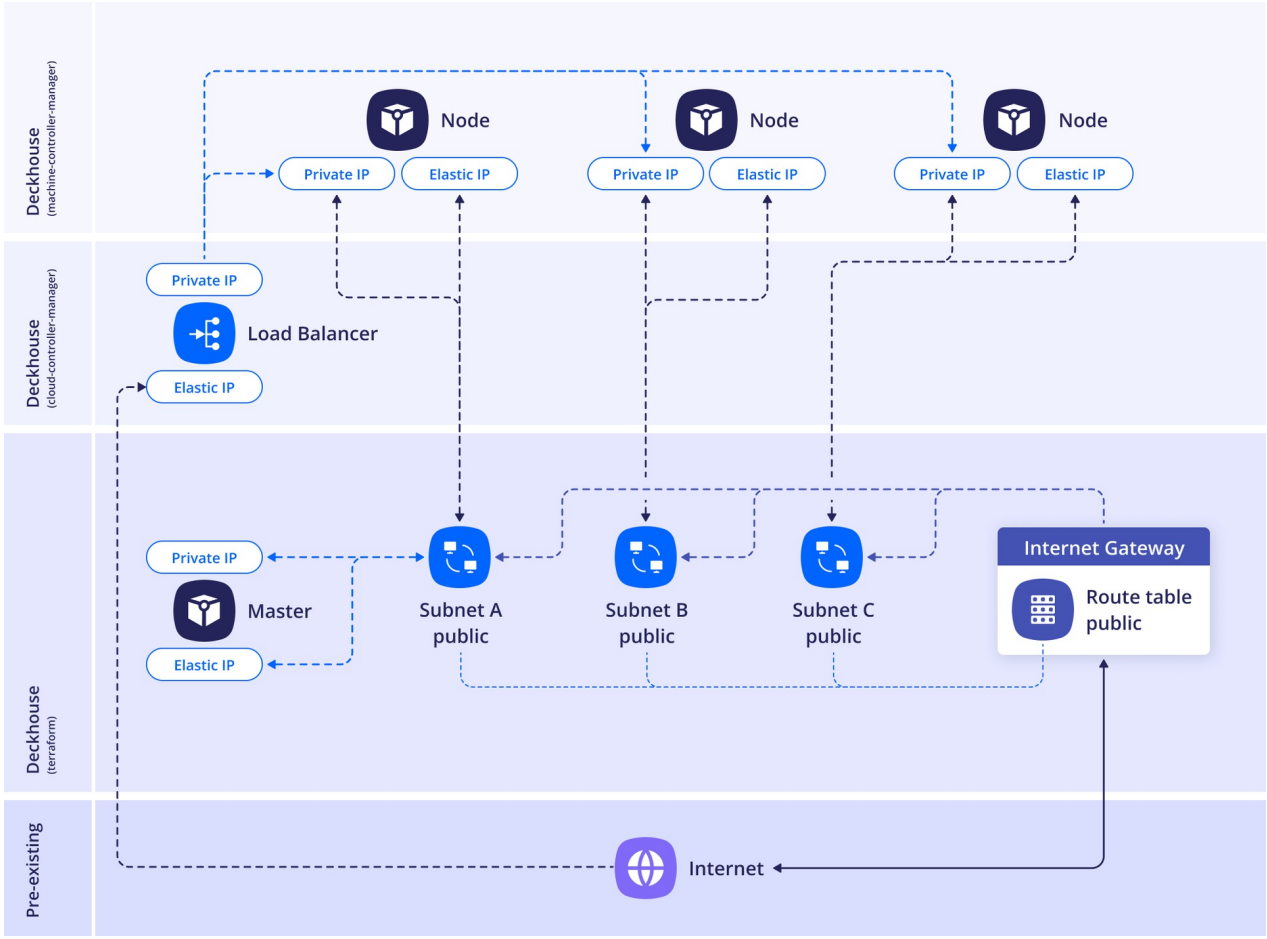
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.



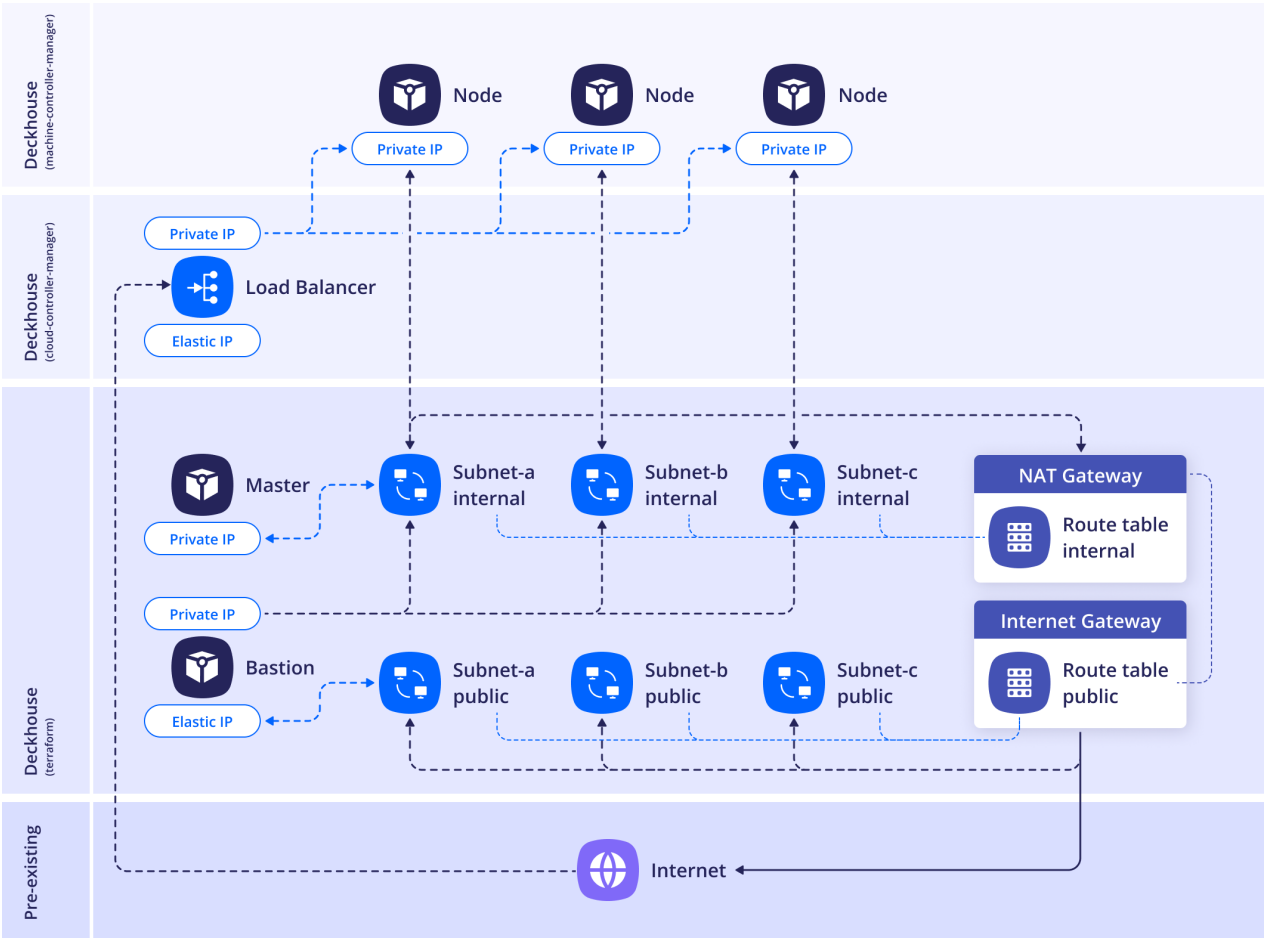
Layouts and configuration in Amazon Web Services

This section describes cluster layouts in AWS infrastructure and their related parameters. The selected layout affects how public IP addresses are assigned, NAT usage, and how nodes are accessed.

WithoutNAT

This is the recommended layout.

Each node is assigned a public IP address (Elastic IP), and no NAT Gateway is used. This layout allows direct access to nodes via public IP addresses and simplifies outgoing traffic routing.



Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: AWSClusterConfiguration
layout: WithoutNAT
vpcNetworkCIDR: "10.241.0.0/16"
nodeNetworkCIDR: "10.241.32.0/20"
sshPublicKey: <SSH_PUBLIC_KEY>
provider:
  providerAccessKeyId: '<AWS_ACCESS_KEY>'
  providerSecretAccessKey: '<AWS_SECRET_ACCESS_KEY>'
  region: eu-central-1
masterNodeGroup:
  # Number of master nodes.
  # If you specify more than one master node, an etcd cluster will be created automatically.
  replicas: 1
  instanceClass:
    # Instance type to use.
    instanceType: m5.xlarge
    # ID of the Amazon Machine Image (AMI).
    # AMI catalog can be found in the AWS Console: EC2 → AMI Catalog.
    ami: ami-0aad10862ade98f27
    # Disk size for the master node VM.
    diskSizeGb: 30
    # Disk type to use for the master node VM.
    diskType: gp3
nodeGroups:
  - name: mydb
    nodeTemplate:
      labels:
        node-role.kubernetes.io/mydb: ""
    replicas: 2
    instanceClass:
      instanceType: t2.medium
      ami: ami-0aad10862ade98f27
    additionalTags:
      backup: srv1
tags:
  team: torpedo
```

WithNAT

⚠ In this layout, the NAT Gateway is always created in zone `a`. If cluster nodes are placed in other zones, a failure in zone a may cause the cluster to become unavailable. A bastion host is required to connect to the nodes.

In this layout, a NAT Gateway is used for accessing the internet, and nodes do not receive public IP addresses. Access to nodes is only possible through a bastion host, which is placed in a separate subnet.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: AWSClusterConfiguration
layout: WithNAT
provider:
  providerAccessKeyId: '<AWS_ACCESS_KEY>'
  providerSecretAccessKey: '<AWS_SECRET_ACCESS_KEY>'
  region: eu-central-1
withNAT:
  bastionInstance:
    zone: eu-central-1a
    instanceClass:
      instanceType: m5.large
      ami: ami-0aad10862ade98f27
      diskType: gp3
masterNodeGroup:
  # Number of master nodes.
  # If you specify more than one master node, an etcd cluster will be created automatically.
  replicas: 1
  instanceClass:
    # Instance type to use.
    instanceType: m5.xlarge
    # ID of the Amazon Machine Image (AMI).
    # AMI catalog can be found in the AWS Console: EC2 → AMI Catalog.
    ami: ami-0aad10862ade98f27
    # Disk size for the master node VM.
    diskSizeGb: 30
    # Disk type to use for the master node VM.
    diskType: gp3
nodeGroups:
  - name: mydb
    nodeTemplate:
      labels:
        node-role.kubernetes.io/mydb: ""
    replicas: 2
    instanceClass:
      instanceType: t2.medium
      ami: ami-0aad10862ade98f27
    additionalTags:
      backup: me
vpcNetworkCIDR: "10.241.0.0/16"
nodeNetworkCIDR: "10.241.32.0/20"
sshPublicKey: "<SSH_PUBLIC_KEY>"
tags:
  team: torpedo
```

Defining AWSClusterConfiguration

The AWSClusterConfiguration resource describes the cluster settings and is used by Deckhouse Platform (DP) to:

- Define the layout and network CIDRs.
- Configure master and worker nodes.
- Specify AWS API connection parameters (such as access keys and region).
- Define common and custom tags.
- Configure the bastion host (for the WithNAT layout).

Required fields:

- `apiVersion`: Must be set to `deckhouse.io/v1`.
- `kind`: Always AWSClusterConfiguration.

Example resource header:

```
apiVersion: deckhouse.io/v1
kind: AWSClusterConfiguration
```

To edit this resource in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

After editing, apply the changes with the following command:

```
dhctl converge
```

Internal addressing and subnets

The `nodeNetworkCIDR` parameter defines the address range to be split among availability zones. This range must match or be a subset of `vpcNetworkCIDR`. Subnets are automatically created based on the number of zones in the region.

Example:

```
nodeNetworkCIDR: 10.241.1.0/20
vpcNetworkCIDR: 10.241.0.0/16
```

Security groups

AWS security groups are used to manage incoming and outgoing traffic to virtual machines. In DP, they can be used to:

- Allow access to cluster nodes from other subnets.
- Open access to applications running on static nodes.
- Restrict or allow access to external resources based on security policies.

When the `disableDefaultSecurityGroup: false` parameter is set, DP creates the following default security groups when a cluster is created:

- `<CLUSTER_PREFIX>-node`, assigned to cluster nodes:
  - Allows any outgoing traffic to `0.0.0.0/0`.
  - Allows any incoming traffic from the `<CLUSTER_PREFIX>-loadbalancer` group.
  - Allows any incoming traffic from nodes in the same `<CLUSTER_PREFIX>-node` group.
  - Allows incoming traffic over the ICMP protocol from the CIDRs listed in `publicNetworkAllowList` (default `0.0.0.0/0`).
- `<CLUSTER_PREFIX>-loadbalancer`, used by load balancers:
  - Allows any incoming traffic from the CIDRs listed in `publicNetworkAllowList`.
  - Allows any outgoing traffic to the `<CLUSTER_PREFIX>-node` group.
- `<CLUSTER_PREFIX>-ssh-accessible`, created if `sshAllowList` is set. It allows incoming traffic over the TCP protocol on port `22` from the listed CIDRs (default `0.0.0.0/0`). It is assigned to master nodes or to the bastion host in the WithNAT layout.

In addition to the default groups, you can attach custom security groups created in the cloud beforehand.

You can assign additional security groups in the following cases:

Node type	Where to configure
Master nodes	In the `masterNodeGroup.instanceClass.additionalSecurityGroups` field of the AWSClusterConfiguration resource
Static worker nodes	In the `nodeGroups[].instanceClass.additionalSecurityGroups` field of the same resource
Ephemeral nodes	In the `spec.additionalSecurityGroups` field of the AWSInstanceClass object

In all cases, the `additionalSecurityGroups` parameter must be an array of strings (AWS security group IDs or names).

If `disableDefaultSecurityGroup: true` is set, the default security groups will not be created.

When using `disableDefaultSecurityGroup: true`, you must manually create all required security groups to allow access to cluster nodes. Additionally, you must explicitly specify them in the following parameters:

- `additionalSecurityGroups` in the `masterNodeGroup` section of the AWSClusterConfiguration resource;
- `additionalSecurityGroups` in the AWSInstanceClass resource;
- `additionalSecurityGroups` in the `nodeGroups.instanceClass` section.

To configure the security groups used by load balancers, specify them using the `service.beta.kubernetes.io/aws-load-balancer-security-groups` annotation.

Setting up VPC peering

The following example shows how to set up VPC peering between two sample VPCs: `vpc-a` and `vpc-b`.

⚠ The IPv4 CIDR blocks of both VPCs must be different.

To configure peering, follow these steps:

1. Go to the region where `vpc-a` is working.
2. Navigate to VPC → VPC Peering Connections → Create Peering Connection, then configure the peering:
   - Name: `vpc-a-vpc-b`.
   - Fill in “Local” and “Another VPC” sections.
3. Go to the region where `vpc-b` is working.
4. Navigate to VPC → VPC Peering Connections.
5. Select the created connection and click **Accept Request**.
6. In `vpc-a`, add routes to the `vpc-b` CIDR in all route tables via the peering connection.
7. In `vpc-b`, add routes to the `vpc-a` CIDR in all route tables via the peering connection.

Configuring access via bastion host

To access nodes in private subnets, use the `withNAT.bastionInstance` parameter in AWSClusterConfiguration. The

bastion host is provisioned with the infrastructure according to the `instanceClass` settings.

The following scenarios are supported:

- The bastion host already exists in an external VPC:
  1. Run the base infrastructure bootstrap: `dhctl bootstrap-phase base-infra`.
  2. Set up VPC peering between the external and new VPC.
  3. Continue installation using the bastion host: `dhctl bootstrap --ssh-bastion...`.
- The bastion host is required in the new VPC:
  1. Run the base infrastructure bootstrap: `dhctl bootstrap-phase base-infra`.
  2. Manually launch the bastion host in the `<CLUSTER PREFIX>-public-0` subnet.
  3. Continue installation using the bastion host: `dhctl bootstrap --ssh-bastion...`.

Creating a cluster in a new VPC with an existing bastion host

1. Bootstrap the cluster's base infrastructure:

   ```
   dhctl bootstrap-phase base-infra --config config
   ```

2. Set up VPC peering as described above.
3. Continue cluster installation. When prompted about the Terraform cache, answer with `y`:

   ```
   dhctl bootstrap --config config --ssh-...
   ```

Creating a cluster in a new VPC and deploying a bastion host

1. Bootstrap the cluster's base infrastructure:

   ```
   dhctl bootstrap-phase base-infra --config config
   ```

2. Manually launch a bastion host in the `<CLUSTER_PREFIX>-public-0` subnet.
3. Continue cluster installation. When prompted about the Terraform cache, answer with `y`:

   ```
   dhctl bootstrap --config config --ssh-...
   ```

Using an existing VPC (existingVPCID)

The `existingVPCID` parameter in the AWSClusterConfiguration resource lets you use an existing VPC for DP cluster deployment instead of automatically creating a new one.

This may be useful when:

- Your AWS infrastructure is already partially deployed.
- You need to integrate with other services or resources in the same VPC.
- Security policies or architectural guidelines prevent automatic VPC creation.

> ⚠ If the existing VPC already has an Internet Gateway, the base infrastructure bootstrap will fail. Reusing an existing Internet Gateway is not supported in the current DP version.

Compatibility with other parameters:

- If `existingVPCID` is specified, do not specify `vpcNetworkCIDR` as they are mutually exclusive.
- The `nodeNetworkCIDR` parameter can (and should) be specified. It must be a subset of the existing VPC.

Preemptible nodes

Preemptible virtual machines in AWS are called Spot Instances. To make a node group order them, set the `spot` parameter of the AWSInstanceClass resource to `true`.

When an EC2 Instance Rebalance Recommendation signals an elevated risk of Spot Instance interruption, the `node-termination-handler` component automatically applies the `aws-node-termination-handler/rebalance-recommendation` taint with `effect: NoSchedule` to the CloudEphemeral node. This taint prevents the scheduler from placing new workloads on the node unless they have a matching toleration.

The `aws-node-termination-handler/spot-itn` taint indicates a notice of an upcoming Spot Instance interruption.

If either taint is present, the `node-manager` module cordons and drains the node, then deletes it. If the node count in a zone falls below the `minPerZone` parameter value, the group provisions new nodes.

The recommendation allows node decommissioning to start before an interruption notice arrives. AWS may send both notifications at the same time.

How to create such nodes and the limitations of their use are described in "How to create preemptible nodes in AWS?".

Replacing the OS image

The OS image of the nodes is set by the `ami` parameter of the AWSInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the AWSClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from "How do I replace the OS image in a cloud cluster?" .

Storage and load balancing in Amazon Web Services

This section covers the following additional aspects of integrating Deckhouse Platform (DP) with AWS:

- Connecting cloud disks using CSI.
- Automatic StorageClass creation.
- Using LoadBalancer.
- Accessing via bastion host.
- Connecting manually created CloudStatic nodes.

Storage (CSI and StorageClass)

DP integrates with AWS storage via CSI. This allows the cluster to automatically provision and attach disks to its nodes.

StorageClasses are created automatically for the following disk types:

- `gp3`
- `gp2`
- `sc1`
- `st1`

Disk types `io1` and `io2` are also supported with IOPS and throughput settings in ModuleConfig.

To exclude unnecessary StorageClasses from the cluster, specify filters in `settings.storageClass.exclude`:

```
settings:
  storageClass:
    exclude:
    - sc.*
    - st1
```

You can also define and configure custom StorageClasses explicitly, including parameters such as `iops`, `throughput`, and `type`:

```
settings:
  storageClass:
    provision:
    - name: fast-io
      type: io2
      iopsPerGB: "50"
```

Expanding volume size

To resize a volume (for example, when running low on disk space), follow these steps:

1. Modify the `spec.resources.requests.storage` parameter in the corresponding PersistentVolumeClaim object. The operation is performed automatically and usually takes less than a minute. You can monitor progress with the following command:

   ```
   kubectl describe pvc <claim-name>
   ```

2. After resizing, wait at least 6 hours and ensure the volume status is `in-use` or `available`. Only then you can safely perform additional size changes. See AWS documentation for details.

Load balancing

DP supports LoadBalancer Services via AWS Load Balancer Controller.

To control how AWS resources are created, use annotations on the Service object:

```
metadata:
  annotations:
    service.beta.kubernetes.io/aws-load-balancer-type: "nlb"
    service.beta.kubernetes.io/aws-load-balancer-subnets: "subnet-12345,subnet-67890"
```

Where:

- `service.beta.kubernetes.io/aws-load-balancer-type`: If set to none, only a target group is created (no

LoadBalancer).
- `service.beta.kubernetes.io/aws-load-balancer-backend-protocol`: Only applicable when `aws-load-balancer-type` is `none`. Specifies the protocol for communication with the target group. Supported values:
  - `tcp` (default)
  - `tls`
  - `http`
  - `https`

> **i** When you change this annotation, `cloud-controller-manager` will attempt to recreate the target group. If it's already associated with an NLB or ALB, the deletion will fail, and the controller will enter a retry loop. To avoid this, manually detach the load balancer from the group.
>
> If Ingress nodes are not available in all zones, explicitly specify subnets using `aws-load-balancer-subnets`.

Configuring LoadBalancer when Ingress nodes are not in all zones

If your AWS cluster does not have Ingress nodes in every zone, you must explicitly list the subnets to be used by the Load Balancer via the `service.beta.kubernetes.io/aws-load-balancer-subnets` annotation:

```
metadata:
  annotations:
    service.beta.kubernetes.io/aws-load-balancer-subnets: "subnet-foo,subnet-bar"
```

This is especially important when manually configuring Ingress controllers or using non-standard node layout.

To retrieve the current list of subnets used in your DP setup, run the following:

```
kubectl -n d8-system exec svc/deckhouse-leader -c deckhouse \
  -- deckhouse-controller module values cloud-provider-aws -o json | \
  jq -r '.cloudProviderAws.internal.zoneToSubnetIdMap'
```

Connecting CloudStatic nodes

To connect manually created EC2 instances to a DP cluster, follow these steps:

1. Attach the IAM role `<prefix>-node`.
2. Attach the security group `<prefix>-node`.
3. Add the following tags:

   ```
   "kubernetes.io/cluster/<cluster_uuid>" = "shared"
   "kubernetes.io/cluster/<prefix>" = "shared"
   ```

To get the `cluster_uuid`, use the following command:

```
kubectl -n kube-system get cm d8-cluster-uuid -o json | jq -r '.data."cluster-uuid"'
```

To get the `prefix`, use the following command:

```
d8 k get mc global -o jsonpath='{.spec.settings.prefix}{"\n"}'
```

If the value is empty, get it from the deprecated `cloud.prefix` parameter of ClusterConfiguration (the prefix has moved to the ModuleConfig `global`):

```
d8 k -n kube-system get secret d8-cluster-configuration -o json | \
  jq -r '.data."cluster-configuration.yaml"' | base64 -d | grep prefix
```

Additional resources

- Global custom resources
- Module `cloud-provider-aws` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with Amazon Web Services

Working with Amazon Elastic Container Registry (ECR)

To allow cluster nodes to access private Amazon ECR repositories, follow these steps:

1. Define read permissions for container images in the repository policies. It’s important that the `Principal` field includes the IAM Role attached to the Deckhouse Platform (DP) nodes.

   Example policy:

   ```
   {
     "Version": "2012-10-17",
     "Statement": [
       {
         "Sid": "RepositoryRead",
         "Effect": "Allow",
         "Principal": {
           "AWS": "arn:aws:iam::xxx:role/xxx-node"
         },
         "Action": [
           "ecr:BatchCheckLayerAvailability",
           "ecr:BatchGetImage",
           "ecr:DescribeImages",
           "ecr:DescribeRepositories",
           "ecr:GetAuthorizationToken",
           "ecr:GetDownloadUrlForLayer",
           "ecr:ListImages",
           "ecr:ListTagsForResource"
         ]
       }
     ]
   }
   ```

2. Set this policy via the AWS Console. Go to **Amazon ECR → Private registry → Repositories →** select the desired repository **→ Permissions**.

3. Add `ecr:GetAuthorizationToken` to `additionalRolePolicies` in your AWSClusterConfiguration so that nodes can automatically retrieve an authorization token to pull images:

   ```
   additionalRolePolicies:
     - ecr:GetAuthorizationToken
     - ecr:BatchGetImage
     - ecr:DescribeRepositories
   ```

The additionalRolePolicies parameter lets you extend the set of IAM actions granted to EC2 instances managed by DP. This is particularly useful if access to the following is required:

- Amazon ECR
- Amazon S3
- Other AWS services that require specific permissions

If this parameter is not set, IAM roles will only include the basic actions:

```
ec2:DescribeTags
ec2:DescribeInstances
```

Additional resources

- Module `cloud-provider-aws` provider configuration

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Microsoft Azure

Requirements

> The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

To ensure Deckhouse Platform (DP) works correctly with Microsoft Azure, the following conditions must be met:

- The selected region must support Availability Zones.
- All virtual machines must have the `cloud-init` package installed. After the VMs start, the following services must be active:
  - `cloud-config.service`
  - `cloud-final.service`

- `cloud-init.service`

⚠ Starting with version 1.77, new clusters in Azure use the Cilium CNI by default with pod traffic tunneling over VXLAN. In existing clusters, the CNI stays unchanged.

Make sure all nodes run Linux kernel 5.8 or newer and that firewall rules allow UDP traffic between nodes. For the list of ports, see Network interaction of the platform components; for CNI settings, see Internal network configuration.

Accessing the Azure API

To manage Azure resources from DP, you need a service account with the `Contributor` role within the appropriate subscription. Follow these steps:

1. Install Azure CLI and log in:

   ```
   export SUBSCRIPTION_ID=$(az login | jq -r '.[0].id')
   ```

2. Create a service account:

   ```
   az ad sp create-for-rbac --role="Contributor" --scopes="/subscriptions/$SUBSCRIPTION_ID" --name
   "DeckhouseCANDI"
   ```

   Example output:

   ```
   {
    "appId": "<CLIENT_ID>",
    "displayName": "DeckhouseCANDI",
    "password": "<CLIENT_SECRET>",
    "tenant": "<TENANT_ID>"
   }
   ```

   Specify the output values in the AzureClusterConfiguration object:

Field	Value from the output
`clientId`	`appId`
`clientSecret`	`password`
`tenantId`	`tenant`

3. Authenticate in Azure CLI using the created service account's credentials:

   ```
   az login --service-principal -u <CLIENT_ID> -p <CLIENT_SECRET> --tenant <TENANT_ID>
   ```

ℹ By default, the `clientSecret` is valid for 1 year, and no automatic renewal is supported. To set a longer expiration period, refer to the official Azure documentation.

Additional resources

- Module `cloud-provider-azure` provider configuration

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in Microsoft Azure

This section describes the cluster deployment layout in Microsoft Azure infrastructure and the associated parameters.

Standard

Standard is the supported deployment layout with the following characteristics:

- A separate resource group is created for the cluster.
- Each instance is assigned a public IP address by default (used only for accessing the internet).
- Up to 64,000 SNAT ports are available per public IP address.
- A NAT Gateway is supported and billable. It allows using static public IP addresses for SNAT.
- Public IPs can be assigned to both master nodes and nodes created via Terraform.
- If the master node does not have a public IP, a bastion host and VNet peering between clusters are required.
- Peering between the cluster's VNet and other VNets is supported.

When a cluster is created, Deckhouse Platform (DP) creates a Network Security Group (NSG) named after the cluster prefix and associates it with the node subnet.

The following rules will be created:

- `AllowIcmp`: Allows incoming traffic over the ICMP protocol from any source.
- `AllowSsh`: Allows incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList`. If the list is not set, traffic is allowed from any source.

You cannot attach a pre-created custom NSG to nodes through the DP parameters. To restrict SSH access, use `sshAllowList`.

Example configuration:

```
apiVersion: deckhouse.io/v1
kind: AzureClusterConfiguration
layout: Standard
sshPublicKey: "<SSH_PUBLIC_KEY>"      # Required.
vNetCIDR: 10.50.0.0/16              # Required.
subnetCIDR: 10.50.0.0/24            # Required.
standard:
  natGatewayPublicIpCount: 1         # Optional (0 by default).
masterNodeGroup:
  replicas: 1
  zones: ["1"]                     # Optional (["1"] by default).
  instanceClass:
    machineSize: Standard_F4         # Required.
    diskSizeGb: 32
    urn: Canonical:UbuntuServer:18.04-LTS:18.04.202010140  # Required.
    enableExternalIP: false          # Optional (true by default).
provider:
  subscriptionId: "<SUBSCRIPTION_ID>"  # Required.
  clientId: "<CLIENT_ID>"            # Required.
  clientSecret: "<CLIENT_SECRET>"     # Required.
  tenantId: "<TENANT_ID>"            # Required.
  location: "westeurope"             # Required.
peeredVNets:                        # Optional.
  - resourceGroupName: kube-bastion   # Required.
    vnetName: kube-bastion-vnet       # Required.
```

Replacing the OS image

The OS image of the nodes is set by the `urn` parameter of the AzureInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the AzureClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Additional resources

- Module `cloud-provider-azure` provider configuration
- Module `cloud-provider-azure` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage and load balancing in Microsoft Azure

Storage

When running on Azure, Deckhouse Platform (DP) automatically creates the following StorageClass resources:

Name	Disk type
`managed-standard`	Standard_LRS
`managed-standard-ssd`	StandardSSD_LRS
`managed-premium`	Premium_LRS

You can additionally:

- Disable unneeded storage classes using the `exclude` parameter.
- Define custom StorageClass resources with the target throughput and IOPS settings.

Example configuration in a ModuleConfig:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-azure
spec:
  version: 1
  enabled: true
  settings:
    storageClass:
      provision:
      - name: managed-ultra-ssd
        type: UltraSSD_LRS
        diskIOPSReadWrite: 600
        diskMBpsReadWrite: 150
      exclude:
      - managed-standard.*
      - managed-premium
```

Load balancing

DP automatically creates LoadBalancer resources in Azure when using Kubernetes Service objects of the LoadBalancer type.

Additional features:

- NAT Gateway is supported. You can explicitly define the number of public IP addresses for SNAT using the `natGatewayPublicIpCount` parameter.
- VNet peering can be configured, including with a bastion host or other VNets in the cloud.
- Service Endpoints are supported. They provide secure and direct connections to Azure services without using public IPs. For more details, refer to Integration with Microsoft Azure services.

Additional resources

- Module `cloud-provider-azure` parameters
- Module `cloud-provider-azure` provider configuration

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with Microsoft Azure services

Deckhouse Platform (DP) leverages Azure cloud features for full integration with Kubernetes. When running a cluster on Azure, it automatically:

- Creates network routes for the PodNetwork.
- Configures external LoadBalancers for Kubernetes Service objects.
- Removes nodes from the cluster that no longer exist in the cloud.
- Updates node metadata to reflect the current configuration.
- Provisions disks for nodes via CSI.
- Connects the required CNI network (`cni-cilium` is used).
- Makes AzureInstanceClass definitions available for virtual machines, which can be used later in NodeGroup configurations.

> All outgoing traffic from the cluster comes through LoadBalancers. If no LoadBalancer is configured to handle UDP traffic, all outgoing UDP traffic will be blocked, which can affect NTP utilities such as `ntpdate`, `chrony`, etc. To resolve this, manually add a rule for any UDP port to an existing LoadBalancer or create a Kubernetes Service of the LoadBalancer type with a UDP port.

Support for Service Endpoints

DP supports connections to Azure services via Service Endpoints. These endpoints:

- Allow access to Azure services without using public IP addresses.
- Route traffic over optimized Azure backbone infrastructure.
- Simplify access control and improve security.

List of supported Service Endpoints:

```
Microsoft.AzureActiveDirectory
Microsoft.AzureCosmosDB
Microsoft.ContainerRegistry
Microsoft.CognitiveServices
Microsoft.EventHub
Microsoft.KeyVault
Microsoft.ServiceBus
Microsoft.Sql
Microsoft.Storage
Microsoft.Storage.Global
Microsoft.Web
```

Specify the required services using the `serviceEndpoints` parameter in the AzureClusterConfiguration object.

Additional resources

- Module `cloud-provider-azure` custom resources
- Module `cloud-provider-azure` provider configuration
- Module `cni-cilium` documentation
- Module `node-manager` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Google Cloud Platform

To manage Google Cloud resources using Deckhouse Platform, you need to create a Service Account.

> ⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

> ⚠ Starting with version 1.77, new clusters in Google Cloud use the Cilium CNI by default with pod traffic tunneling over VXLAN. In existing clusters, the CNI stays unchanged.
>
> Make sure all nodes run Linux kernel 5.8 or newer and that firewall rules allow UDP traffic between nodes. For the list of ports, see Network interaction of the platform components; for CNI settings, see Internal network configuration.

Creating a service account

You can find detailed instructions on how to create a service account in the official Google Cloud documentation.

> ⚠ A created `service account key` cannot be recovered. If lost, it must be deleted and recreated.

Setup via Google Cloud console

Go to the Google Cloud console, select your project, and create a new service account (you can also choose an existing one).

The created service account must be assigned the following roles:

```
Compute Admin
Service Account User
Network Management Admin
```

You can assign roles during service account creation or modify them later.

To generate the `service account key` in JSON format, on the service accounts page, click the three vertical dots in the **Actions** column and select **Manage keys**. Then click **Add key → Create new key → Key type → JSON**.

Setup via Google Cloud CLI

Install and initialize the Google Cloud CLI by following the official instructions.

To create a service account using the CLI, follow these steps:

1. Export environment variables:

   ```
   export PROJECT_ID=sandbox
   export SERVICE_ACCOUNT_NAME=deckhouse
   ```

2. Set the project:

```
gcloud config set project $PROJECT_ID
```

3. Create a service account:

```
gcloud iam service-accounts create $SERVICE_ACCOUNT_NAME
```

4. Assign roles to the created service account:

```
for role in roles/compute.admin roles/iam.serviceAccountUser roles/networkmanagement.admin;
do gcloud projects add-iam-policy-binding ${PROJECT_ID} --
member=serviceAccount:${SERVICE_ACCOUNT_NAME}@${PROJECT_ID}.iam.gserviceaccount.com \
   --role=${role}; done
```

   A list of required roles:

```
roles/compute.admin
roles/iam.serviceAccountUser
roles/networkmanagement.admin
```

5. Verify the assigned roles:

```
gcloud projects get-iam-policy ${PROJECT_ID} --flatten="bindings[].members" --
format='table(bindings.role)' \
     --filter="bindings.members:${SERVICE_ACCOUNT_NAME}@${PROJECT_ID}.iam.gserviceaccount.com"
```

6. Generate a `service account key`:

```
gcloud iam service-accounts keys create --iam-account
${SERVICE_ACCOUNT_NAME}@${PROJECT_ID}.iam.gserviceaccount.com \
     ~/service-account-key-${PROJECT_ID}-${SERVICE_ACCOUNT_NAME}.json
```

Using the service account

The generated `service account key` must be specified in the `provider.serviceAccountJSON: "<SERVICE_ACCOUNT_JSON>"` section of the GCPClusterConfiguration resource.

Example:

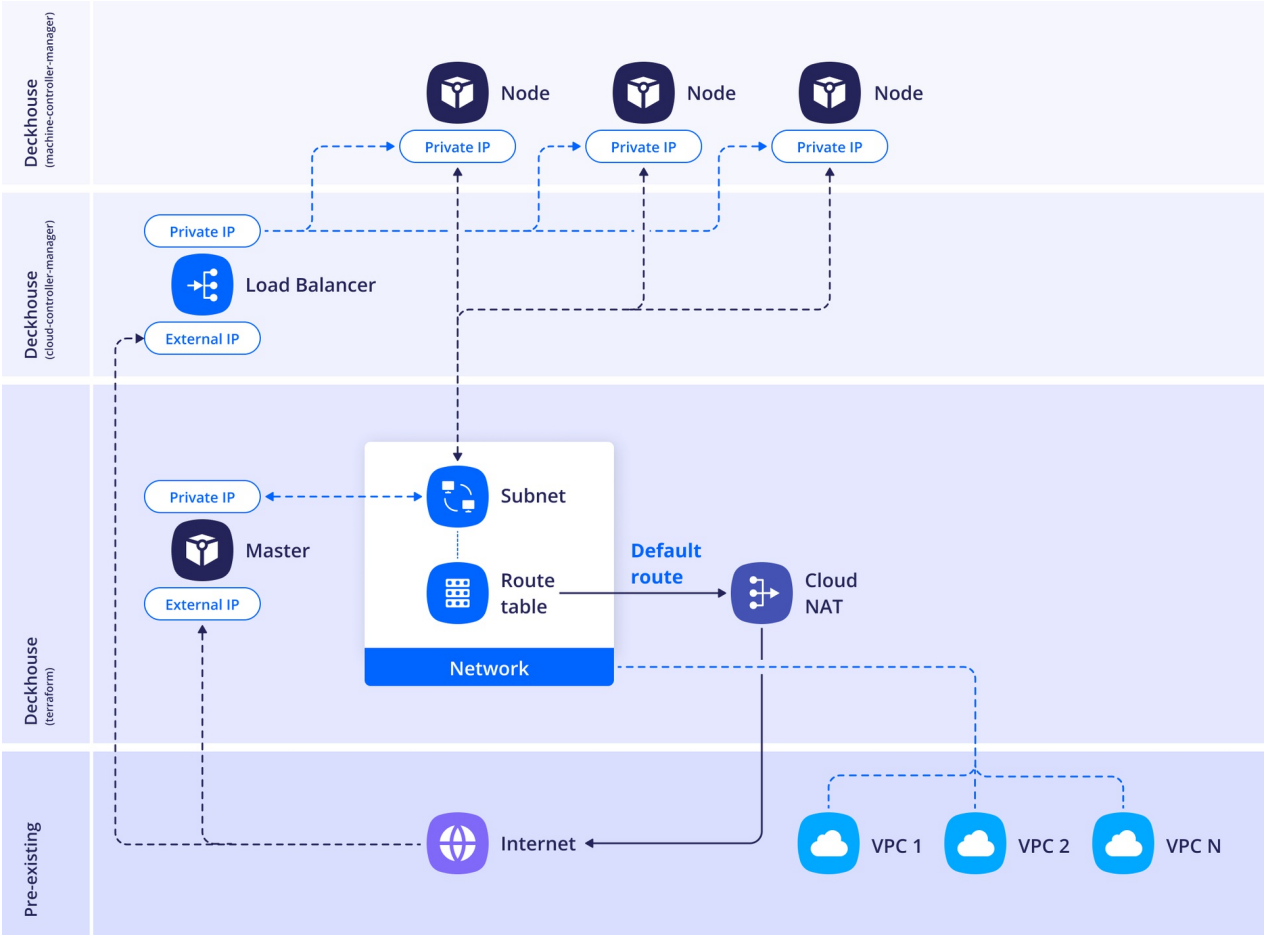
```
apiVersion: deckhouse.io/v1
kind: GCPClusterConfiguration
layout: WithoutNAT
sshKey: "<SSH_PUBLIC_KEY>"
subnetworkCIDR: 10.36.0.0/24
masterNodeGroup:
  replicas: 1
  zones:
  - europe-west3-b
  instanceClass:
    machineType: n1-standard-4
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20240523a
    diskSizeGb: 50
nodeGroups:
- name: static
  replicas: 1
  zones:
  - europe-west3-b
  instanceClass:
    machineType: n1-standard-4
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20240523a
    diskSizeGb: 50
    additionalNetworkTags:
    - tag1
    additionalLabels:
      kube-node: static
provider:
  region: europe-west3
  serviceAccountJSON: "<SERVICE_ACCOUNT_JSON>"
```

Additional resources

- Module `cloud-provider-gcp` provider configuration

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in Google Cloud Platform



Layouts

This section describes the possible node placement layouts in Google Cloud Platform (GCP) infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Deckhouse Platform (DP) supports two layouts for deploying resources in GCP.

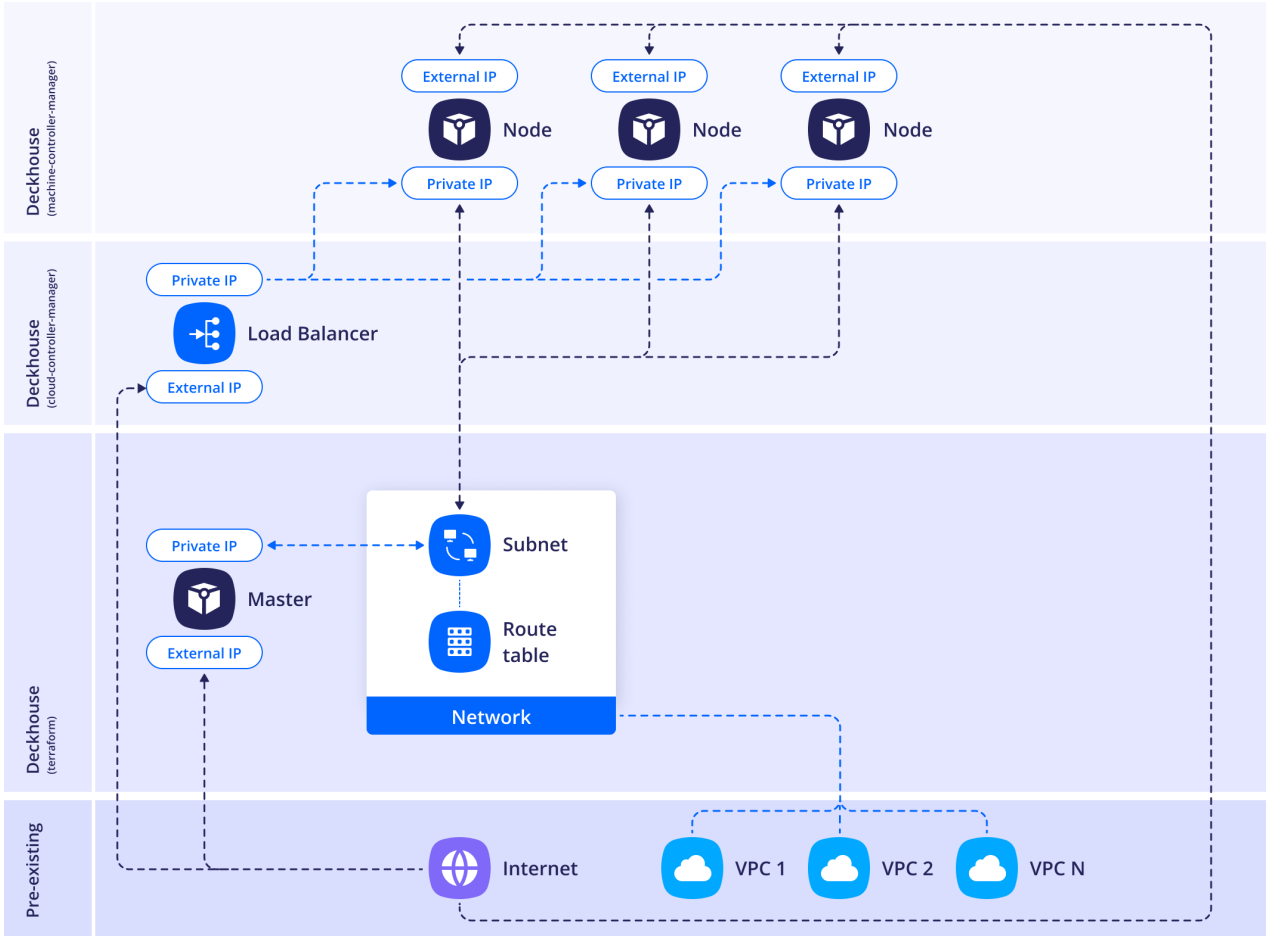
Standard

- A dedicated VPC is created for the cluster along with Cloud NAT.
- Cluster nodes do not have public IP addresses by default.
- Public IP addresses can be assigned to static and master nodes:
  - In this case, One-to-One NAT is used to map the public IP address to the node's internal IP address (Cloud NAT will not be used in this scenario).
- If the master node does not have a public IP address, an additional instance with a public IP address (for example, a bastion host) is required for cluster installation and access.
- Peering can be configured between the cluster's VPC and other VPCs.

When a cluster is created, DP creates the following firewall rules in the cluster VPC:

- `<CLUSTER_PREFIX>-ssh-and-ping`: Allows incoming traffic over the ICMP and TCP (port `22`) protocols to nodes with the `<CLUSTER_PREFIX>` network tag from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- `<CLUSTER_PREFIX>-intercommunication`: Allows any traffic between nodes with the `<CLUSTER_PREFIX>` network tag, as well as from the pod subnet (`podSubnetCIDR`).

Custom firewall rules are applied to nodes through additional network tags (`additionalNetworkTags`):



- For master nodes, in the `masterNodeGroup.instanceClass.additionalNetworkTags` parameter of the GCPClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalNetworkTags` parameter of the GCPClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalNetworkTags` parameter of the GCPInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: GCPClusterConfiguration
layout: Standard
standard:
  # Optional. Listed addresses will be used for
  # addressing Cloud NAT.
  cloudNATAddresses:
  - example-address-1
  - example-address-2
subnetworkCIDR: 10.0.0.0/24       # Required.
# Optional. A list of GCP VPC Networks used by Kubernetes VPC
# Network to connect over peering.
peeredVPCs:
- default
sshKey: "<SSH_PUBLIC_KEY>"  # Required.
labels:
  kube: example
masterNodeGroup:
  replicas: 1
  zones:                      # Optional.
  - europe-west4-b
  instanceClass:
    machineType: n1-standard-4     # Required.
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20260128  # Required.
    diskSizeGb: 20               # Optional. A local disk is used if not set.
    disableExternalIP: false       # Optional. The master node has externalIP by default.
    additionalNetworkTags:         # Optional.
    - tag1
    additionalLabels:            # Optional.
      kube-node: master
nodeGroups:
- name: static
  replicas: 1
  zones:                      # Optional.
  - europe-west4-b
  instanceClass:
    machineType: n1-standard-4     # Required.
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20260128  # Required.
    diskSizeGb: 20               # Optional. A local disk is used if not set.
    disableExternalIP: true        # Optional. The nodes don't have externalIP by default.
    additionalNetworkTags:         # Optional.
    - tag1
    additionalLabels:            # Optional.
      kube-node: static
provider:
  region: europe-west4           # Required.
  serviceAccountJSON: |          # Required.
    {
      "type": "service_account",
      "project_id": "sandbox",
      "private_key_id": "98sdcj5e8c7asd98j4j3n9csakn",
      "private_key": "-----BEGIN PRIVATE KEY-----",
      "client_id": "342975658279248",
      "auth_uri": "https://accounts.google.com/o/oauth2/auth",
      "token_uri": "https://oauth2.googleapis.com/token",
      "auth_provider_x509_cert_url": "https://www.googleapis.com/oauth2/v1/certs",
      "client_x509_cert_url": "https://www.googleapis.com/robot/v1/metadata/x509/k8s-
test%40sandbox.iam.gserviceaccount.com"
    }
```

WithoutNAT

- A dedicated VPC is created for the cluster. All cluster nodes are assigned public IP addresses.
- Peering can be configured between the cluster’s VPC and other VPCs.

When a cluster is created, DP creates the following firewall rules in the cluster VPC:

- `<CLUSTER PREFIX>-ssh-and-ping`: Allows incoming traffic over the ICMP and TCP (port `22`) protocols to nodes with the `<CLUSTER PREFIX>` network tag from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- `<CLUSTER_PREFIX>-intercommunication`: Allows any traffic between nodes with the `<CLUSTER_PREFIX>` network tag, as well as from the pod subnet (`podSubnetCIDR`).

Custom firewall rules are applied to nodes through additional network tags (`additionalNetworkTags`):

- For master nodes, in the `masterNodeGroup.instanceClass.additionalNetworkTags` parameter of the GCPClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalNetworkTags` parameter of the GCPClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalNetworkTags` parameter of the GCPInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: GCPClusterConfiguration
layout: WithoutNAT
subnetworkCIDR: 10.0.0.0/24       # Required.
# Optional. A list of GCP VPC Networks used by Kubernetes VPC
# Network to connect over peering.
peeredVPCs:
- default
labels:
  kube: example
masterNodeGroup:
  replicas: 1
  zones:                        # Optional.
  - europe-west4-b
  instanceClass:
    machineType: n1-standard-4     # Required.
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20260128  # Required.
    diskSizeGb: 20               # Optional. A local disk is used if not set.
    additionalNetworkTags:         # Optional.
    - tag1
    additionalLabels:             # Optional.
      kube-node: master
nodeGroups:
- name: static
  replicas: 1
  zones:                        # Optional.
  - europe-west4-b
  instanceClass:
    machineType: n1-standard-4     # Required.
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20260128  # Required.
    diskSizeGb: 20               # Optional. A local disk is used if not set.
    additionalNetworkTags:         # Optional.
    - tag1
    additionalLabels:             # Optional.
      kube-node: static
provider:
  region: europe-west4            # Required.
  serviceAccountJSON: |           # Required.
    {
      "type": "service_account",
      "project_id": "sandbox",
      "private_key_id": "98sdcj5e8c7asd98j4j3n9csakn",
      "private_key": "-----BEGIN PRIVATE KEY-----",
      "client_id": "342975658279248",
      "auth_uri": "https://accounts.google.com/o/oauth2/auth",
      "token_uri": "https://oauth2.googleapis.com/token",
      "auth_provider_x509_cert_url": "https://www.googleapis.com/oauth2/v1/certs",
      "client_x509_cert_url": "https://www.googleapis.com/robot/v1/metadata/x509/k8s-
test%40sandbox.iam.gserviceaccount.com"
    }
```

Configuration

Integration with GCP is handled via the GCPClusterConfiguration resource, which describes the cloud cluster configuration in GCP and is used by the cloud provider when the control plane is hosted in the cloud. The responsible DP module configures itself automatically based on the selected layout.

To update the configuration of a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After modifying node-related parameters, you must run the `dhctl converge` command for the changes to take effect.

Example configuration:

```
apiVersion: deckhouse.io/v1
kind: GCPClusterConfiguration
layout: WithoutNAT
sshKey: "<SSH_PUBLIC_KEY>"
subnetworkCIDR: 10.36.0.0/24
masterNodeGroup:
  replicas: 1
  zones:
  - europe-west3-b
  instanceClass:
    machineType: n1-standard-4
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20240523a
    diskSizeGb: 50
nodeGroups:
- name: static
  replicas: 1
  zones:
  - europe-west3-b
  instanceClass:
    machineType: n1-standard-4
    image: projects/ubuntu-os-cloud/global/images/ubuntu-2404-noble-amd64-v20240523a
    diskSizeGb: 50
    additionalNetworkTags:
    - tag1
    additionalLabels:
      kube-node: static
provider:
  region: europe-west3
  serviceAccountJSON: "<SERVICE_ACCOUNT_JSON>"
```

Machine provisioning and parameters are configured in the NodeGroup custom resource, where the instance class for the node group is specified (the `cloudInstances.classReference` parameter). For GCP, the instance class is a GCPInstanceClass custom resource that defines the machine parameters.

DP also automatically creates StorageClasses that cover all available disk types in GCP:

Disk type	Replication	StorageClass name
standard	none	`pd-standard-not-replicated`
standard	regional	`pd-standard-replicated`
balanced	none	`pd-balanced-not-replicated`
balanced	regional	`pd-balanced-replicated`
ssd	none	`pd-ssd-not-replicated`
ssd	regional	`pd-ssd-replicated`

You can exclude unnecessary StorageClasses by specifying them in the `exclude` parameter.

Enabling nested virtualization

To run virtual machine workloads (e.g., KVM-based VMs) inside GCP instances, enable nested virtualization.

> **i** Only specific machine types support nested virtualization. See the GCP documentation for the list of compatible types.

```
apiVersion: deckhouse.io/v1
kind: GCPInstanceClass
metadata:
  name: vm-nodes
spec:
  machineType: n2-standard-8
  nestedVirtualization: true
```

Adding additional disks

To attach additional disks to instances (for example, for LINSTOR, Ceph, NFS storage nodes, and similar solutions), specify them in the `additionalDisks` parameter:

```
apiVersion: deckhouse.io/v1
kind: GCPInstanceClass
metadata:
  name: storage-nodes
spec:
  machineType: n1-standard-8
  additionalDisks:
  - sizeGb: 200
    type: pd-ssd
  - sizeGb: 500
    type: pd-standard
    autoDelete: true
```

Adding CloudStatic nodes to the cluster

To add manually created virtual machines to the cluster as nodes, add a `Network Tag` matching the cluster prefix.

You can find the cluster prefix by running the following command:

```
d8 k get mc global -o jsonpath='{.spec.settings.prefix}{"\n"}'
```

If the value is empty, get it from the deprecated `cloud.prefix` parameter of ClusterConfiguration (the prefix has moved to the ModuleConfig `global`):

```
d8 k -n kube-system get secret d8-cluster-configuration -o json | jq -r '.data."cluster-configuration.yaml"' \
  | base64 -d | grep prefix
```

Preemptible nodes

Preemptible virtual machines in Google Cloud are called preemptible instances. To make a node group order them, set the `preemptible` parameter of the GCPInstanceClass resource to `true`.

How to create such nodes and how they behave is described in “How to create preemptible nodes in GCP?”.

Replacing the OS image

The OS image of the nodes is set by the `image` parameter of the GCPInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the GCPClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?” .

Additional resources

- Global custom resources
- Module `cloud-provider-gcp` documentation
- Module `control-plane-manager` parameters
- Module `node-manager` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Private cloud providers

Deckhouse Platform provides built-in tools for integration with private clouds deployed in your own infrastructure. These tools let you automatically provision virtual machines and connect them to a cluster, deploy clusters within private cloud environments, and scale resources as needed.

- Basis Dynamix
- Built-in virtualization
- Huawei Cloud
- OpenStack
- VK Private Cloud

The following sections describe how you can configure integration with each of these private cloud platforms.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in VK Cloud

To manage resources in VK Private Cloud using Deckhouse Platform, you must connect to the VK Private Cloud API.

The list of VK Private Cloud API services required for deployment is available in the Configuration section.

The user credentials required to access the VK Private Cloud API are provided in the OpenStack RC file (openrc file).

Instructions for downloading the openrc file via the standard web interface of VK Private Cloud and using it are available in the VK Private Cloud documentation.

If you’re using a cloud provider’s implementation of the VK Private Cloud API, the process for obtaining the openrc file may differ.

⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

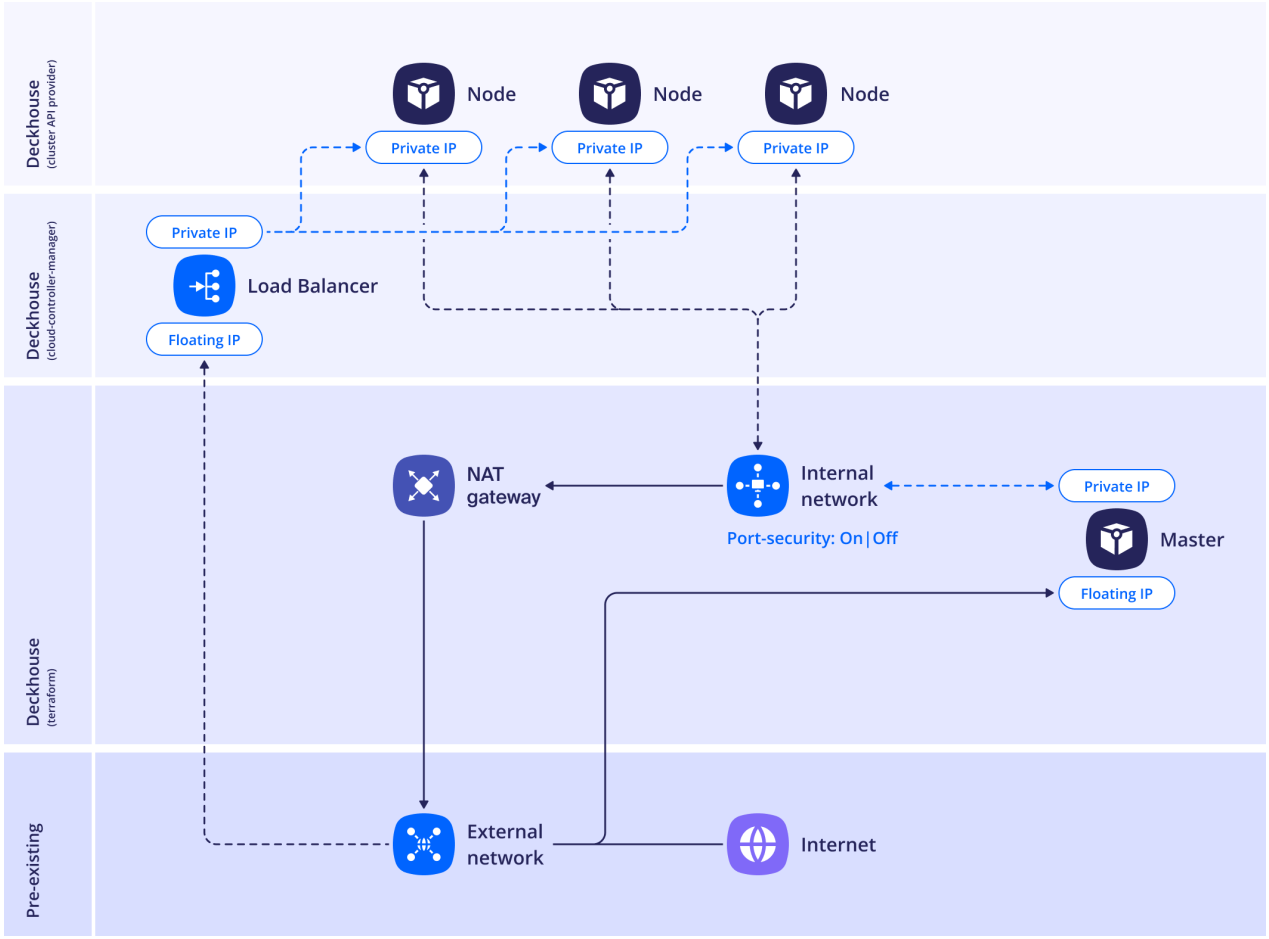
Layouts and configuration in VK Cloud

List of required OpenStack services

The following VK Private Cloud services must be available for Deckhouse Platform (DP) to operate:

Service	API Version
Identity (Keystone)	v3
Compute (Nova)	v2.1
Network (Neutron)	v2.0
Block Storage (Cinder)	v3
Load Balancing (Octavia) *	v2

* If you need to order a Load Balancer.



API endpoints and ports are listed in the official documentation.

Layouts

This section describes the possible node placement layouts in VK Private Cloud infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

In this scheme, an internal cluster network is created with a gateway to the public network; the nodes do not have public IP addresses. The floating IP is assigned to the master node.

> ⚠ If the provider does not support SecurityGroups, all applications running on nodes with Floating IPs assigned will be available at a public IP. For example, `kube-apiserver` on master nodes will be available on port `6443`. To avoid this, we recommend using the SimpleWithInternalNetwork or Standard layout with a bastion host.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

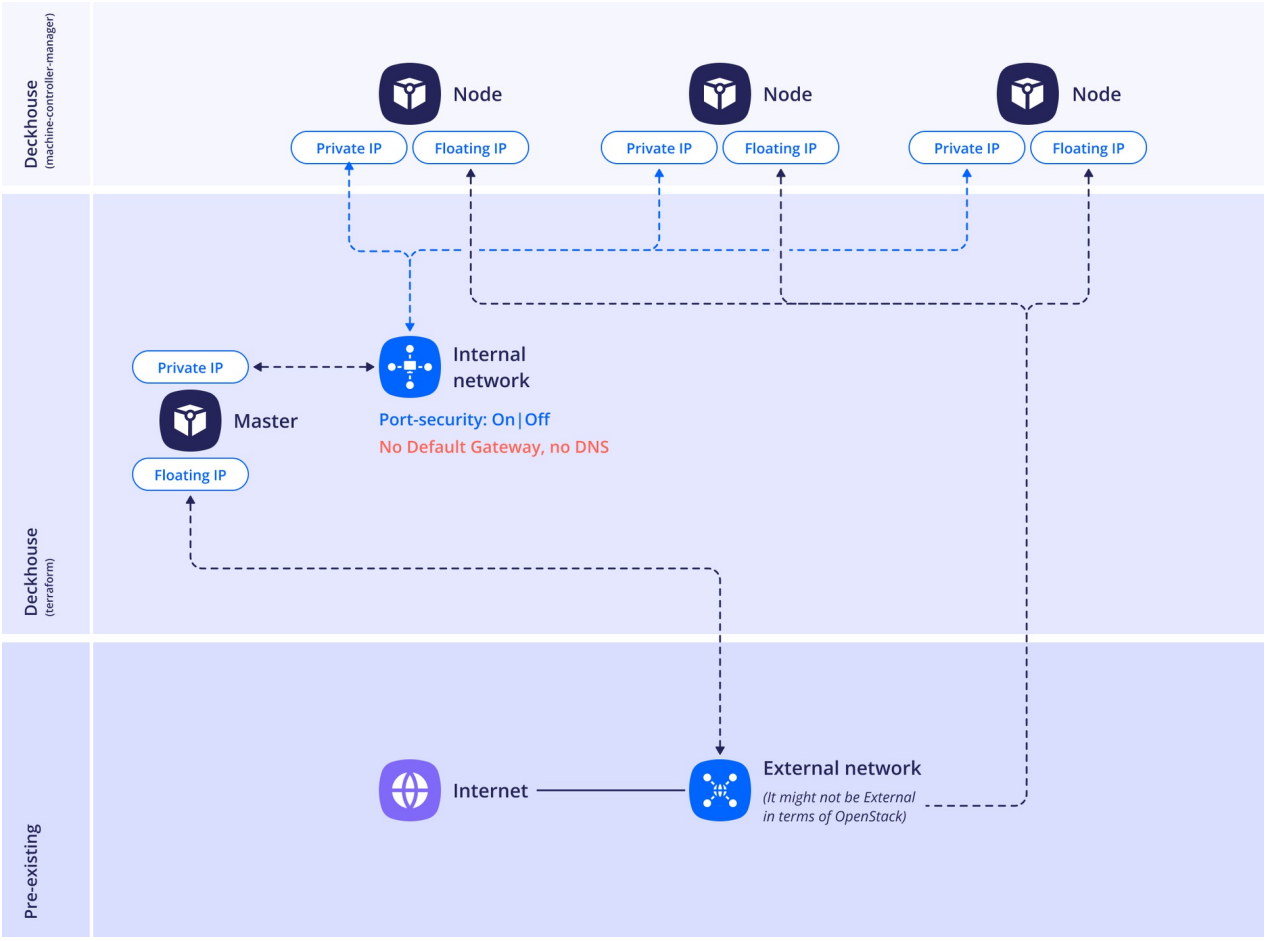
- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000-32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Standard
standard:
  internalNetworkCIDR: 192.168.199.0/24       # Required.
  internalNetworkDNSServers:                # Required.
  - 8.8.8.8
  - 4.2.2.2
  internalNetworkSecurity: true|false         # Optional, true by default.
  externalNetworkName: shared               # Required.
  bastion:
    zone: ru2-b                           # Optional.
    volumeType: fast-ru-2b                  # Optional.
    instanceClass:
      flavorName: m1.large                  # Required.
      imageName: ubuntu-20-04-cloud-amd64     # Required.
```



```
     rootDiskSize: 50                    # Optional, 50 GB by default.
     additionalTags:
       severity: critical                # Optional.
       environment: production            # Optional.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                  # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
    additionalTags:
      severity: critical
      environment: production
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    ru-1a: fast-ru-1a

```

StandardWithNoRouter

An internal cluster network is created that does not have access to the public network. All nodes (including master ones) have two interfaces: the first one to the public network, the second one to the internal network. This layout should be used if you want all nodes in the cluster to be directly accessible.

⚠

- This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.
- Using this strategy, make sure to explicitly specify the name of the internal network in `additionalNetworks` when creating an OpenStackInstanceClass in the cluster.

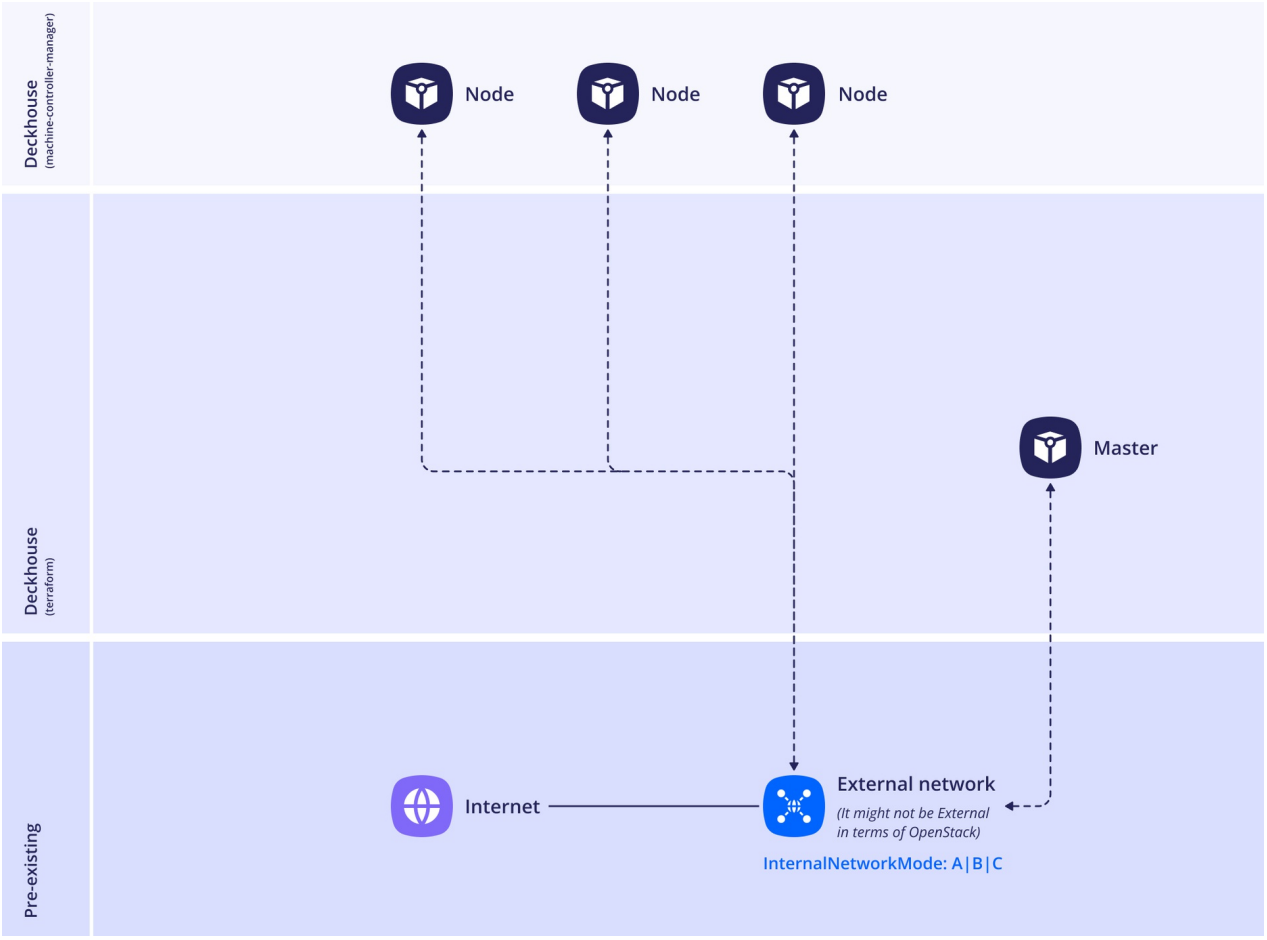
The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.



Example layout configuration:

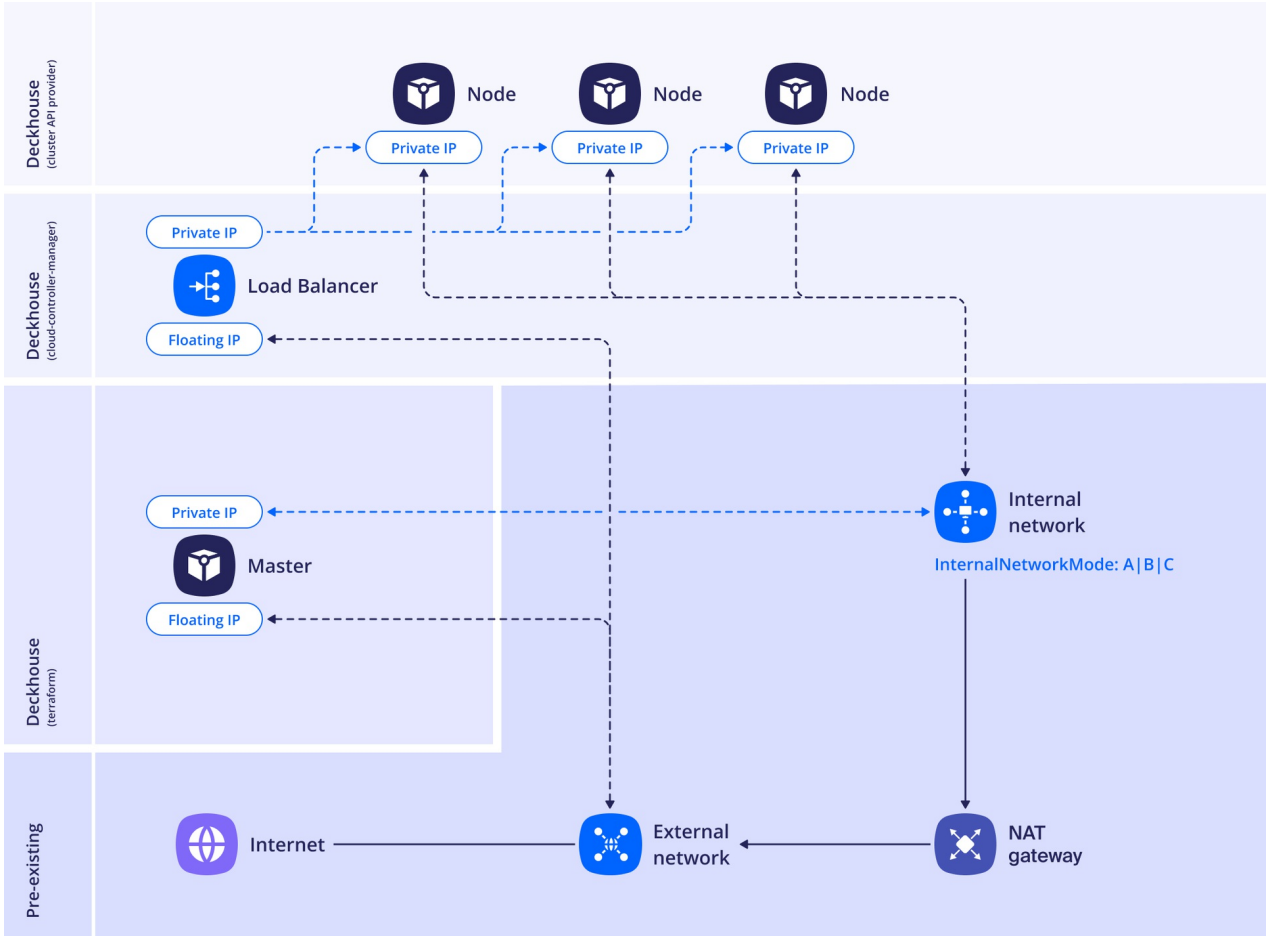
```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: StandardWithNoRouter
standardWithNoRouter:
  internalNetworkCIDR: 192.168.199.0/24        # Required.
  externalNetworkName: ext-net                # Required.
  # Optional, defines whether DHCP is enabled in specified external
  # network (true by default).
  externalNetworkDHCP: false
  internalNetworkSecurity: true|false          # Optional, true by default.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the gateway of the network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                      # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required if rootDiskSize is specified. Volume type map for node's root volume.
  volumeTypeMap:
    nova: ceph-ssd
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Simple

The master node and cluster nodes are connected to the existing network. This placement strategy can be useful if you need to merge a Kubernetes cluster with existing VMs.

⚠ This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:



- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Simple
simple:
  externalNetworkName: ext-net              # Required.
  externalNetworkDHCP: false                # Optional, true by default.
  # Optional, VXLAN by default, may also be DirectRouting
  # or DirectRoutingWithPortSecurityEnabled.
  podNetworkMode: VXLAN
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

SimpleWithInternalNetwork

The master node and cluster nodes are connected to the existing network. This layout can be useful if you need to merge a Kubernetes cluster with existing VMs.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: SimpleWithInternalNetwork
simpleWithInternalNetwork:
  # All cluster nodes have to be in the same subnet. Set either the subnet name
  # in internalSubnetName or its UUID in internalSubnetID.
  internalSubnetName: pivot-standard
  # Optional, DirectRoutingWithPortSecurityEnabled by default,
  # may also be DirectRouting or VXLAN.
  podNetworkMode: DirectRoutingWithPortSecurityEnabled
  # Optional. If set, it will be used for the load balancer default
  # configuration and ordering the master floating IP.
  externalNetworkName: ext-net
  # Optional, true by default.
  masterWithExternalFloatingIP: false
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Configuration

Integration with VK Private Cloud is performed using the OpenStackClusterConfiguration resource. It defines the configuration of the cloud cluster in VK Private Cloud and is used by the cloud provider when the cluster control plane is hosted in the cloud. The DP module responsible for the integration is automatically configured based on the selected layout.

To modify the configuration in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After changing node-related parameters, run the `dhctl converge` command to apply the changes.

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the VK Private Cloud cloud provider, the instance class is a custom resource called OpenStackInstanceClass, which contains the specific configuration of the VMs.

> **i** An OpenStack cluster is deployed in a single region (`provider.region`). Zones from other regions cannot be used. For details on configuring zones for CloudPermanent and CloudEphemeral nodes, see How do I create NodeGroups in availability zones? section.

If the instance class of the group sets the `rootDiskSize` parameter, the root disk is created in Cinder. In clouds where volume types are bound to availability zones, set the volume type for each zone in the `volumeTypeMap` parameter of the OpenStackInstanceClass resource. Otherwise, provisioning a node in a zone where the default volume type is unavailable fails with the `HTTP 400 Availability zone '…' is invalid` error.

> **⚠** When the module settings are changed, **existing Machine objects in the cluster are NOT recreated** (new Machine objects will use the updated parameters). The recreation only occurs if you modify the NodeGroup or the OpenStackInstanceClass parameters.

Configuration examples

The following are two simple configuration examples for the OpenStack cloud provider.

Example 1

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: test
spec:
  flavorName: m1.large
```

Example 2

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-openstack
spec:
  version: 1
  enabled: true
  settings:
    connection:
      authURL: https://test.tests.com:5000/v3/
      domainName: default
      tenantName: default
      username: jamie
      password: nein
      region: SomeRegion
    externalNetworkNames:
    - public
    internalNetworkNames:
    - kube
    instances:
      sshKeyPairName: my-ssh-keypair
      securityGroups:
      - default
      - allow-ssh-and-icmp
    zones:
    - zone-a
    - zone-b
    tags:
      project: cms
      owner: default
```

LoadBalancer configuration

⚠ To correctly determine the client IP address, use a LoadBalancer with Proxy Protocol support.

It is recommended to limit the list of nodes added to the load balancer pool using the `loadbalancer.openstack.org/node-selector` annotation.

Without a `node-selector` restriction, cloud-controller-manager may use all suitable cluster nodes as load balancer targets. As a result, adding or removing nodes that are not related to the workload served by the load balancer may trigger an update of the load balancer pool membership. In large or frequently changing clusters, such updates may occur regularly and, in some configurations, may cause brief disruptions to existing connections.

The `annotations` field of the corresponding inlet configuration in the IngressNginxController resource supports the following annotations:

- `loadbalancer.openstack.org/node-selector`: Selects the nodes that will be used as LoadBalancer targets.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id`: Instructs OpenStack CCM to use a pre-created Octavia load balancer.
- `loadbalancer.openstack.deckhouse.io/load-balancer-address`: Instructs OpenStack CCM to associate a pre-allocated floating IP with the load balancer it creates.

DP automatically adds the specified annotations to the generated Service object of type LoadBalancer.

When using the `loadbalancer.openstack.deckhouse.io/load-balancer-id` annotation, the load balancer must meet the following requirements:

- reside in the cluster subnet
- be in the `ACTIVE` state

If `loadbalancer.openstack.deckhouse.io/load-balancer-id` is used to reference a pre-created load balancer with a custom name, associate the floating IP with its VIP port before creating the cluster. In this case, do not specify the `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotation.

When using only `loadbalancer.openstack.deckhouse.io/load-balancer-address`, the floating IP must meet the following requirements:

- not be associated with any port
- reside in the floating network configured for OpenStack CCM

If the specified floating IP is unavailable, OpenStack CCM will not be able to assign an external IP address to the Service object.

Do not add the `loadbalancer.openstack.deckhouse.io/load-balancer-id` or `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotations to application Ingress resources. Specify them only in the IngressNginxController configuration. DP will add them to the generated Service object, which is processed by `openstack-cloud-controller-manager`.

IngressNginxController with a pre-created load balancer

In the example below:

- Ingress controller pods are scheduled on frontend nodes.
- `loadbalancer.openstack.org/node-selector` limits the load balancer target pool to those frontend nodes.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id` references a pre-created Octavia load balancer whose VIP port already has a floating IP associated with it.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-id: "df7c6f73-8c68-4a11-a3e2-6268a655ce9b"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

IngressNginxController with a pre-allocated floating IP

In the example below, OpenStack CCM creates a load balancer and associates the specified unassigned floating IP with it:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-address: "203.0.113.10"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Uploading an image to VK Private Cloud

1. Download the latest stable Ubuntu 18.04 image:

   ```
   curl -L https://cloud-images.ubuntu.com/bionic/current/bionic-server-cloudimg-amd64.img --output ~/ubuntu-18-04-cloud-amd64
   ```

2. Prepare an openrc file that contains credentials for accessing the VK Private Cloud API.

   > **i** The method of obtaining the openrc file may vary depending on the VK Private Cloud provider. If your provider offers the standard interface for VK Private Cloud, follow this guide to download the file.

3. Alternatively, install the OpenStack CLI tools following the instructions.

   You can also run a container, mounting both the openrc file and the downloaded Ubuntu image:

   ```
   docker run -ti --rm -v ~/ubuntu-18-04-cloud-amd64:/ubuntu-18-04-cloud-amd64 -v ~/.openrc:/openrc jmcvea/openstack-client
   ```

4. Initialize environment variables from the openrc file:

   ```
   source /openrc
   ```

5. List the available volume types:

   ```
   openstack volume type list
   ```

   Example output:

   ```
   +--------------------------------------+---------------+-----------+
   | ID                                   | Name          | Is Public |
   +--------------------------------------+---------------+-----------+
   | 8d39c9db-0293-48c0-8d44-015a2f6788ff | ko1-high-iops | True      |
   | bf800b7c-9ae0-4cda-b9c5-fae283b3e9fd | dp1-high-iops | True      |
   | 74101409-a462-4f03-872a-7de727a178b8 | ko1-ssd       | True      |
   | eadd8860-f5a4-45e1-ae27-8c58094257e0 | dp1-ssd       | True      |
   | 48372c05-c842-4f6e-89ca-09af3868b2c4 | ssd           | True      |
   | a75c3502-4de6-4876-a457-a6c4594c067a | ms1           | True      |
   | ebf5922e-42af-4f97-8f23-716340290de2 | dp1           | True      |
   | a6e853c1-78ad-4c18-93f9-2bba317a1d13 | ceph          | True      |
   +--------------------------------------+---------------+-----------+
   ```

6. Create an image and assign the volume type as a property (this is necessary if VK Private Cloud does not support local disks or they are unsuitable for workloads):

   ```
   openstack image create --private --disk-format qcow2 --container-format bare \
     --file /ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=dp1-high-iops ubuntu-18-04-cloud-amd64
   ```

7. Ensure the image has been created:

```
openstack image show ubuntu-18-04-cloud-amd64
```

Example output:

```
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| Field            | Value
|
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| checksum         | 3443a1fd810f4af9593d56e0e144d07d
|
| container_format | bare
|
| created_at       | 2020-01-10T07:23:48Z

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the OpenStackInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the OpenStackClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Verifying security group support by the cloud provider

Run the `openstack security group list` command. If you don’t receive any errors, it means that security groups are supported.

Cinder CSI resilience during re-authentication in OpenStack

The Cinder CSI driver supports OpenStack re-authentication with service catalog refresh. This improves the reliability of

volume operations in `cinder-csi-plugin` pods that have been running for a long time without being restarted.

When a token expires or a `401 Unauthorized` response is received, the driver re-authenticates with OpenStack and updates the data used to access OpenStack API services. As a result, PersistentVolume operations, including volume attachment and detachment, continue without requiring CSI driver pods to be restarted.

This behavior is especially important for clusters where `cinder-csi-plugin` pods run for a long time without being restarted, while the OpenStack service catalog may change between the initial authentication and subsequent API requests.

Configuring online volume resize

When resizing a disk via the OpenStack API, Cinder does not pass updated size information to Nova. As a result, the disk size inside the guest OS remains unchanged.

To fix this, you must configure access to the Nova API in the `cinder.conf` file. For example:

```
[nova]
interface = admin
insecure = {{ keystone_service_internaluri_insecure | bool }}
auth_type = {{ cinder_keystone_auth_plugin }}
auth_url = {{ keystone_service_internaluri }}/v3
password = {{ nova_service_password }}
project_domain_id = default
project_name = service
region_name = {{ nova_service_region }}
user_domain_id = default
username = {{ nova_service_user_name }}
```

For more details, see the OpenStack-Ansible bug report.

Using rootDiskSize

Disks in VK Private Cloud

A node’s disk can be either local or network-attached. In VK Private Cloud terminology:

- A local disk is called an ephemeral disk.
- A network-attached disk is called a persistent disk (Cinder storage).

The ephemeral disk is deleted along with the VM, while the persistent disk remains in the cloud even after the VM is deleted.

- For master nodes, network-attached disks are preferred so the nodes could migrate between hypervisors.
- For ephemeral nodes, local disks are preferred for cost efficiency. However, not all cloud providers support local disks. If not supported, you have to use network-attached disks for ephemeral nodes.

Local disk (ephemeral)	Network-attached disk (persistent)
Deleted with the VM	Remains in cloud and can be reused
Less expensive	More expensive
Suitable for ephemeral nodes	Suitable for master nodes

rootDiskSize parameter

The OpenStackInstanceClass resource includes a `rootDiskSize` parameter. In VK Private Cloud, flavors may also define a disk size.

The resulting disk type depends on the combination of the following parameters:

	flavor disk size = 0	flavor disk size > 0
`rootDiskSize` not set	*Disk size must be specified*. VM creation will fail without it.	Local disk with size from the flavor.
`rootDiskSize` set	Network-attached disk with size that equals `rootDiskSize`.	Both network-attached (`rootDiskSize`) and local (from flavor). Avoid this setup, as the cloud provider may charge for both.

> **i** In Selectel Cloud, when creating nodes with CloudEphemeral type outside zone A, you must pre-create a flavor with the target disk size. In this case, you do not need to set the `rootDiskSize` parameter.

Recommendations for master nodes and bastion with network-attached disks

- Use a flavor with zero disk size.
- Set `rootDiskSize` in the OpenStackInstanceClass resource.
- Ensure the disk type is correct:

- If specified in the OS image, it will be used.
- If not specified, the type will be taken from `volumeTypeMap`.

Recommendations for ephemeral nodes with local disks

- Use a flavor with a defined disk size.
- Do not use the `rootDiskSize` parameter in OpenStackInstanceClass.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the cloud provider's default disk type will be used.

Checking the disk size in a flavor

Run the following command:

```
openstack flavor show m1.medium-50g -C disk
```

Example output:

```
+-------+-------+
| Field | Value |
+-------+-------+
| disk  | 50    |
+-------+-------+
```

Overriding the cloud provider's default disk type

If your cloud provider offers multiple volume types, you can specify the default type for an image by setting the `cinder_img_volume_type` property in the image metadata. Any VM created from that image will use the specified volume type.

You can also create a new VK Private Cloud image and upload it.

Example:

```
openstack volume type list
openstack image set ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=VOLUME_NAME
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in OpenStack

To manage resources in OpenStack using Deckhouse Platform, you must connect to the OpenStack API.

The list of OpenStack API services required for deployment is available in the Configuration section.

The user credentials required to access the OpenStack API are provided in the OpenStack RC file (openrc file).

Instructions for downloading the openrc file via the standard web interface of OpenStack and using it are available in the OpenStack documentation.

If you're using a cloud provider's implementation of the OpenStack API, the process for obtaining the openrc file may differ.

> The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

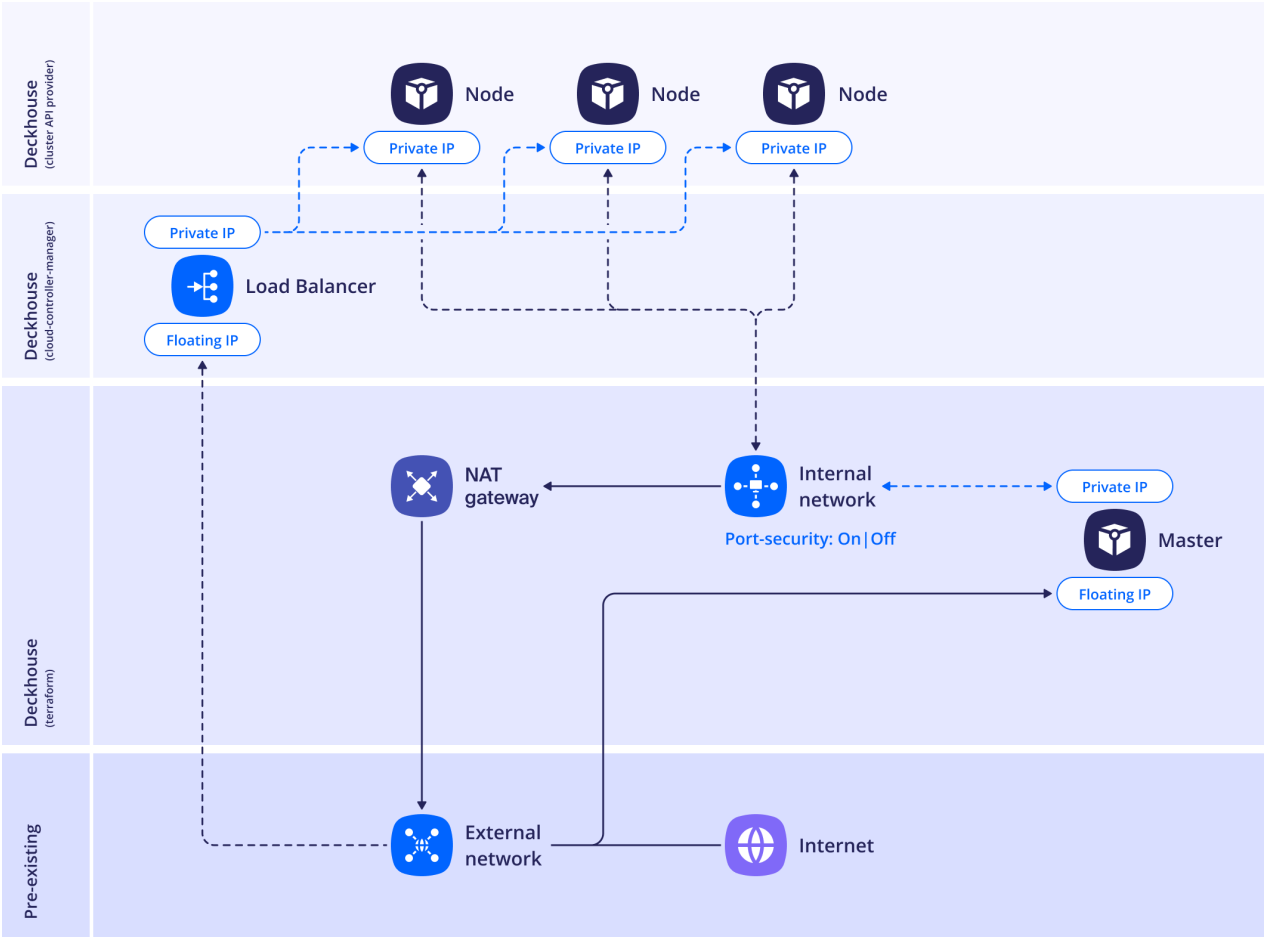
Layouts and configuration in OpenStack

List of required OpenStack services

The following OpenStack services must be available for Deckhouse Platform (DP) to operate:

Service	API Version
Identity (Keystone)	v3

Service	API Version
Compute (Nova)	v2.1
Network (Neutron)	v2.0
Block Storage (Cinder)	v3
Load Balancing (Octavia) *	v2



* If you need to order a Load Balancer.

Layouts

This section describes the possible node placement layouts in OpenStack infrastructure and the related configuration options. The selected layout affects networking behavior, availability of public IP addresses, outgoing traffic routing, and how nodes are accessed.

Standard

In this scheme, an internal cluster network is created with a gateway to the public network; the nodes do not have public IP addresses. The floating IP is assigned to the master node.

⚠ If the provider does not support SecurityGroups, all applications running on nodes with Floating IPs assigned will be available at a public IP. For example, `kube-apiserver` on master nodes will be available on port `6443`. To avoid this, we recommend using the SimpleWithInternalNetwork or Standard layout with a bastion host.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000-32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.

- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Standard
standard:
  internalNetworkCIDR: 192.168.199.0/24       # Required.

provider:
  ...
```

StandardWithNoRouter

An internal cluster network is created that does not have access to the public network. All nodes (including master ones) have two interfaces: the first one to the public network, the second one to the internal network. This layout should be used if you want all nodes in the cluster to be directly accessible.

⚠

- This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.
- Using this strategy, make sure to explicitly specify the name of the internal network in `additionalNetworks` when creating an OpenStackInstanceClass in the cluster.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix (`prefix`) and assigns it to the nodes.

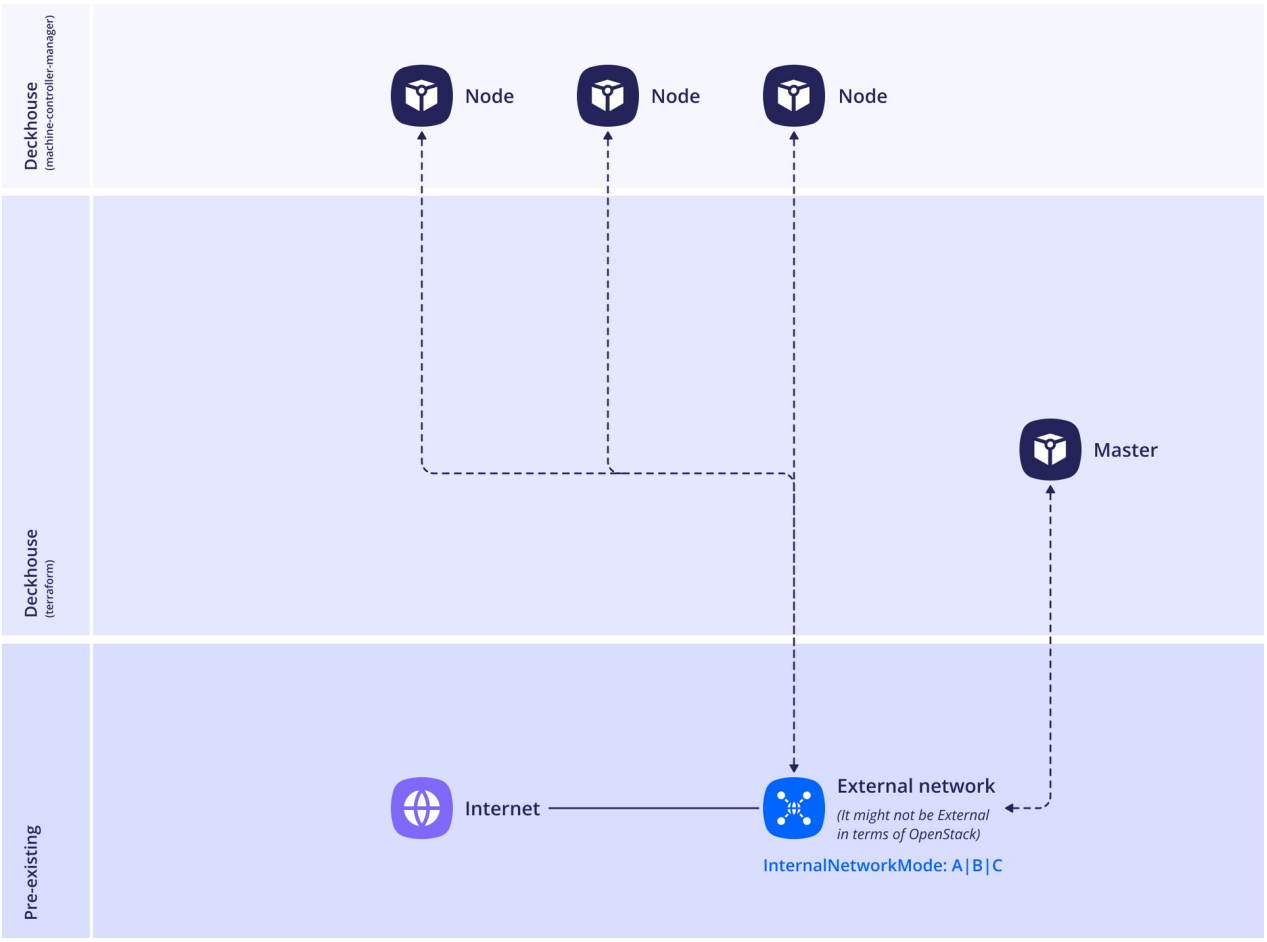
The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from the CIDRs listed in `sshAllowList` (default `0.0.0.0/0`).
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000`–`32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.
- Allow any incoming traffic from nodes in the same security group.

In addition to the group created by DP, you can attach your own security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and specify them in `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the

OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.



Example layout configuration:

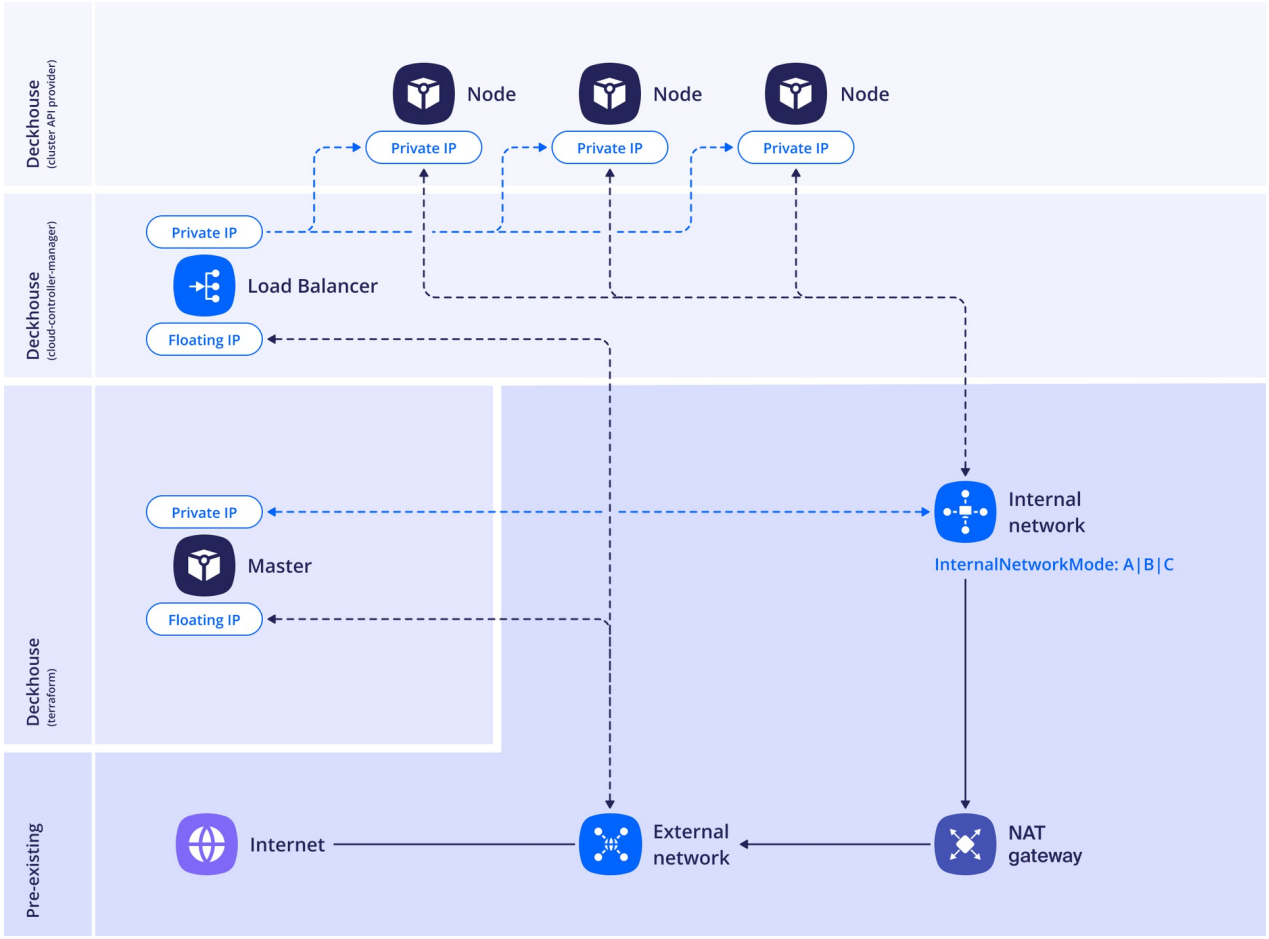
```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: StandardWithNoRouter
standardWithNoRouter:
  internalNetworkCIDR: 192.168.199.0/24        # Required.
  externalNetworkName: ext-net                # Required.
  # Optional, defines whether DHCP is enabled in specified external
  # network (true by default).
  externalNetworkDHCP: false
  internalNetworkSecurity: true|false          # Optional, true by default.
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                     # Required.
    imageName: ubuntu-18-04-cloud-amd64        # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the gateway of the network will be used as the default gateway.
    # Matches the prefix parameter in the global ModuleConfig.
    mainNetwork: kube
    additionalNetworks:                      # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required if rootDiskSize is specified. Volume type map for node's root volume.
  volumeTypeMap:
    nova: ceph-ssd
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Simple

The master node and cluster nodes are connected to the existing network. This placement strategy can be useful if you need to merge a Kubernetes cluster with existing VMs.

⚠ This strategy does not support a LoadBalancer since a Floating IP is not available for the router-less network. Thus, you cannot provision a LoadBalancer with the Floating IP. An internal LoadBalancer with the virtual IP in the public network is only accessible from cluster nodes.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:



- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: Simple
simple:
  externalNetworkName: ext-net              # Required.
  externalNetworkDHCP: false                # Optional, true by default.
  # Optional, VXLAN by default, may also be DirectRouting
  # or DirectRoutingWithPortSecurityEnabled.
  podNetworkMode: VXLAN
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

SimpleWithInternalNetwork

The master node and cluster nodes are connected to the existing network. This layout can be useful if you need to merge a Kubernetes cluster with existing VMs.

In this layout, DP does not create security groups. Prepare them in the cloud beforehand by following the OpenStack documentation and attach them to the nodes via `additionalSecurityGroups`:

- For master nodes, in the `masterNodeGroup.instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For static nodes, in the `nodeGroups[].instanceClass.additionalSecurityGroups` parameter of the OpenStackClusterConfiguration resource.
- For ephemeral nodes, in the `spec.additionalSecurityGroups` parameter of the OpenStackInstanceClass resource.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1
kind: OpenStackClusterConfiguration
layout: SimpleWithInternalNetwork
simpleWithInternalNetwork:
  # All cluster nodes have to be in the same subnet. Set either the subnet name
  # in internalSubnetName or its UUID in internalSubnetID.
  internalSubnetName: pivot-standard
  # Optional, DirectRoutingWithPortSecurityEnabled by default,
  # may also be DirectRouting or VXLAN.
  podNetworkMode: DirectRoutingWithPortSecurityEnabled
  # Optional. If set, it will be used for the load balancer default
  # configuration and ordering the master floating IP.
  externalNetworkName: ext-net
  # Optional, true by default.
  masterWithExternalFloatingIP: false
masterNodeGroup:
  replicas: 3
  instanceClass:
    flavorName: m1.large                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 50
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
  # Required, volume type map for etcd and Kubernetes certificates
  # (always use the fastest disk supplied by the provider).
  volumeTypeMap:
    # If rootDiskSize is specified, this volume type will
    # be also used for master root volume.
    nova: ceph-ssd
nodeGroups:
- name: front
  replicas: 2
  instanceClass:
    flavorName: m1.small                    # Required.
    imageName: ubuntu-18-04-cloud-amd64       # Required.
    # Optional, local disk is used if not specified.
    rootDiskSize: 20
    # Optional, false by default, determines if configuration drive
    # is required during vm bootstrap process. It's needed
    # if there is no DHCP in the network that is used as a default
    # gateway.
    configDrive: false
    # Required, the network will be used as a default gateway.
    # Matches the name of the pre-created network.
    mainNetwork: kube
    additionalNetworks:                     # Optional.
    - office
    - shared
    # Optional, if there are networks with disabled port
    # security, their names must be specified.
    networksWithSecurityDisabled:
    - office
    # Optional, a list of network pools where to order floating IPs.
    floatingIPPools:
    - public
    - shared
    # Optional, additional security groups.
    additionalSecurityGroups:
    - sec_group_1
    - sec_group_2
sshPublicKey: "<SSH_PUBLIC_KEY>"
provider:
  ...
```

Configuration

Integration with OpenStack is performed using the OpenStackClusterConfiguration resource. It defines the configuration of the cloud cluster in OpenStack and is used by the cloud provider when the cluster control plane is hosted in the cloud. The DP module responsible for the integration is automatically configured based on the selected layout.

To modify the configuration in a running cluster, run the following command:

```
d8 system edit provider-cluster-configuration
```

> **i** After changing node-related parameters, run the `dhctl converge` command to apply the changes.

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the OpenStack cloud provider, the instance class is a custom resource called OpenStackInstanceClass, which contains the specific configuration of the VMs.

> **i** An OpenStack cluster is deployed in a single region (`provider.region`). Zones from other regions cannot be used. For details on configuring zones for CloudPermanent and CloudEphemeral nodes, see How do I create NodeGroups in availability zones? section.

If the instance class of the group sets the `rootDiskSize` parameter, the root disk is created in Cinder. In clouds where volume types are bound to availability zones, set the volume type for each zone in the `volumeTypeMap` parameter of the OpenStackInstanceClass resource. Otherwise, provisioning a node in a zone where the default volume type is unavailable fails with the `HTTP 400 Availability zone '…' is invalid` error.

> **⚠** When the module settings are changed, **existing Machine objects in the cluster are NOT recreated** (new Machine objects will use the updated parameters). The recreation only occurs if you modify the NodeGroup or the OpenStackInstanceClass parameters.

Configuration examples

The following are two simple configuration examples for the OpenStack cloud provider.

Example 1

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: test
spec:
  flavorName: m1.large
```

Example 2

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-openstack
spec:
  version: 1
  enabled: true
  settings:
    connection:
      authURL: https://test.tests.com:5000/v3/
      domainName: default
      tenantName: default
      username: jamie
      password: nein
      region: SomeRegion
    externalNetworkNames:
    - public
    internalNetworkNames:
    - kube
    instances:
      sshKeyPairName: my-ssh-keypair
      securityGroups:
      - default
      - allow-ssh-and-icmp
    zones:
    - zone-a
    - zone-b
    tags:
      project: cms
      owner: default
```

LoadBalancer configuration

⚠ To correctly determine the client IP address, use a LoadBalancer with Proxy Protocol support.

It is recommended to limit the list of nodes added to the load balancer pool using the `loadbalancer.openstack.org/node-selector` annotation.

Without a `node-selector` restriction, cloud-controller-manager may use all suitable cluster nodes as load balancer targets. As a result, adding or removing nodes that are not related to the workload served by the load balancer may trigger an update of the load balancer pool membership. In large or frequently changing clusters, such updates may occur regularly and, in some configurations, may cause brief disruptions to existing connections.

The `annotations` field of the corresponding inlet configuration in the IngressNginxController resource supports the following annotations:

- `loadbalancer.openstack.org/node-selector`: Selects the nodes that will be used as LoadBalancer targets.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id`: Instructs OpenStack CCM to use a pre-created Octavia load balancer.
- `loadbalancer.openstack.deckhouse.io/load-balancer-address`: Instructs OpenStack CCM to associate a pre-allocated floating IP with the load balancer it creates.

DP automatically adds the specified annotations to the generated Service object of type LoadBalancer.

When using the `loadbalancer.openstack.deckhouse.io/load-balancer-id` annotation, the load balancer must meet the following requirements:

- reside in the cluster subnet
- be in the `ACTIVE` state

If `loadbalancer.openstack.deckhouse.io/load-balancer-id` is used to reference a pre-created load balancer with a custom name, associate the floating IP with its VIP port before creating the cluster. In this case, do not specify the `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotation.

When using only `loadbalancer.openstack.deckhouse.io/load-balancer-address`, the floating IP must meet the following requirements:

- not be associated with any port
- reside in the floating network configured for OpenStack CCM

If the specified floating IP is unavailable, OpenStack CCM will not be able to assign an external IP address to the Service object.

Do not add the `loadbalancer.openstack.deckhouse.io/load-balancer-id` or `loadbalancer.openstack.deckhouse.io/load-balancer-address` annotations to application Ingress resources. Specify them only in the IngressNginxController configuration. DP will add them to the generated Service object, which is processed by `openstack-cloud-controller-manager`.

IngressNginxController with a pre-created load balancer

In the example below:

- Ingress controller pods are scheduled on frontend nodes.
- `loadbalancer.openstack.org/node-selector` limits the load balancer target pool to those frontend nodes.
- `loadbalancer.openstack.deckhouse.io/load-balancer-id` references a pre-created Octavia load balancer whose VIP port already has a floating IP associated with it.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-id: "df7c6f73-8c68-4a11-a3e2-6268a655ce9b"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

IngressNginxController with a pre-allocated floating IP

In the example below, OpenStack CCM creates a load balancer and associates the specified unassigned floating IP with it:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.deckhouse.io/load-balancer-address: "203.0.113.10"
      loadbalancer.openstack.org/node-selector: "node-role.deckhouse.io/frontend="
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Uploading an image to OpenStack

1. Download the latest stable Ubuntu 18.04 image:

   ```
   curl -L https://cloud-images.ubuntu.com/bionic/current/bionic-server-cloudimg-amd64.img --output ~/ubuntu-18-04-cloud-amd64
   ```

2. Prepare an openrc file that contains credentials for accessing the OpenStack API.

   > **i** The method of obtaining the openrc file may vary depending on the OpenStack provider. If your provider offers the standard interface for OpenStack, follow this guide to download the file.

3. Alternatively, install the OpenStack CLI tools following the instructions.

   You can also run a container, mounting both the openrc file and the downloaded Ubuntu image:

   ```
   docker run -ti --rm -v ~/ubuntu-18-04-cloud-amd64:/ubuntu-18-04-cloud-amd64 -v ~/.openrc:/openrc jmcvea/openstack-client
   ```

4. Initialize environment variables from the openrc file:

   ```
   source /openrc
   ```

5. List the available volume types:

   ```
   openstack volume type list
   ```

   Example output:

   ```
   +--------------------------------------+---------------+-----------+
   | ID                                   | Name          | Is Public |
   +--------------------------------------+---------------+-----------+
   | 8d39c9db-0293-48c0-8d44-015a2f6788ff | ko1-high-iops | True      |
   | bf800b7c-9ae0-4cda-b9c5-fae283b3e9fd | dp1-high-iops | True      |
   | 74101409-a462-4f03-872a-7de727a178b8 | ko1-ssd       | True      |
   | eadd8860-f5a4-45e1-ae27-8c58094257e0 | dp1-ssd       | True      |
   | 48372c05-c842-4f6e-89ca-09af3868b2c4 | ssd           | True      |
   | a75c3502-4de6-4876-a457-a6c4594c067a | ms1           | True      |
   | ebf5922e-42af-4f97-8f23-716340290de2 | dp1           | True      |
   | a6e853c1-78ad-4c18-93f9-2bba317a1d13 | ceph          | True      |
   +--------------------------------------+---------------+-----------+
   ```

6. Create an image and assign the volume type as a property (this is necessary if OpenStack does not support local disks or they are unsuitable for workloads):

   ```
   openstack image create --private --disk-format qcow2 --container-format bare \
     --file /ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=dp1-high-iops ubuntu-18-04-cloud-amd64
   ```

7. Ensure the image has been created:

```
openstack image show ubuntu-18-04-cloud-amd64
```

Example output:

```
+------------------+------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------------------------------------------------------------------------------------
------------------+
| Field            | Value
|
+------------------+------------------------------------------------------------------------------

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the OpenStackInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the OpenStackClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Verifying security group support by the cloud provider

Run the `openstack security group list` command. If you don’t receive any errors, it means that security groups are supported.

Cinder CSI resilience during re-authentication in OpenStack

The Cinder CSI driver supports OpenStack re-authentication with service catalog refresh. This improves the reliability of

volume operations in `cinder-csi-plugin` pods that have been running for a long time without being restarted.

When a token expires or a `401 Unauthorized` response is received, the driver re-authenticates with OpenStack and updates the data used to access OpenStack API services. As a result, PersistentVolume operations, including volume attachment and detachment, continue without requiring CSI driver pods to be restarted.

This behavior is especially important for clusters where `cinder-csi-plugin` pods run for a long time without being restarted, while the OpenStack service catalog may change between the initial authentication and subsequent API requests.

Configuring online volume resize

When resizing a disk via the OpenStack API, Cinder does not pass updated size information to Nova. As a result, the disk size inside the guest OS remains unchanged.

To fix this, you must configure access to the Nova API in the `cinder.conf` file. For example:

```
[nova]
interface = admin
insecure = {{ keystone_service_internaluri_insecure | bool }}
auth_type = {{ cinder_keystone_auth_plugin }}
auth_url = {{ keystone_service_internaluri }}/v3
password = {{ nova_service_password }}
project_domain_id = default
project_name = service
region_name = {{ nova_service_region }}
user_domain_id = default
username = {{ nova_service_user_name }}
```

For more details, see the OpenStack-Ansible bug report.

Using rootDiskSize

Disks in OpenStack

A node’s disk can be either local or network-attached. In OpenStack terminology:

- A local disk is called an ephemeral disk.
- A network-attached disk is called a persistent disk (Cinder storage).

The ephemeral disk is deleted along with the VM, while the persistent disk remains in the cloud even after the VM is deleted.

- For master nodes, network-attached disks are preferred so the nodes could migrate between hypervisors.
- For ephemeral nodes, local disks are preferred for cost efficiency. However, not all cloud providers support local disks. If not supported, you have to use network-attached disks for ephemeral nodes.

Local disk (ephemeral)	Network-attached disk (persistent)
Deleted with the VM	Remains in cloud and can be reused
Less expensive	More expensive
Suitable for ephemeral nodes	Suitable for master nodes

rootDiskSize parameter

The OpenStackInstanceClass resource includes a `rootDiskSize` parameter. In OpenStack, flavors may also define a disk size.

The resulting disk type depends on the combination of the following parameters:

	flavor disk size = 0	flavor disk size > 0
`rootDiskSize` not set	*Disk size must be specified*. VM creation will fail without it.	Local disk with size from the flavor.
`rootDiskSize` set	Network-attached disk with size that equals `rootDiskSize`.	Both network-attached (`rootDiskSize`) and local (from flavor). Avoid this setup, as the cloud provider may charge for both.

> **i** In Selectel Cloud, when creating nodes with CloudEphemeral type outside zone A, you must pre-create a flavor with the target disk size. In this case, you do not need to set the `rootDiskSize` parameter.

Recommendations for master nodes and bastion with network-attached disks

- Use a flavor with zero disk size.
- Set `rootDiskSize` in the OpenStackInstanceClass resource.
- Ensure the disk type is correct:

  - If specified in the OS image, it will be used.
  - If not specified, the type will be taken from `volumeTypeMap`.

Recommendations for ephemeral nodes with local disks

- Use a flavor with a defined disk size.
- Do not use the `rootDiskSize` parameter in OpenStackInstanceClass.
- Ensure the disk type is correct:
  - If specified in the OS image, it will be used.
  - If not specified, the cloud provider's default disk type will be used.

Checking the disk size in a flavor

Run the following command:

```
openstack flavor show m1.medium-50g -C disk
```

Example output:

```
+-------+-------+
| Field | Value |
+-------+-------+
| disk  | 50    |
+-------+-------+
```

Overriding the cloud provider's default disk type

If your cloud provider offers multiple volume types, you can specify the default type for an image by setting the `cinder_img_volume_type` property in the image metadata. Any VM created from that image will use the specified volume type.

You can also create a new OpenStack image and upload it.

Example:

```
openstack volume type list
openstack image set ubuntu-18-04-cloud-amd64 --property cinder_img_volume_type=VOLUME_NAME
```

Offline disk resizing

If you encounter the following error during volume resizing, reduce the number of replicas in the affected StatefulSet to 0, wait for the volume size to update, and then scale the replicas back to the original value.

```
Warning  VolumeResizeFailed     5s (x11 over 41s)  external-resizer cinder.csi.openstack.org
resize volume "pvc-555555-ab66-4f8d-947c-296520bae4c1" by resizer "cinder.csi.openstack.org" failed:
rpc error: code = Internal desc = Could not resize volume "bb5a275b-3f30-4916-9480-9efe4b6dfba5" to size 2:

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Huawei Cloud

Requirements

> The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

To ensure proper operation of Deckhouse Platform (DP) with Huawei Cloud, make sure of the following:

- The `cloud-init` package is installed on the virtual machines.
- After the VMs start, the following services must be active:
  - `cloud-config.service`
  - `cloud-final.service`
  - `cloud-init.service`

Accessing the Huawei Cloud API

DP uses the Huawei Cloud API to manage resources. To configure access, you need to create an IAM user and assign the necessary permissions.

Creating a user group

To create a user group and assign policies, follow these steps:

1. Go to the **Identity and Access Management (IAM)** section.
2. Open the **User Groups** tab and click **Create User Group**.
3. Specify a group name (for example, `deckhouse`) and click **OK**.
4. Select the created group and go to the **Permissions** tab.
5. Click **Authorize** and assign the following policies:
   - `ECS Admin`
   - `VPC Administrator`
   - `NAT Admin`
   - `ELB FullAccess`
   - `DEW KeypairFullAccess`
6. Confirm your selections by clicking **Next**, then **OK**, and finalize with **Finish**.

Creating an IAM user

To create an IAM user, follow these steps:

1. Go to the **Users** tab and click **Create User**.
2. Enter a username (for example, `deckhouse`).
3. Under **Access type**, select **Programmatic access**, and ensure that **Management console access** is disabled.
4. Under **Credential Type**, choose **Access key**.
5. Click **Next**, select the previously created group, and then click **Create**.
6. Download the **Access Key ID** and **Secret Access Key**. These credentials are required to access the Huawei Cloud API and cannot be recovered later.

> **i** Make sure the saved keys are securely stored, as they are required to access the cloud API.

JSON policies

Below are the policy contents in JSON format:

ECS Admin policy

```
{
"Version": "1.1",

  ]
}
```

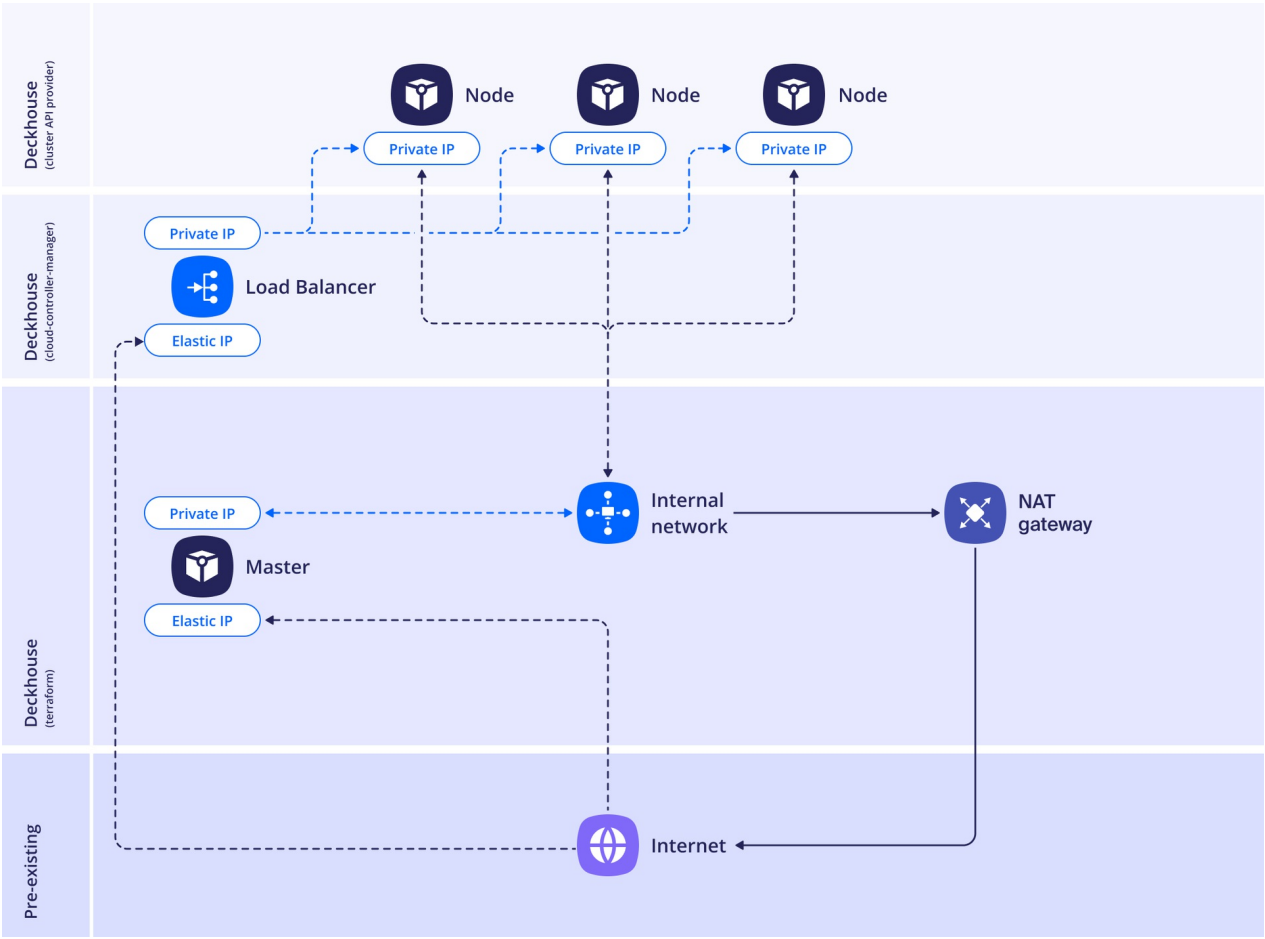
Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in Huawei Cloud

This section describes the cluster layouts in Huawei Cloud infrastructure and the associated parameters.

List of required Huawei Cloud services



A list of services required for Deckhouse Platform (DP) to work in Huawei Cloud:

Service	API version
Identity	v3
Compute	v2.1
Network (VPC)	v1/v2
Network (OpenStack Neutron API)	v2.0
Block Storage	v3
Load Balancing (ELB) *	v3

* Required if load balancers need to be provisioned in the cluster.

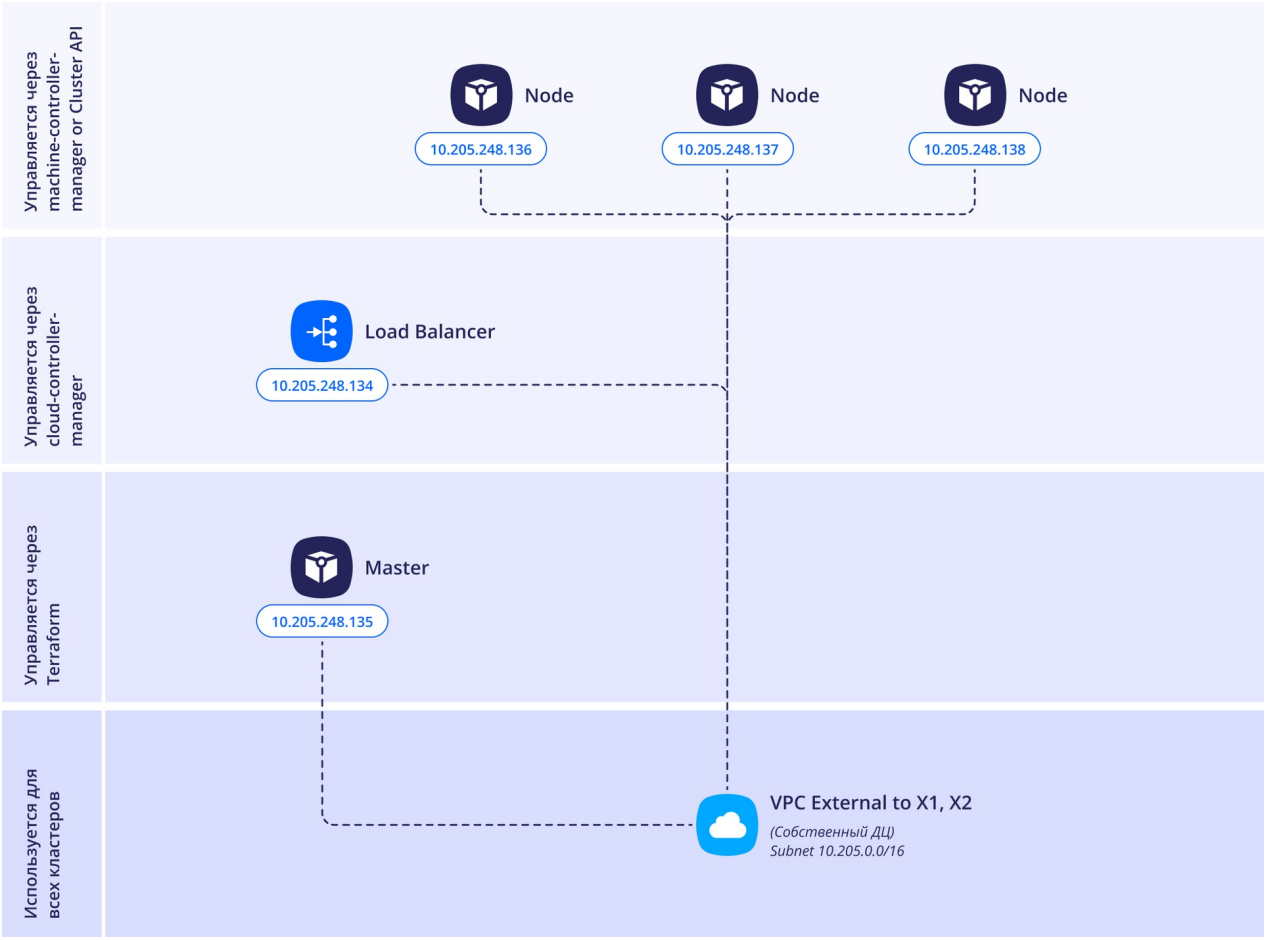
Standard

- An internal cluster network is created with a gateway to the public network.
- An Elastic IP can be assigned to the master node.
- Nodes managed by the Cluster API do not have public IP addresses.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from `0.0.0.0/0`.
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000-32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.



Attach custom security groups for CloudEphemeral nodes in the HuaweiCloudInstanceClass resource via `spec.securityGroups`. They are applied together with the group created by DP.

Example configuration:

```
apiVersion: deckhouse.io/v1
kind: HuaweiCloudClusterConfiguration
layout: Standard
sshPublicKey: "<SSH_PUBLIC_KEY>"
standard:
  internalNetworkDNSServers:
    - 8.8.8.8
  internalNetworkCIDR: 192.168.199.0/24
  internalNetworkSecurity: true
  enableEIP: true
provider:
  cloud: hc.sbercloud.ru
  region: ru-moscow-1
  accessKey: "<Access key>"
  secretKey: "<Secret key>"
  projectID: "<Project ID>"
masterNodeGroup:
  replicas: 1
  instanceClass:
    imageName: alt-p11
    flavorName: s7n.xlarge.2
    rootDiskSize: 50
  serverGroup:
    policy: AntiAffinity
  volumeTypeMap:
    ru-moscow-1a: SSD
```

VpcPeering

- An existing VPC network and subnet are used.
- Virtual machines are connected to the specified subnet.

The `internalNetworkSecurity` parameter (default `true`) enables the creation of a security group (SecurityGroup) when a cluster is created. DP creates the group named after the cluster prefix and assigns it to the nodes.

The following inbound rules will be created:

- Allow incoming traffic over the TCP protocol on port `22` from `0.0.0.0/0`.
- Allow incoming traffic over the ICMP protocol from `0.0.0.0/0`.
- Allow incoming traffic over the TCP protocol on ports `30000-32767` for services of the `NodePort` type. Inbound UDP traffic to `NodePort` ports is not allowed by default.

Attach custom security groups for CloudEphemeral nodes in the HuaweiCloudInstanceClass resource via `spec.securityGroups`. They are applied together with the group created by DP.

Example configuration:

```
apiVersion: deckhouse.io/v1
kind: HuaweiCloudClusterConfiguration
layout: VpcPeering
sshPublicKey: "<SSH_PUBLIC_KEY>"
vpcPeering:
  internalNetworkDNSServers:
    - 8.8.8.8
  internalNetworkCIDR: 10.221.128.0/24
  internalNetworkSecurity: true
  subnet: subnet-43b4
```

Additional resources

- Module `cloud-provider-huaweicloud` provider configuration
- Module `cloud-provider-huaweicloud` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage and load balancing in Huawei Cloud

Storage

Deckhouse Platform provisions disks in Huawei Cloud using the CSI driver. Storage type is configured via parameters in the HuaweiCloudClusterConfiguration resource, specifically the `volumeTypeMap` field.

Example configuration:

```
masterNodeGroup:
  volumeTypeMap:
    ru-moscow-1a: SSD
```

When the `rootDiskSize` parameter is specified, the same disk type is used for the boot (root) volume.

The following parameters can also be set in the HuaweiCloudInstanceClass:

- `rootDiskSize`: Disk size in GiB.
- `rootDiskType`: Type of the root disk (SSD, GPSSD, SAS, etc.).

Example:

```
spec:
  rootDiskSize: 50
  rootDiskType: GPSSD
```

It is recommended that you use the fastest available disk types supported in the cloud provider’s region.

Load balancing

Load balancing in Huawei Cloud is handled via Elastic Load Balancer (ELB) services. To access the load balancer API, the IAM policy must include the `ELB FullAccess` permission.

In the Standard layout, the `enableEIP` parameter is available to assign Elastic IPs to master nodes.

By default, nodes managed by the Cluster API do not receive public IP addresses.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with Huawei Cloud services

Deckhouse Platform leverages Huawei Cloud’s capabilities to operate Kubernetes clusters. The following features are

supported:

- Resource management in Huawei Cloud via `cloud-controller-manager`.
- Disk provisioning using the CSI driver.
- Integration with the `node-manager` module, allowing the use of HuaweiCloudInstanceClass in NodeGroup.

Working with InstanceClass

The HuaweiCloudInstanceClass resource is used to define the parameters of virtual machines. It is referenced by NodeGroup.

Example resource:

```
apiVersion: deckhouse.io/v1
kind: HuaweiCloudInstanceClass
metadata:
  name: worker
spec:
  imageName: alt-p11
  flavorName: s7n.xlarge.2
  rootDiskSize: 50
  rootDiskType: SSD
```

Replacing the OS image

The OS image of the nodes is set by the `imageName` parameter of the HuaweiCloudInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the HuaweiCloudClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new image, follow the steps from “How do I replace the OS image in a cloud cluster?”.

Additional resources

- Module `cloud-provider-huaweicloud` custom resources

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in Basis Dynamix

> The Basis Dynamix integration is experimental. Compatibility with future versions isn’t guaranteed and the behavior may change.

The integration provides the following capabilities:

- Ordering and removing virtual machines via the Basis Dynamix API
- Using prepared cloud images to deploy nodes
- Configuring virtual machine parameters (CPU, RAM, disk, network)
- Support for external and internal networks, including CIDR and DNS settings
- Support for multiple layouts with an external or a combined network
- Disk placement by a storage policy

Requirements

> ⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

To integrate Deckhouse Platform with Basis Dynamix, you need the following:

- Basis Dynamix 4.6 or newer, otherwise the preflight check stops the installation
- Access to the API controller and to the Basis Dynamix SSO
- The account name and the application parameters (`appId` and `appSecret`)
- Account access to the Basis Dynamix user API groups
- An OS cloud image uploaded to the cloud
- An external network (`externalNetwork`) and, if required, the internal network parameters (CIDR, DNS)
- The name of a storage policy available to the account (`storagePolicy`)
- A public SSH key for accessing the cluster nodes

Preparing a cloud image

To deploy virtual machines, Deckhouse Platform uses OS cloud images prepared by vendors for virtual environments. Such images usually include:

- `cloud-init`

- Virtual hardware drivers
- Guest agents

Use official cloud images distributed in the `.img`, `.qcow2`, and similar formats.

To add an image to Basis Dynamix:

1. Go to “Images” → “Template images”.
2. Upload the prepared cloud image.

Configuring access to the portal

If your infrastructure has no DNS server, add the IP addresses and domains of the Basis Dynamix portal to the `cloud-init` template manually, so that the system works correctly when the nodes start.

1. Edit the `hosts` file template located in the following directory:

   ```
   /etc/cloud/templates/
   ```

2. Add the IP address and domain name entries specific to your operating system and configuration. This may include entries for the Basis Dynamix portal, such as:

   ```
   <IP address> <domain name>
   ```

3. After the changes, clean up the `cloud-init` state:

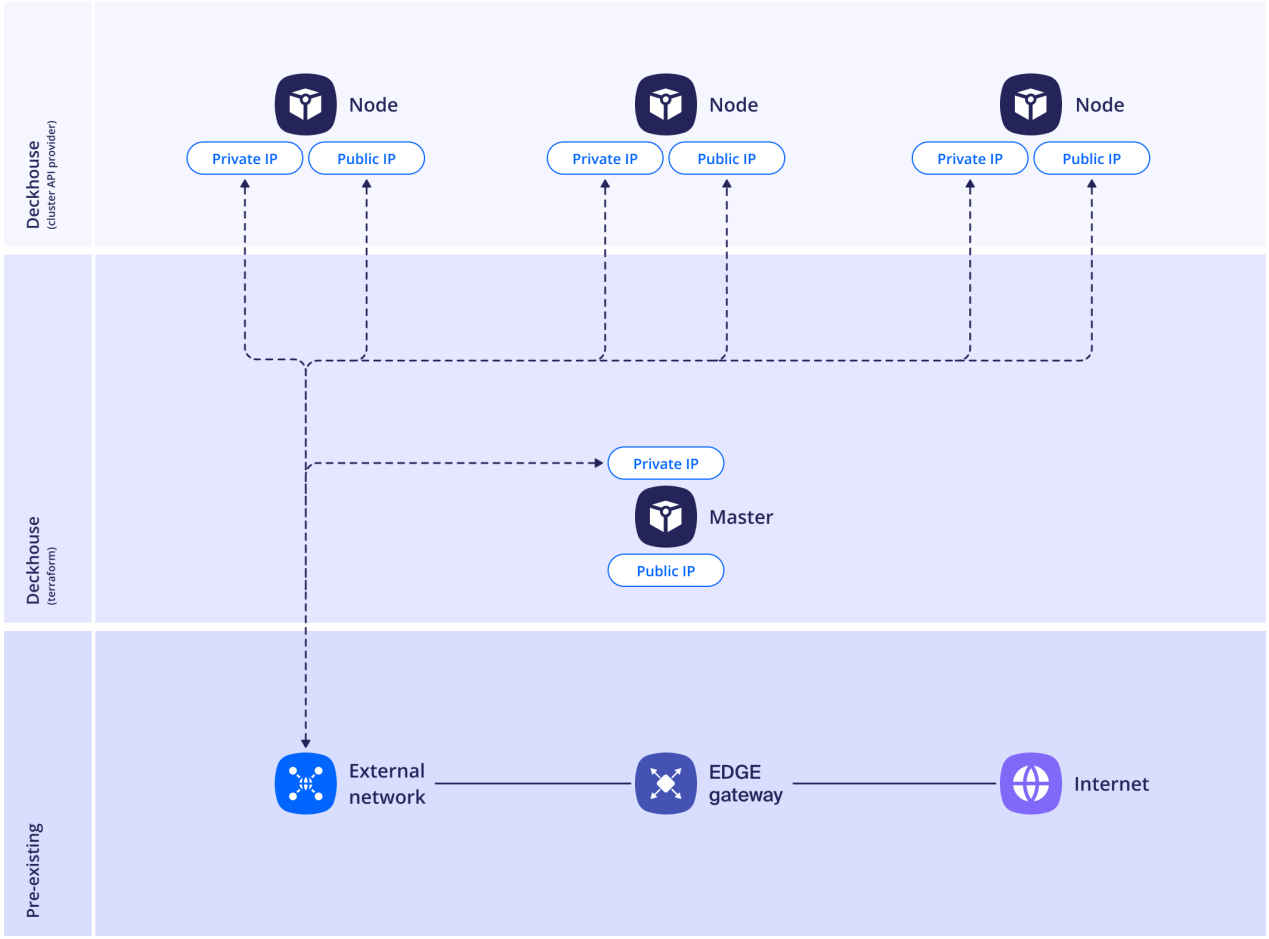
   ```
   cloud-init clean
   ```

4. Create a template from the prepared virtual machine. This is required for the `/etc/hosts` file to be generated correctly on the first boot.

Additional resources

- Module `cloud-provider-dynamix` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.



Layouts and configuration in Basis Dynamix

Deckhouse Platform supports two layouts in the Basis Dynamix cloud:

- Standard: A layout that uses only an external network
- StandardWithInternalNetwork: A layout with an internal (private) network and DNS servers

Both layouts let you manage cluster node placement, network settings, the OS image, and data storage.

Standard

If the external network doesn’t provide DNS server addresses to the nodes, set them in the `nameservers` parameter.

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: DynamixClusterConfiguration
layout: Standard
sshPublicKey: "<SSH_PUBLIC_KEY>"
location: dynamix
account: acc_user
storagePolicy: storage_policy01
provider:
  controllerUrl: "<controller url>"
  oAuth2Url: "<oAuth2 url>"
  appId: "<app id>"
  appSecret: "<app secret>"
  insecure: true
masterNodeGroup:
  replicas: 1
  instanceClass:
    numCPUs: 6
    memory: 16384
    rootDiskSizeGb: 50
    imageName: "<image name>"
    externalNetwork: "<external network>"
```

StandardWithInternalNetwork

Example layout configuration:

```
apiVersion: deckhouse.io/v1
kind: DynamixClusterConfiguration
layout: StandardWithInternalNetwork
sshPublicKey: "<SSH_PUBLIC_KEY>"
location: dynamix
account: acc_user
storagePolicy: storage_policy01
nodeNetworkCIDR: "10.241.32.0/24"
nameservers:
  - "10.0.0.10"
provider:
  controllerUrl: "<controller url>"
  oAuth2Url: "<oAuth2 url>"
  appId: "<app id>"
  appSecret: "<app secret>"
  insecure: true
masterNodeGroup:
  replicas: 1
  instanceClass:
    numCPUs: 6
    memory: 16384
    rootDiskSizeGb: 50
    imageName: "<image name>"
    externalNetwork: "<external network>"
```

Required parameters

- `layout`: Layout
- `sshPublicKey`: Public key for accessing the nodes
- `location`: Name of the Basis Dynamix location where the cluster resource group is created
- `account`: Account name in the cloud
- `storagePolicy`: Name of the storage policy used by default for virtual machine disks
- `provider.controllerUrl`, `oAuth2Url`, `appId`, `appSecret`: API access parameters
- `imageName`: OS image name
- `externalNetwork`: External network name
- `nodeNetworkCIDR`: Address space of the internal network (only for the `StandardWithInternalNetwork` layout)

⚠ Changing `storagePolicy` recreates nodes of the `CloudEphemeral` type. The nodes that are recreated are listed in the Changing the storage policy section.

To apply the parameter changes, run `dhctl converge`.

Additional resources

- Module `cloud-provider-dynamix` provider configuration

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage and load balancing in Basis Dynamix

Storage

Virtual machine disk placement in Basis Dynamix is defined by a storage policy. It sets the storage endpoint and pool pairs available to the account, as well as an IOPS limit. Basis Dynamix chooses the exact placement of a disk within the policy.

The `storagePolicy` parameter at the root of DynamixClusterConfiguration sets the storage policy for the disks of all virtual machines in the cluster. To use a different storage policy for a node group, set `storagePolicy` in its `instanceClass`, including `masterNodeGroup.instanceClass`, or in a DynamixInstanceClass. The `rootDiskSizeGb` parameter sets the root disk size of each virtual machine in gigabytes.

Example configuration:

```
storagePolicy: storage_policy01
masterNodeGroup:
  replicas: 1
  instanceClass:
    rootDiskSizeGb: 50
```

The module creates a StorageClass for every `ENABLED` storage policy. The StorageClass naming rules and the way to exclude StorageClasses from the cluster are described in the module FAQ.

Disable a storage policy in Basis Dynamix only when the cluster nodes and volumes no longer use it. When a policy is disabled, the module detaches it from the cluster resource group and deletes its StorageClass.

Changing the storage policy

The storage policy of a disk is set when the virtual machine is created and doesn't change for an existing machine. Therefore, when the storage policy changes, the module recreates nodes of the `CloudEphemeral` type:

- When `storagePolicy` changes in a DynamixInstanceClass: The nodes of the groups that use this DynamixInstanceClass.
- When `storagePolicy` changes at the root of DynamixClusterConfiguration: The nodes of all groups, including groups with their own storage policy.

The module doesn't recreate master nodes and the nodes of the `nodeGroups` groups. A new storage policy applies to such a node only when the node is created again.

Load balancing

The Basis Dynamix platform doesn't provide a built-in load balancer. To handle inbound traffic to a Deckhouse Platform cluster, the following approaches are recommended:

1. An external load balancer. If your infrastructure has an external load balancer (hardware or software), configure it to forward ports 80 and 443 to the cluster's frontend nodes.
2. Using MetalLB. You can use MetalLB in L2 mode to provide fault-tolerant load balancing.

Recommendations:

- Allocate a separate L2 network with DHCP and internet access.
- Configure the IP address range MetalLB will announce addresses from.
- Make sure this network is connected to the cluster's frontend nodes.
- Leave the network interfaces empty in the VirtualMachine Template configuration. Deckhouse Platform creates them automatically.

> **i** Support for BGP mode depends on the network infrastructure and isn't guaranteed on Basis Dynamix.

Configuring a Service of the LoadBalancer type

To configure a Service of the LoadBalancer type, add the following annotations to the Service manifest:

```
metadata:
  annotations:
    dynamix.cpi.flant.com/internal-network-name: <internal_name>
    dynamix.cpi.flant.com/external-network-name: <external_name>
```

Both annotations are required:

- `dynamix.cpi.flant.com/internal-network-name`: The name of the internal network in Basis Dynamix
- `dynamix.cpi.flant.com/external-network-name`: The name of the external network in Basis Dynamix

The terms "internal network" and "external network" are used in the context of Basis Dynamix. The external network doesn't have to be public and may use private IP addresses.

If one of the annotations isn't specified, `cloud-controller-manager` fails to process the Service with an error.

Additional resources

- Module `cloud-provider-dynamix` documentation
- Module `node-manager` custom resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with Basis Dynamix cloud services

Deckhouse Platform integrates with the Basis Dynamix cloud platform and uses DynamixInstanceClass resources to describe the characteristics of virtual machines deployed in the cluster.

Key capabilities

- Ordering and removing virtual machines via the Basis Dynamix API
- Configuring virtual machine parameters, including the number of CPUs, memory size, and root disk size
- Specifying the OS template (image name) and the storage policy used for disk placement
- Connecting to external networks
- Using multiple node groups with individual parameters

Example DynamixInstanceClass:

```
apiVersion: deckhouse.io/v1
kind: DynamixInstanceClass
metadata:
  name: frontend
spec:
  numCPUs: 4
  memory: 8192
  rootDiskSizeGb: 40
  imageName: alt-p10-cloud-x86_64.img
  storagePolicy: storage_policy01
  externalNetwork: extnet_vlan_1700
```

It is referenced by the NodeGroup's `cloudInstances.classReference` parameter.

Recommendations

- Place OS images in the "Images" → "Template images" section of the Basis Dynamix portal.
- Use image names that exactly match the `imageName` values in DynamixInstanceClass.
- Make sure the selected storage policy is available to the account and has the `ENABLED` status.
- Verify that virtual machines have access to the internet and to DNS servers.

Cloud integration provides automatic scaling, configuration, and node management according to the parameters set in DynamixInstanceClass and the cluster configuration.

- Module `node-manager` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtualization systems

Deckhouse Platform (DP) supports the following virtualization systems:

- Deckhouse Virtualization Platform (DVP);
- VMware Cloud Director;
- VMware vSphere;
- zVirt.

The following sections describe how you can configure integration with each of these virtualization systems.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with built-in virtualization

Deckhouse Platform integrates with the built-in virtualization infrastructure and uses DVPInstanceClass resources to define the characteristics of virtual machines created as part of the cluster.

Key features:

- Management of built-in virtualization resources via the `cloud-controller-manager module`
- Provisioning of disks using the CSI storage component
- Integration with the `node-manager` module to support DVPInstanceClass when defining a NodeGroup

> The virtualization integration is enabled automatically for all cloud clusters deployed in built-in virtualization. No additional configuration is required.

Load balancers

Virtualization supports Service objects of the `LoadBalancer` type. For every such object, `cloud-controller-manager` creates a `LoadBalancer` Service in the parent cluster and directs traffic to the nodes of the child one. The object is created in the namespace set by the `namespace` parameter, next to the cluster virtual machines.

The external address is assigned by the parent cluster, so a balancer controller must run there, for example the `metallb` module. The controller serves only those Service objects that have a resolved balancer class.

To set the default class, create a MetalLoadBalancerClass resource in the parent cluster with the `isDefault` parameter set to `true`. Such a class serves the Service objects with no class specified, so you can leave the class out in the child cluster.

To pick another class, set it in the `spec.loadBalancerClass` parameter of the Service object in the child cluster. The platform copies the value to the parent cluster along with the `externalIPs` parameter and the deprecated `loadBalancerIP` parameter.

⚠ The `spec.loadBalancerClass` parameter is immutable. Set the class when creating the Service object, otherwise the object has to be recreated.

With no balancer class, the Service object stays in the `Pending` state, and `cloud-controller-manager` reports no errors. Check the state of the object in the parent cluster:

```
d8 k -n <NAMESPACE> get svc
```

Replace `<NAMESPACE>` with the namespace set by the `namespace` parameter.

Load balancer network policy

If the `networkPolicy` parameter is set to `Isolated`, the parent cluster restricts ingress traffic to the cluster virtual machines (VMs). This value is used by default. To let the balancer traffic reach the nodes, `cloud-controller-manager` creates a NetworkPolicy resource for every balancer in the same namespace of the parent cluster.

The policy allows ingress traffic from any source to the NodePort ports of the Service object in the child cluster over the protocols specified in this object. The policy applies only to the VMs the balancer directs traffic to, so every balancer has its own policy, even if several balancers use the same nodes.

`cloud-controller-manager` overwrites manual changes to the policy the next time it updates the balancer. The policy is deleted together with the balancer Service object in the parent cluster.

To find the balancer policy, follow these steps:

1. Get the UID of the Service object in the child cluster:

   ```
   d8 k -n <SERVICE_NAMESPACE> get svc <SERVICE_NAME> -o jsonpath='{.metadata.uid}'
   ```

   Replace `<SERVICE_NAMESPACE>` with the namespace of the Service object and `<SERVICE_NAME>` with its name.

2. Display the policy in the parent cluster:

   ```
   d8 k -n <NAMESPACE> get networkpolicy lb-<SERVICE_UID>
   ```

   Replace `<NAMESPACE>` with the namespace set by the `namespace` parameter and `<SERVICE_UID>` with the UID obtained in the previous step.

Additional resources

- Module `cloud-provider-dvp` parameters
- Module `metallb` documentation
- Module `node-manager` documentation

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in built-in virtualization

To interact with built-in virtualization resources, Deckhouse Platform components use the virtualization API. To configure access, create a user (ServiceAccount), assign the necessary permissions, and generate a kubeconfig.

⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

⚠ If the `update-hostname` module of the `cloud-init` package is not disabled, it is recommended to change its run frequency from `always` to `once-per-instance`.

To do this, modify the `update-hostname` module configuration in the `/etc/cloud/cloud.cfg` file:

```
cloud_init_modules:
  ...
  - [update-hostname, once-per-instance]
  ...
```

The `update-hostname` module can also be disabled completely by removing it from the `cloud_init_modules` module list in the `/etc/cloud/cloud.cfg` file.

Creating a user

Create a new user in the built-in virtualization cluster using the following command:

```
d8 k create -f -<<EOF
apiVersion: v1
kind: ServiceAccount
metadata:
  name: sa-demo
  namespace: default
---
apiVersion: v1
kind: Secret
metadata:
  name: sa-demo-token
  namespace: default
  annotations:
    kubernetes.io/service-account.name: sa-demo
type: kubernetes.io/service-account-token
EOF
```

Assigning a role

Assign a role to the created user in the built-in virtualization cluster using the following command:

```
d8 k create -f -<<EOF
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: sa-demo-rb
  namespace: default
subjects:
  - kind: ServiceAccount
    name: sa-demo
    namespace: default
roleRef:
  kind: ClusterRole
  name: d8:namespace:manager
  apiGroup: rbac.authorization.k8s.io
EOF
```

If the virtualization cluster runs a DP version earlier than 1.78, the `d8:namespace:*` roles do not exist there. In this case, specify the `d8:use:role:manager` role in `roleRef.name`.

Generating a kubeconfig

Generate a kubeconfig to be used in the cluster initial configuration file:

```
cat <<EOF > kubeconfig
apiVersion: v1
clusters:
- cluster:
    server: https://<KUBE-APISERVER-URL>   # Replace this with the actual API server address for the
cluster.
  name: <CLUSTER-NAME>                     # Replace with the cluster name.
contexts:
- context:
    cluster: <CLUSTER-NAME>                # Replace with the cluster name.
    user: sa-demo
    namespace: default
  name: sa-demo-context
current-context: sa-demo-context
kind: Config
preferences: {}
users:
- name: sa-demo
  user:
    token: $(d8 k get secret sa-demo-token -n default -o json | jq -rc .data.token | base64 -d)
EOF
```

Encode the generated kubeconfig file using Base64 encoding (put it in the `d8-credentials` Secret in the `stringData.secret` field of the initial configuration file):

```
base64 kubeconfig | tr -d '\n'
```

Credentials Secret

The credentials for accessing the parent cluster API are stored in a separate Secret rather than in the ModuleConfig. The provider reads it when starting the components that access the DVP API.

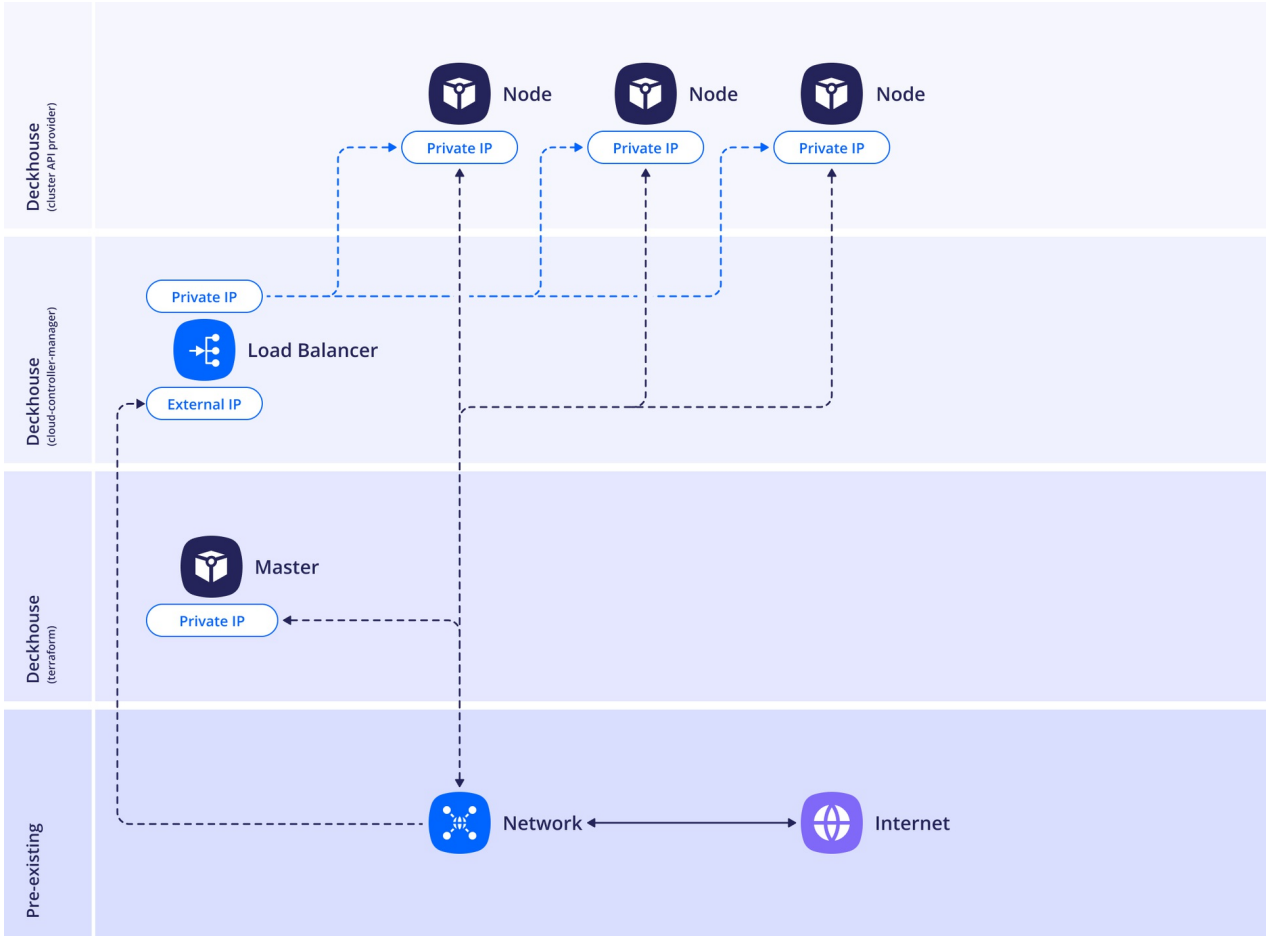
The Secret is created during cluster installation together with the other resources of the initial configuration. If the module is added to a running cluster, the Secret is applied after the module creates the namespace, and the order is covered in the Hybrid cluster with DVP section. The Secret must meet the following requirements:

- The name is `d8-credentials` and the namespace is `d8-cloud-provider-dvp`.
- The type is `cloud-provider.deckhouse.io/credentials`.
- The `authScheme` field is set to `kubeconfig`.
- The `secret` field contains the Base64-encoded kubeconfig.

```
apiVersion: v1
kind: Secret
metadata:
  name: d8-credentials
  namespace: d8-cloud-provider-dvp
type: cloud-provider.deckhouse.io/credentials
stringData:
  authScheme: kubeconfig
  secret: <KUBE_CONFIG_BASE64>
```

Replace `<KUBE_CONFIG_BASE64>` with the Base64-encoded kubeconfig.

To change the credentials, update the `secret` field:



```
d8 k -n d8-cloud-provider-dvp edit secret d8-credentials
```

In clusters migrated to ModuleConfig, the kubeconfig is moved to this Secret from the `provider.kubeconfigDataBase64` parameter of the DVPClusterConfiguration resource.

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in built-in virtualization

Standard

> ⚠ If the cluster was installed with the DVPClusterConfiguration schema, migration to ModuleConfig-based configuration is required. Until the migration is completed, the `D8CloudProviderDVPMigrationPending` alert may fire and Deckhouse updates may be blocked.
>
> See: How to migrate a cloud provider to ModuleConfig-based configuration.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-dvp
spec:
  version: 2
  enabled: true
  settings:
    nodes:
      parameters:
        layout: Standard
        sshPublicKey: <SSH_PUBLIC_KEY>
        ipAddresses:
          master:
            - Auto
    provider:
      parameters:
        namespace: demo
---
apiVersion: v1
kind: Secret
metadata:
  name: d8-credentials
  namespace: d8-cloud-provider-dvp
type: cloud-provider.deckhouse.io/credentials
stringData:
  authScheme: kubeconfig
  secret: <KUBE_CONFIG_BASE64>
---
apiVersion: deckhouse.io/v1alpha1
kind: DVPInstanceClass
metadata:
  name: master
spec:
  virtualMachine:
    cpu:
      cores: 4
      coreFraction: 100%

    minPerZone: 1
  nodeTemplate:
    labels:
      node-role.kubernetes.io/control-plane: ""
      node-role.kubernetes.io/master: ""
```

Configuration

The built-in virtualization cloud provider parameters are set in four resources:

- The ModuleConfig of the `cloud-provider-dvp` module defines the layout and the parent cluster connection

parameters.
- The `d8-credentials` Secret in the `d8-cloud-provider-dvp` namespace stores the credentials for accessing the parent cluster API. Its format is covered in the Credentials Secret section.
- The DVPInstanceClass resource describes the virtual machine parameters.
- The NodeGroup resource describes the node groups and references the instance class.

To modify the provider settings in a running cluster, edit the ModuleConfig:

```
d8 k edit mc cloud-provider-dvp
```

After changing node parameters, run the command:

```
dhctl converge
```

Example of a configuration with multiple parameters:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-dvp
spec:
  version: 2
  enabled: true

  nodeType: CloudPermanent
  cloudInstances:
    classReference:
      kind: DVPInstanceClass
      name: worker
    maxPerZone: 1
    minPerZone: 1
    zones:
      - zone-a
      - zone-b
      - zone-c
```

Replacing the OS image

The `rootDisk.image` parameter of DVPInstanceClass defines the image for `CloudEphemeral` nodes. With a ModuleConfig-based provider configuration, this parameter also defines the image for `CloudPermanent` nodes and master nodes.

With a DVPClusterConfiguration-based configuration, the image for `CloudPermanent` nodes and master nodes is set by `rootDisk.image` in `nodeGroups[].instanceClass` and `masterNodeGroup.instanceClass`, respectively.

The replacement procedure is described in “How do I replace the OS image in a cloud cluster?” .

Connection and authorization in VMware Cloud Director

Resource preparation

> ⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

To manage resources in VCD using the “Deckhouse Platform”, the following resources must be configured in the system:

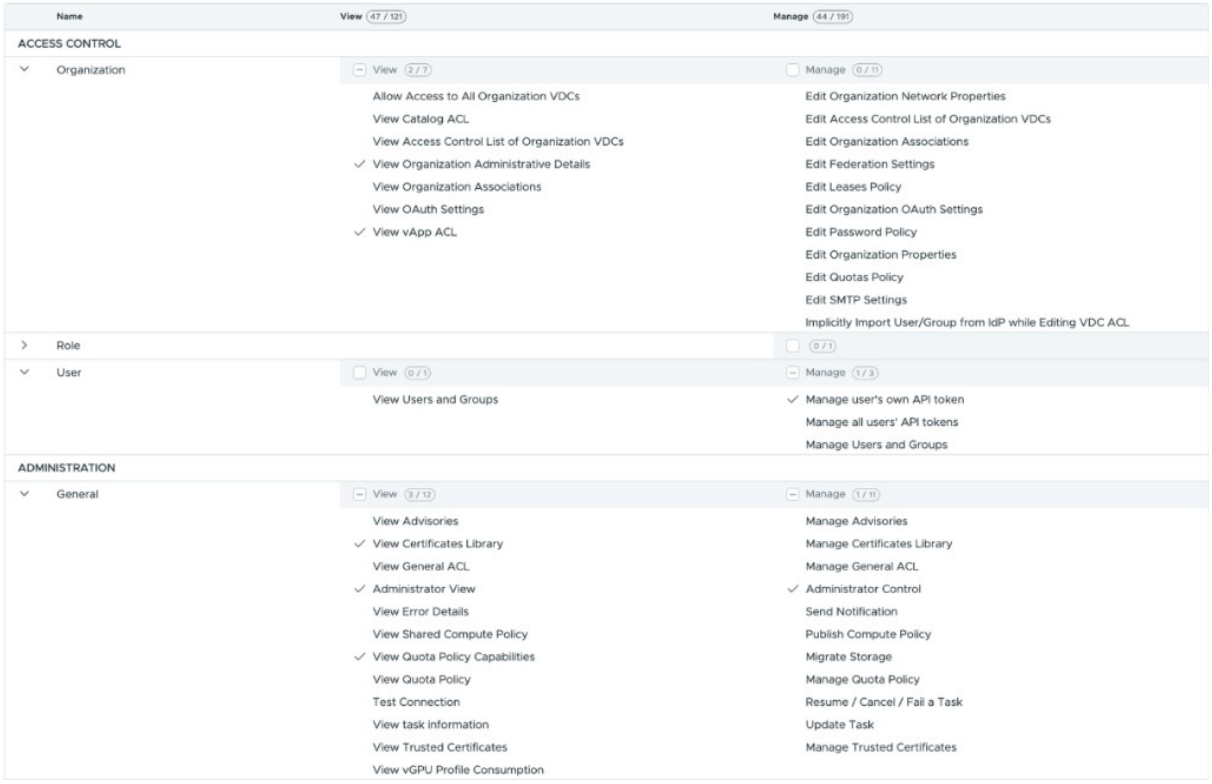
- Organization
- VirtualDataCenter
- vApp (for the “Standard” placement scheme)
- StoragePolicy
- SizingPolicy
- Network (for the “Standard” placement scheme)
- EdgeRouter
- Catalog

The Organization, VirtualDataCenter, StoragePolicy, SizingPolicy, EdgeRouter, and Catalog resources must be provided by your VMware Cloud Director service provider.

The Network (internal network) can be configured by your VMware Cloud Director service provider or by yourself. When using the “StandardWithNetwork” placement scheme, the network is created automatically. Below is a method for manually setting up an internal network.

User permissions

For access to the VMware Cloud Director API, one of the following options is sufficient:

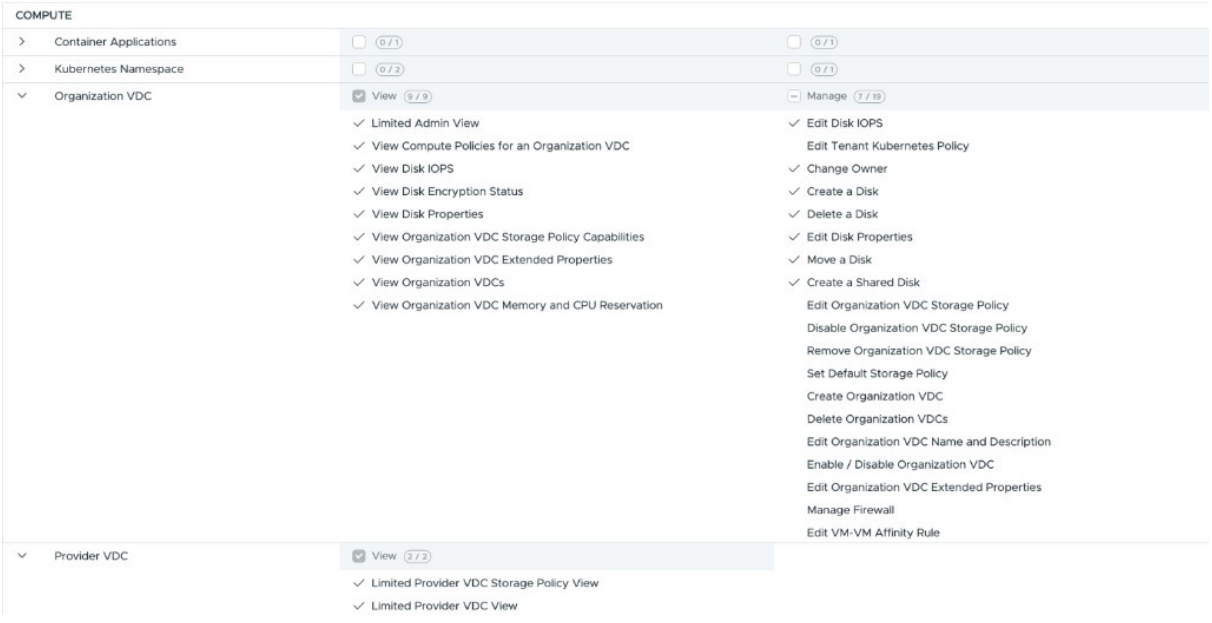


- The `Organization Administrator` role with the `Preserve All ExtraConfig Elements During OVF Import and Export` right. This option does not require configuring a separate role, but grants the user full administrative access to the organization.
- A custom role with the set of rights listed below. This set is sufficient to create a cluster, provision nodes (including CloudEphemeral with static addressing and DHCP), and work with CSI disks and StorageClass without granting additional administrative rights.

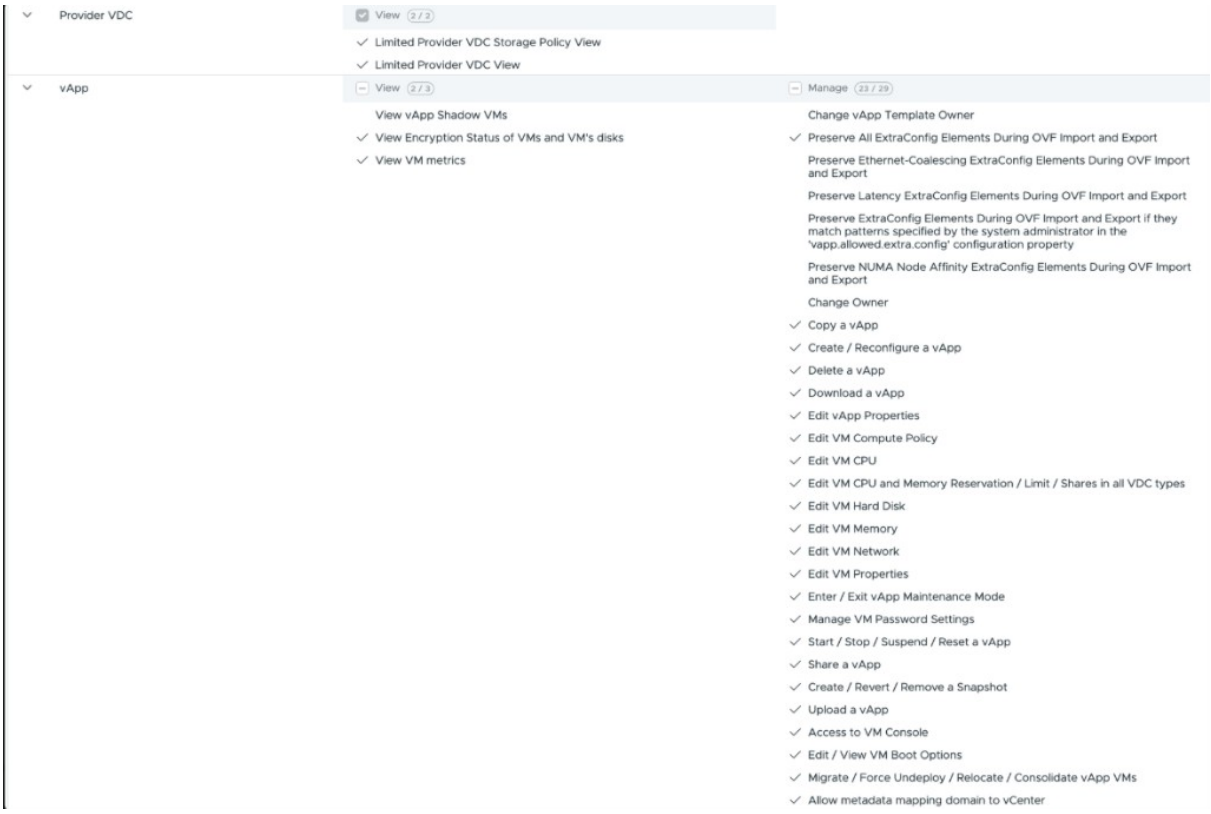
In VMware Cloud Director, user permissions come from the role and from a **Rights Bundle** — a set of rights published to the organization. Add the `Preserve All ExtraConfig Elements During OVF Import and Export` right both to the role and to the organization’s Rights Bundle.

> ⚠ Without the `Preserve All ExtraConfig Elements During OVF Import and Export` right in both the role and the organization’s Rights Bundle, `userdata` is not passed to the virtual machines of ephemeral nodes.

To create a custom role, enable the rights as shown below. Right names match the VCD UI.



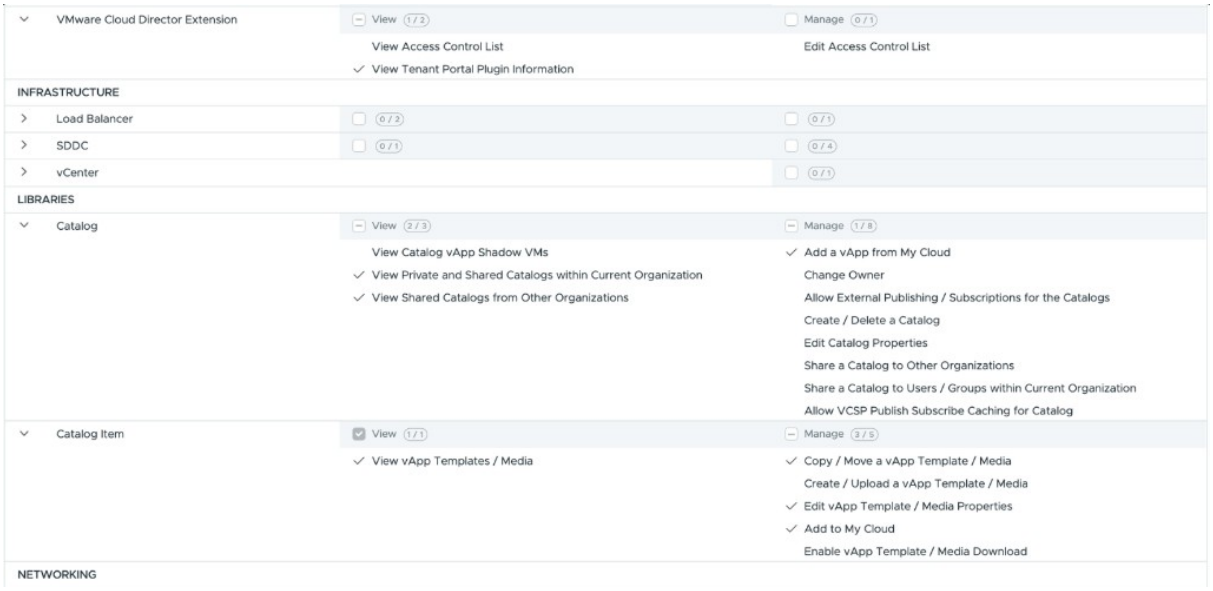
1. In the “ACCESS CONTROL” and “ADMINISTRATION” sections, enable the following rights:
   - Organization → View: `View Organization Administrative Details`, `View vApp ACL`
   - User → Manage: `Manage user's own API token`
   - General → View: `View Certificates Library`, `Administrator View`, `View Quota Policy Capabilities`
   - General → Manage: `Administrator Control`



2. In the “COMPUTE” → “Organization VDC” section, enable all View rights and the following Manage rights:

   - `Edit Disk IOPS`
   - `Edit Tenant Kubernetes Policy`
   - `Change Owner`
   - `Create a Disk`
   - `Delete a Disk`
   - `Edit Disk Properties`
   - `Move a Disk`
   - `Create a Shared Disk`

   In the “Provider VDC” → View section, enable `Limited Provider VDC Storage Policy View` and `Limited Provider VDC View`:

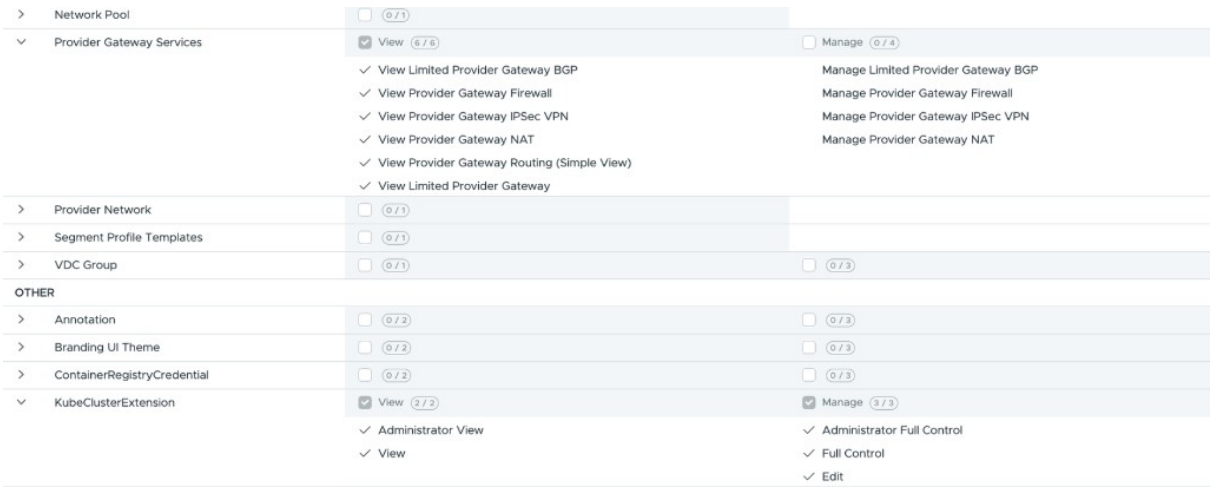


3. In the “COMPUTE” → “vApp” section, enable the rights as shown in the screenshot. Make sure that `Preserve All ExtraConfig Elements During OVF Import and Export` is enabled. In the verified role, View includes `View Encryption Status of VMs and VM's disks` and `View VM metrics`; `View vApp Shadow VMs` and the other Preserve ExtraConfig options are not enabled:

4. In the “LIBRARIES” section, enable the following rights:

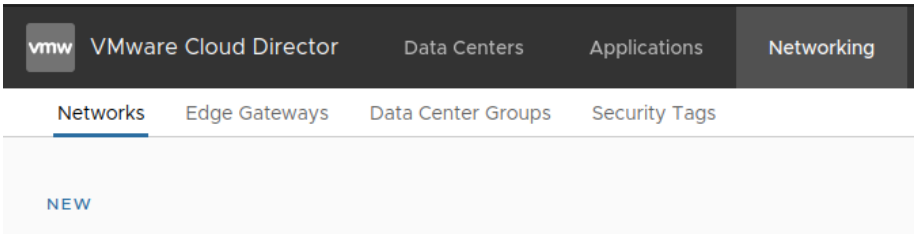
   - Catalog → View: `View Private and Shared Catalogs within Current Organization`, `View Shared Catalogs from Other Organizations` (to use images from shared catalogs)
   - Catalog → Manage: `Add a vApp from My Cloud`
   - Catalog Item → View: `View vApp Templates / Media`
   - Catalog Item → Manage: `Copy / Move a vApp Template / Media`, `Edit vApp Template / Media Properties`, `Add to My Cloud`

   In the “VMware Cloud Director Extension” → View section, enable `View Tenant Portal Plugin Information`:

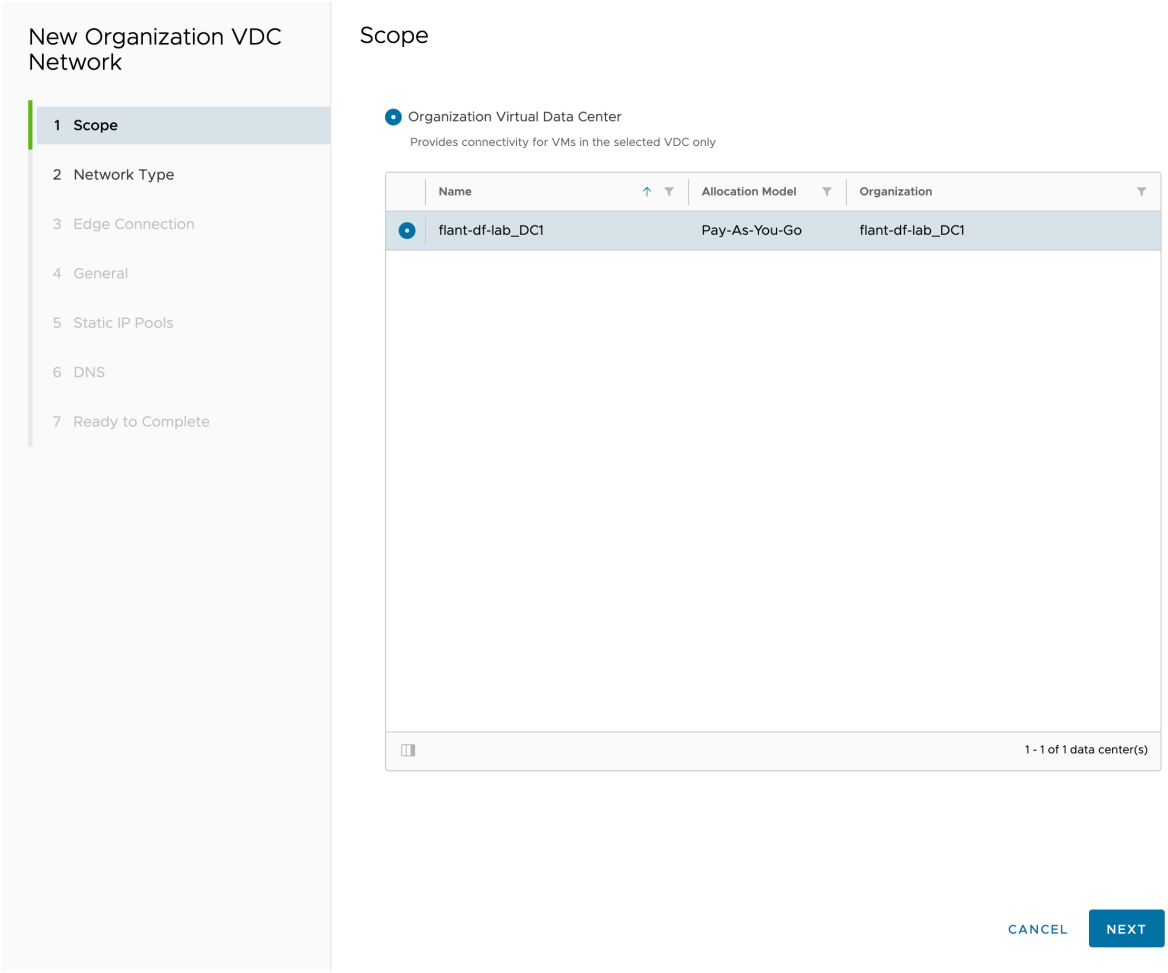


5. In the “NETWORKING” section, enable the following rights:

   - Edge Gateway → View: `View Gateway`
   - Edge Gateway Services → View: all items
   - Edge Gateway Services → Manage: `Load Balancer Configure`, `NAT Configure`
   - IP Spaces → View: `View IP Spaces`
   - IP Spaces → Manage: `Allocate IP Spaces`, `Manage IP Spaces`
   - Organization VDC Network → View: `View Properties`
   - Organization VDC Network → Manage: `Edit Properties` (required to create networks in the organization)

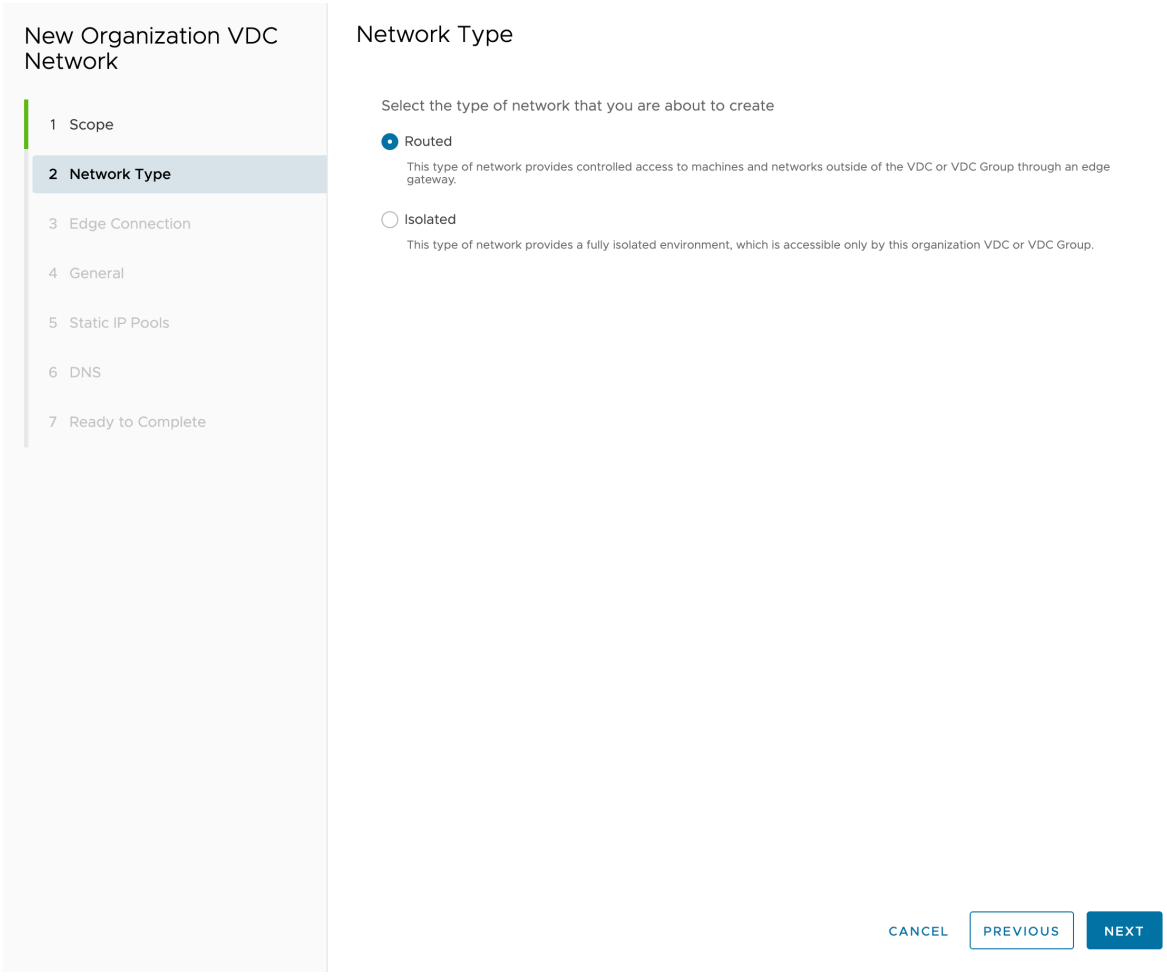


6. In the “Provider Gateway Services” section, enable all View rights. In the “KubeClusterExtension” section, enable all View and Manage rights:

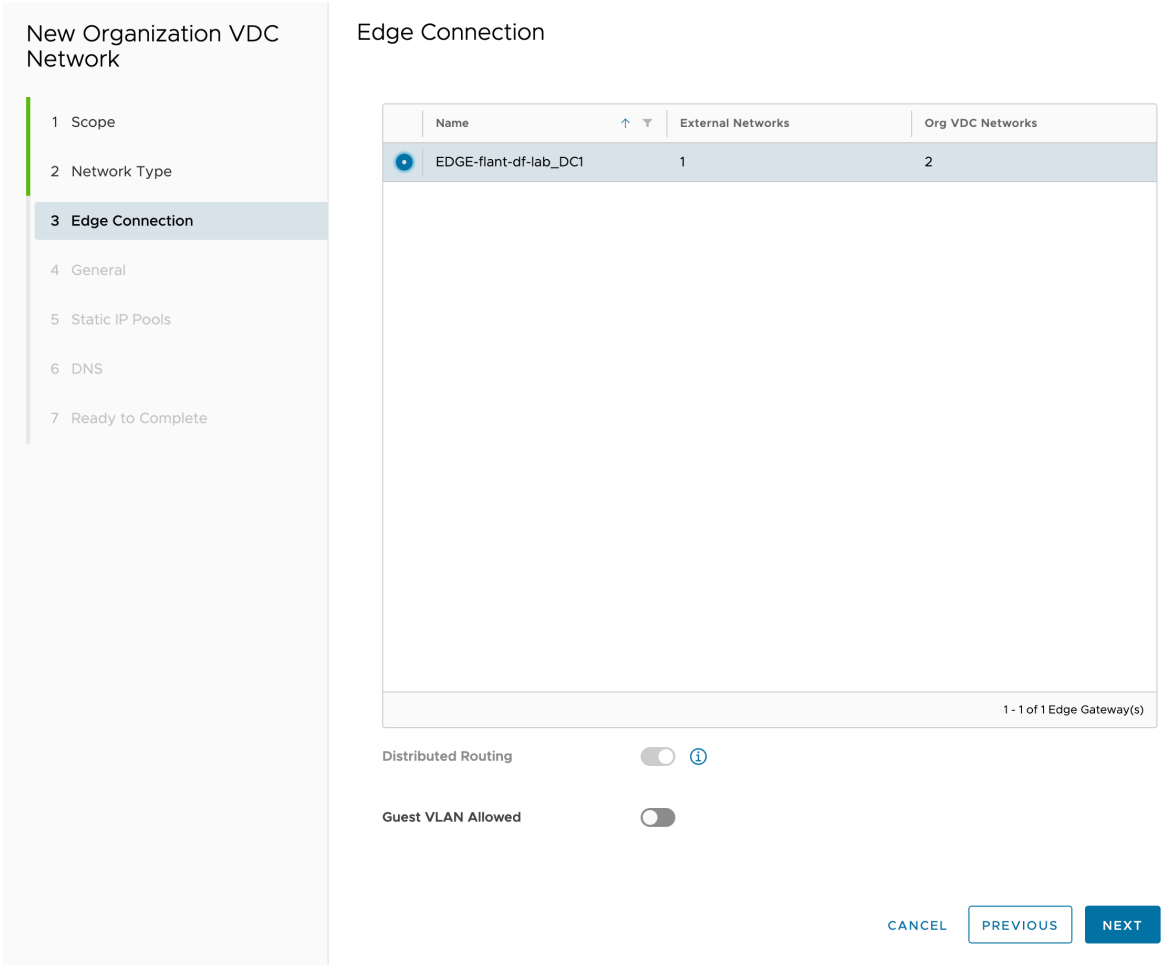


Adding a network

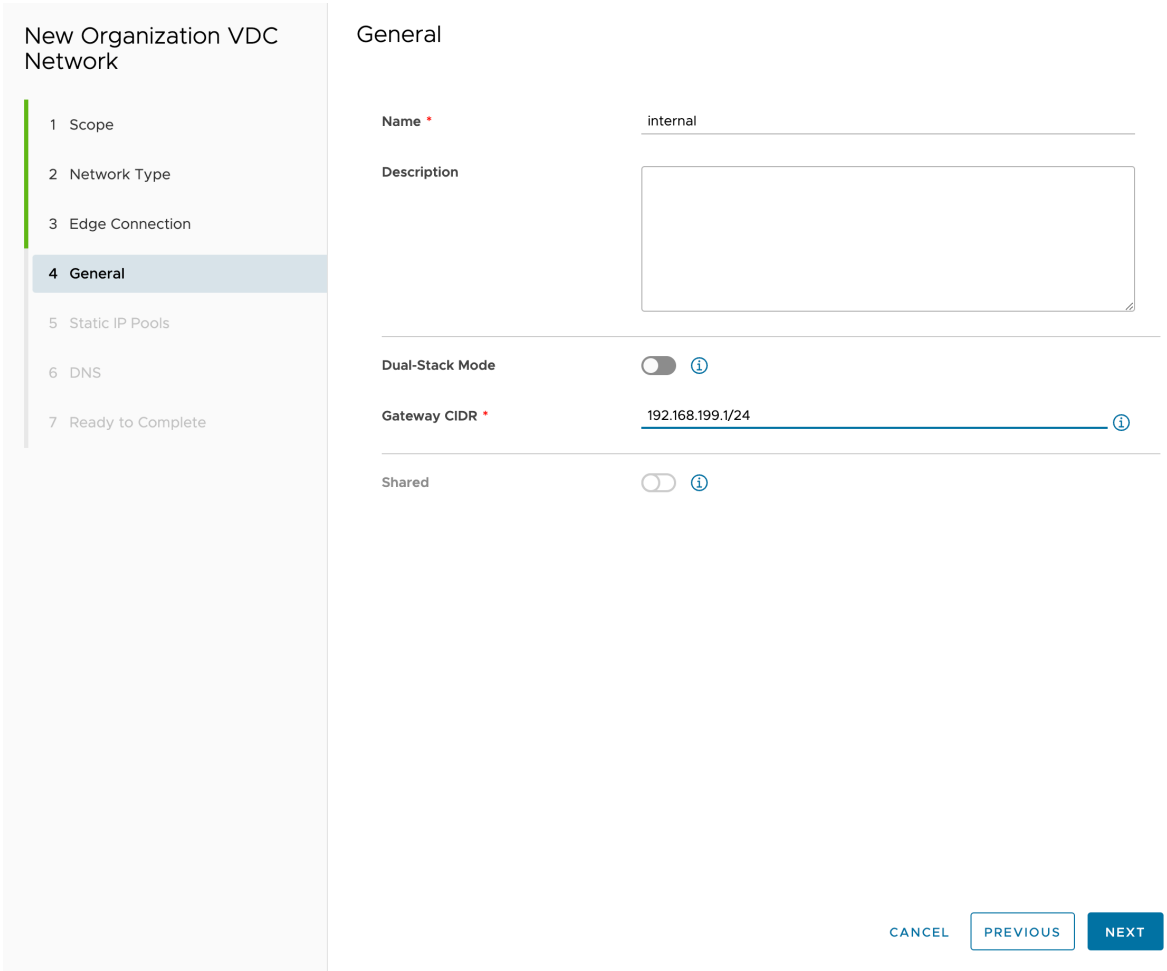
> **i** This instruction applies only to the “Standard” placement scheme.



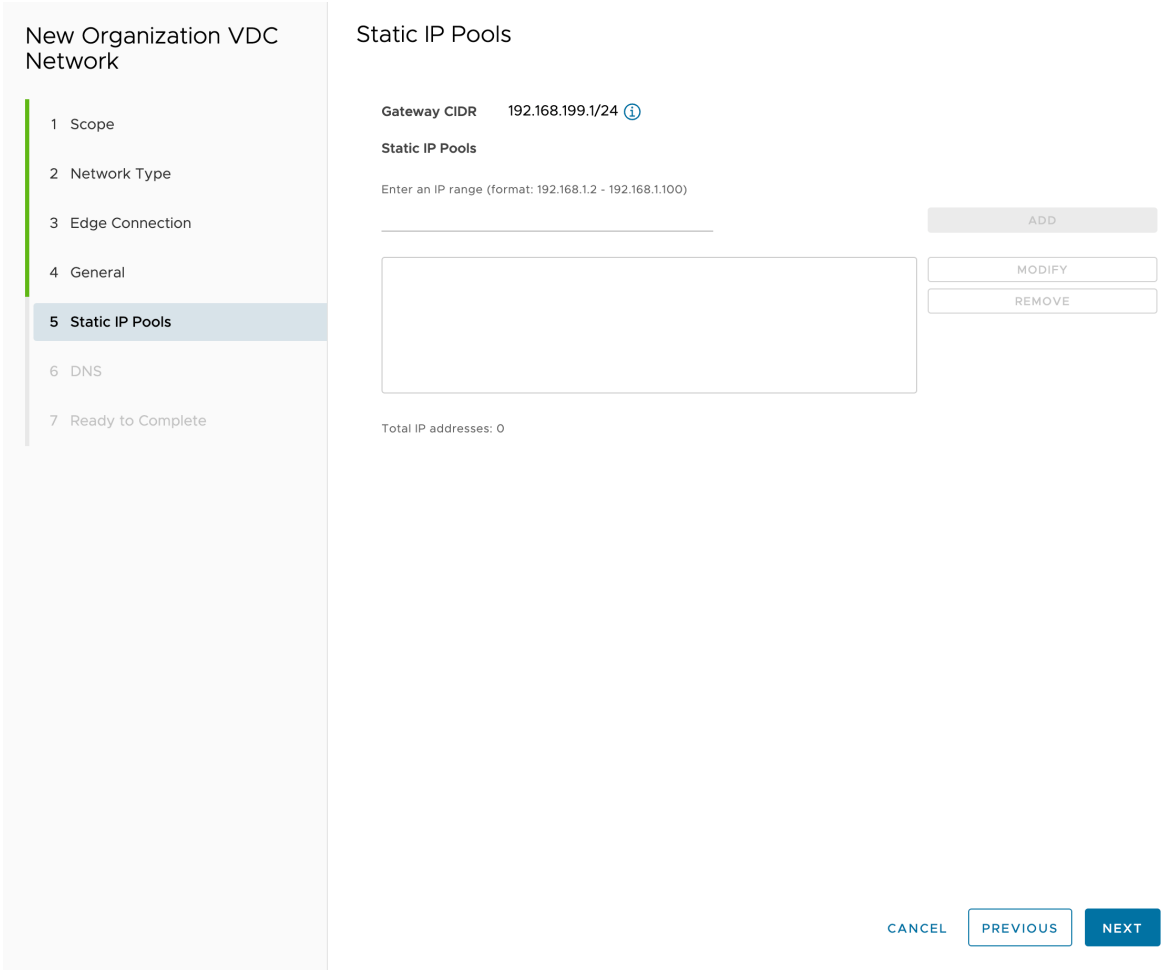
1. Go to the “Networking” tab and click “NEW”:



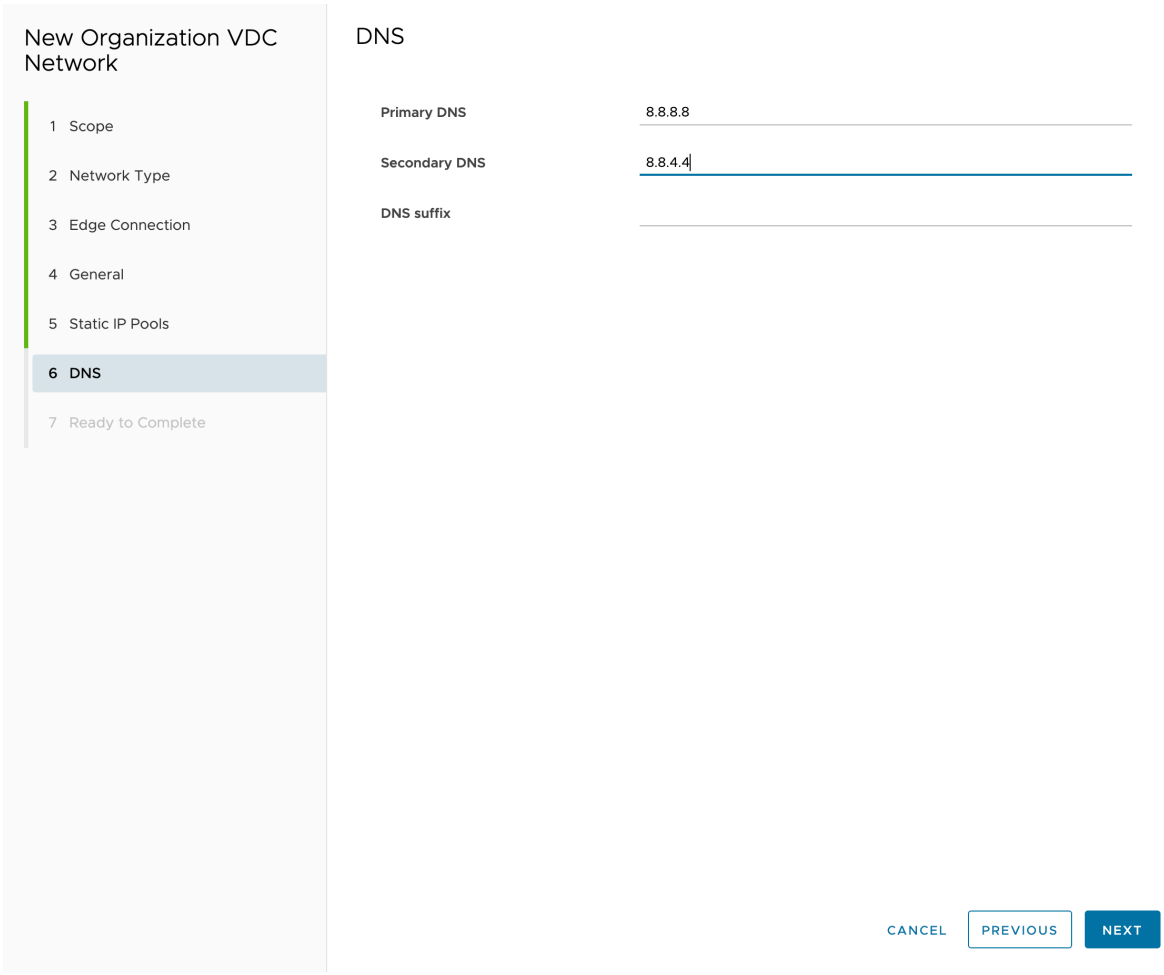
2. Select the desired “Data Center”:



3. In the “Network type” step, select “Routed”:



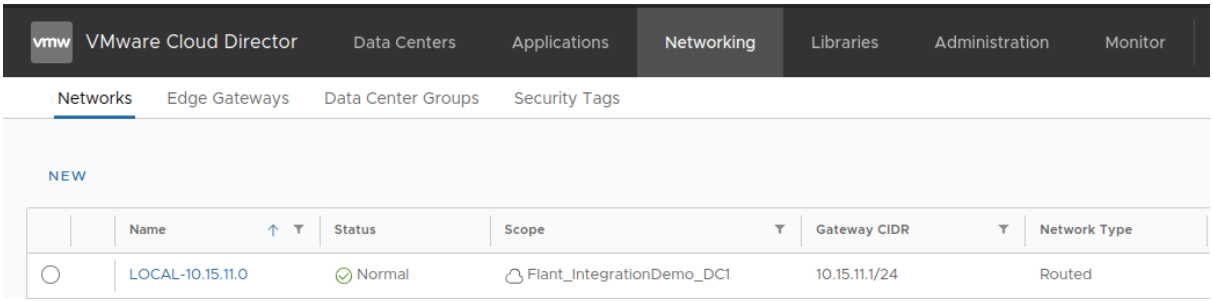
4. Connect the “EdgeRouter” to the network:



5. Specify the network name and CIDR:

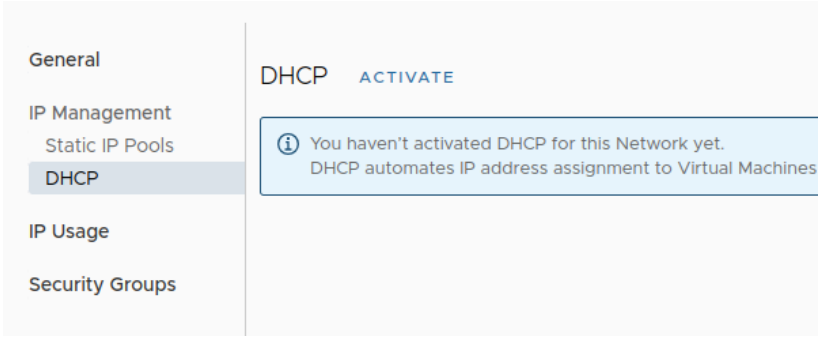
6. Do not add “Static IP Pools” since DHCP will be used:

7. Specify DNS server addresses:



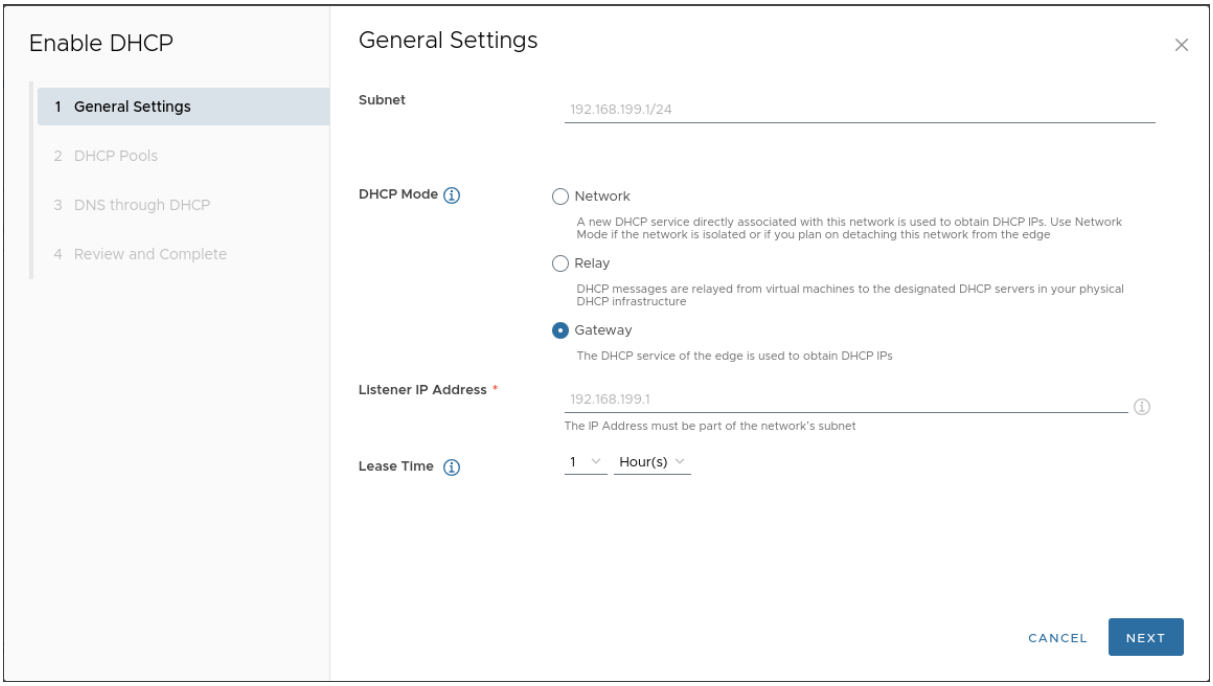
DHCP setup

> **i** This instruction applies only to the “Standard” placement scheme.

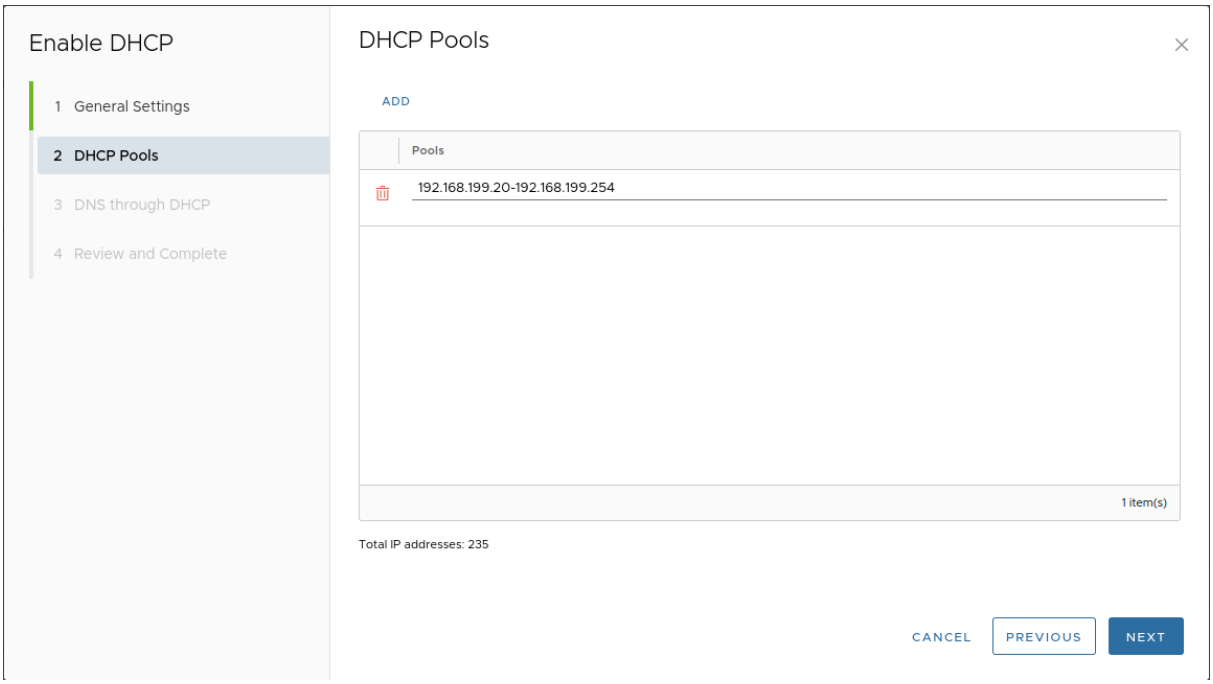


To dynamically provision nodes, enable the DHCP server for the internal network.

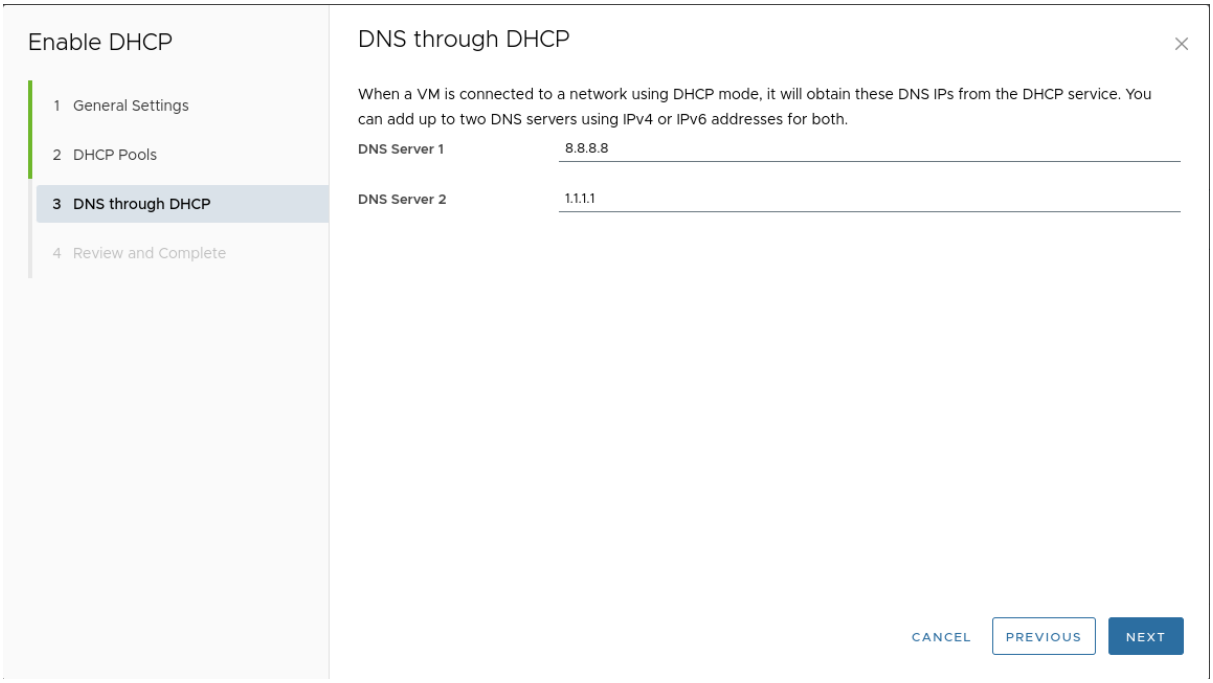
> **i** We recommend reserving the beginning of the address range for system workloads (control plane, frontend nodes, system nodes), and using the rest for the DHCP pool.
> For example, for a “/24” network, reserving 20 addresses for system workloads is sufficient.



1. Go to the “Networking” tab and open the created network:

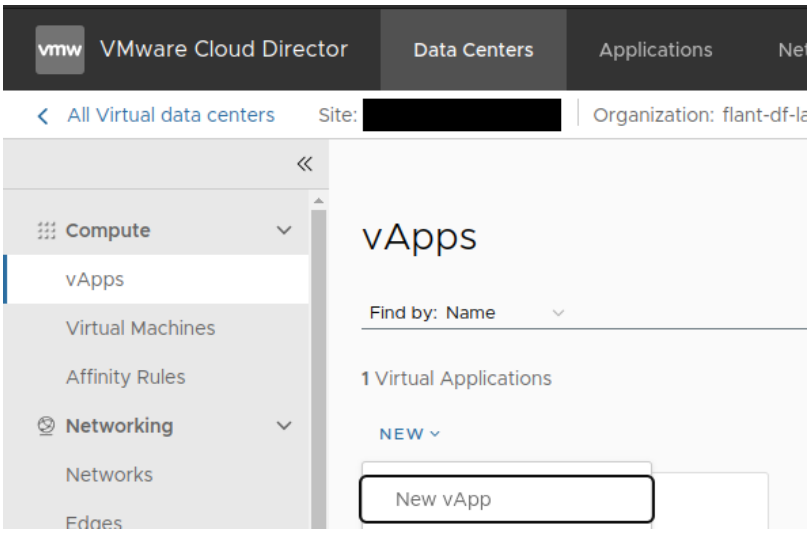


2. In the opened window, select “IP Management” → “DHCP” → “Activate”:

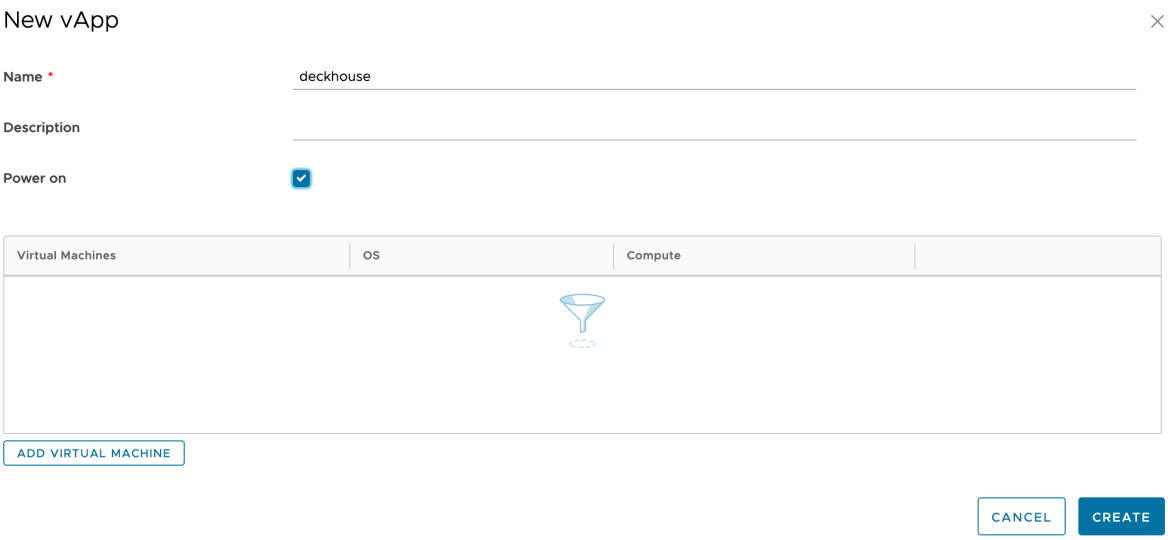


3. In the “General settings” tab, configure parameters as shown in the example:

4. Add a pool:



5. Specify DNS server addresses:

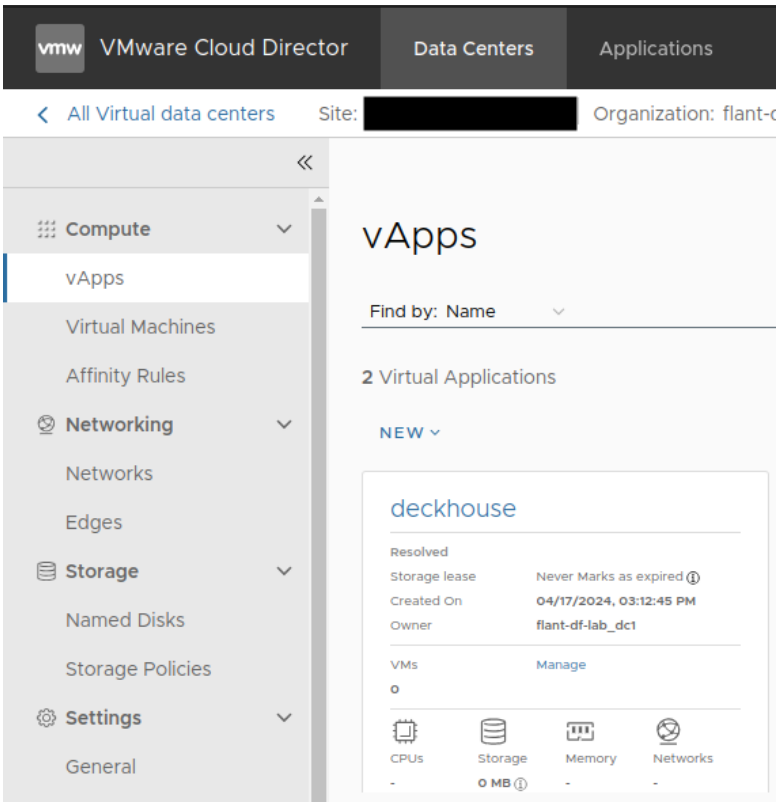


Adding a vApp

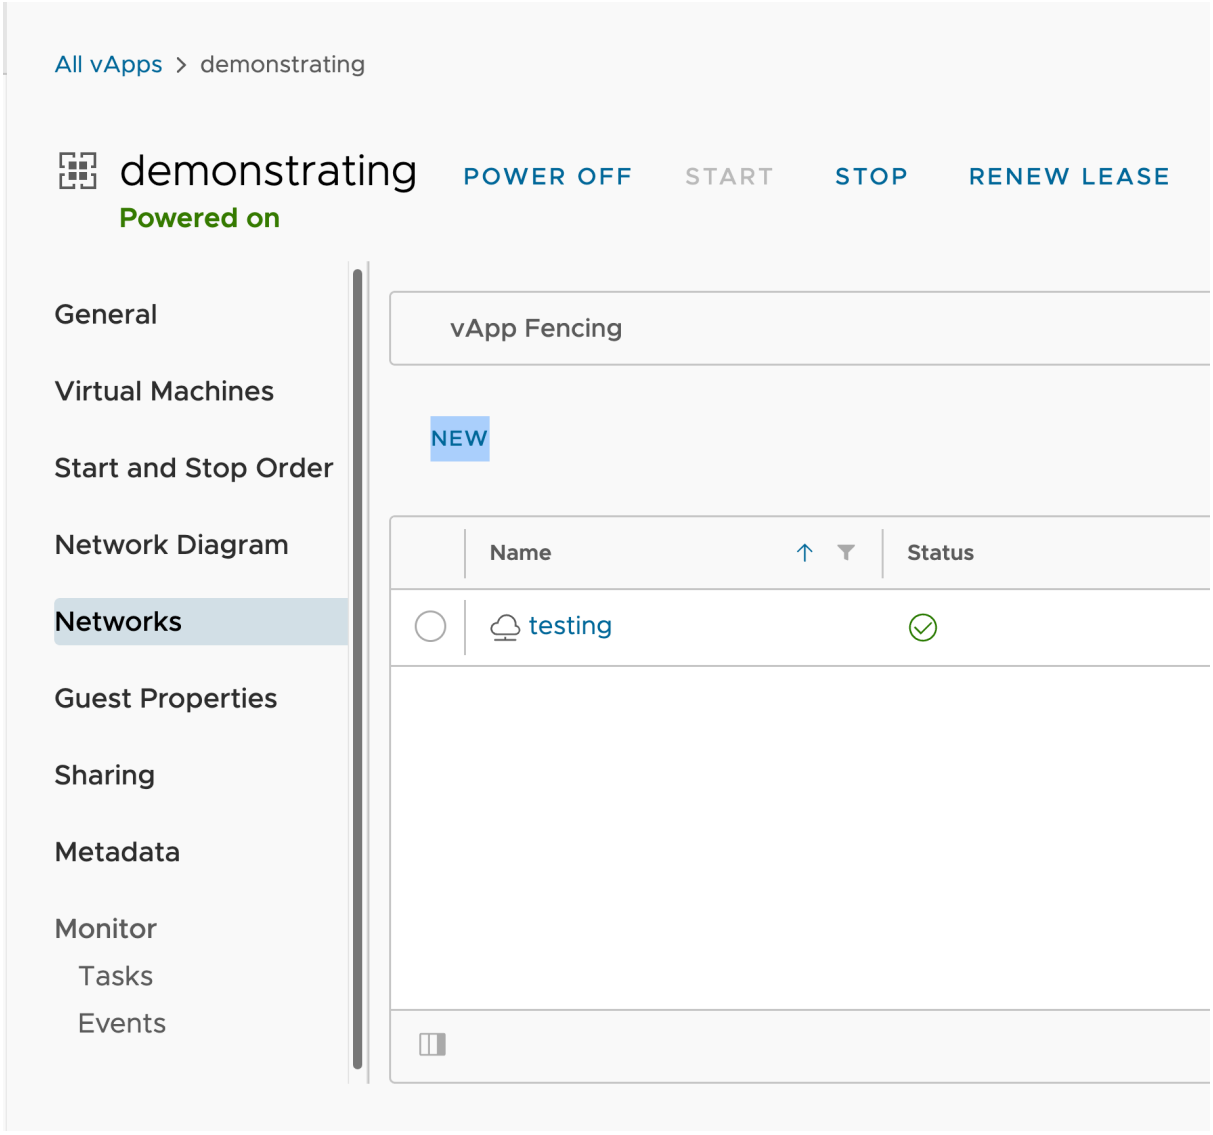
> **i** This instruction applies only to the “Standard” placement scheme.

1. Go to “Data Centers” → “vApps” → “NEW” → “New vApp”:

2. Specify a name and enable the vApp:

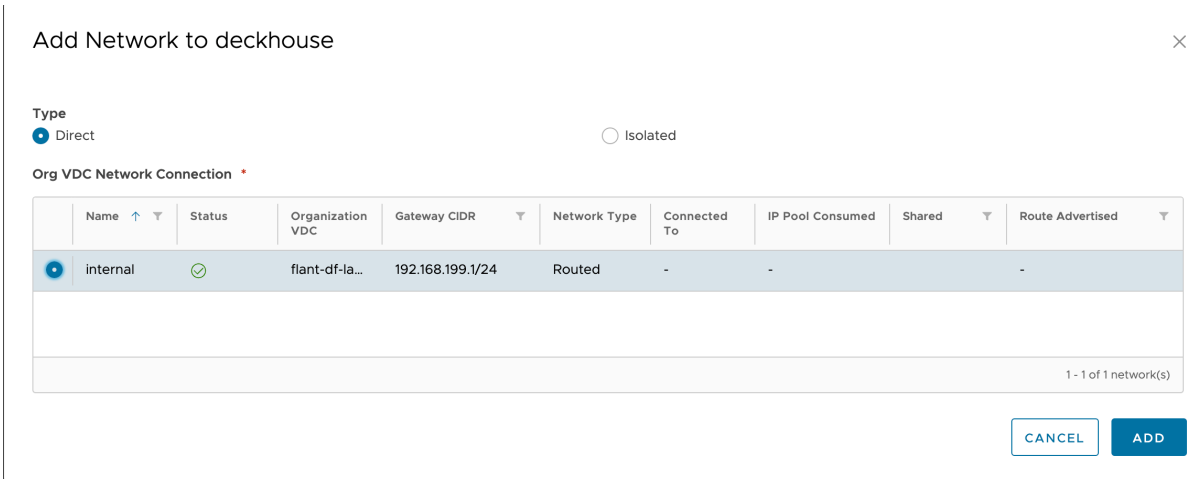


Adding a network to a vApp



> **i** This instruction applies only to the “Standard” placement scheme.

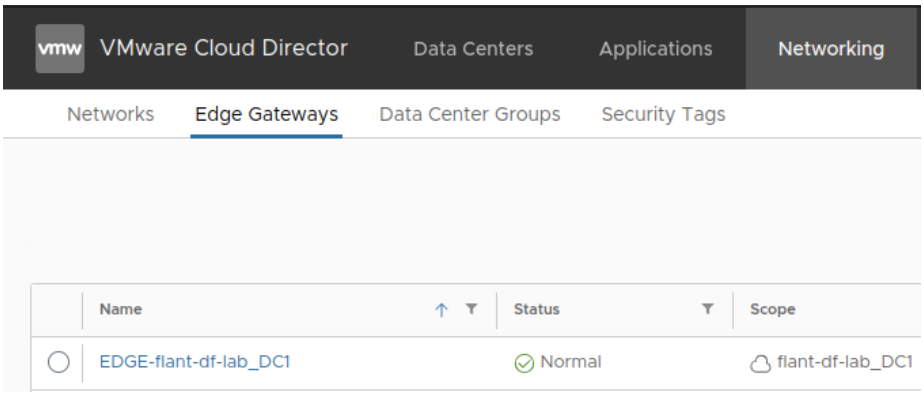
After creating the vApp, attach the created internal network to it.



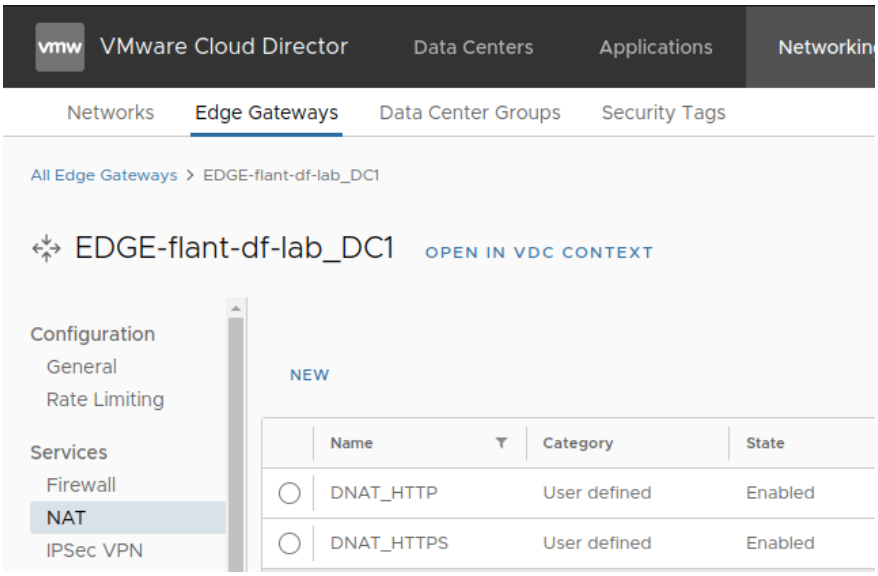
1. Go to “Data Centers” → “vApps” and open the desired vApp:

2. Go to the “Networks” tab and click “NEW”:

3. In the pop-up window, select “Direct” type and choose the network:

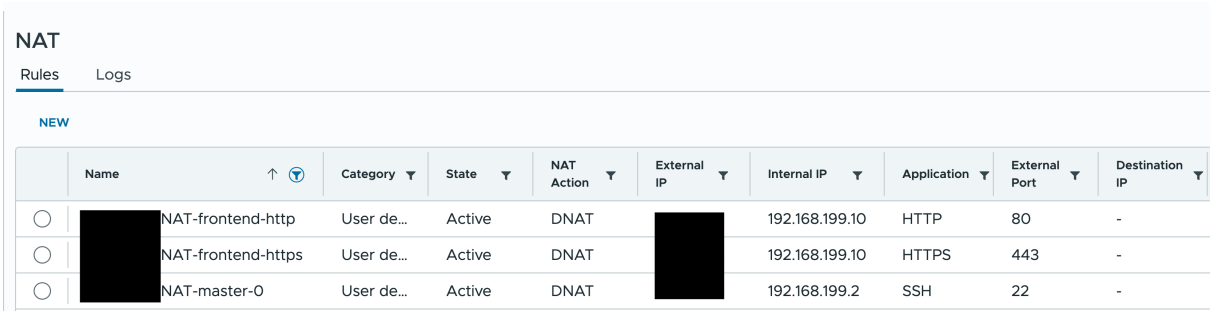


Incoming traffic



Incoming traffic must be directed to the edge router (ports “80”, “443”) using DNAT rules to the allocated address in the internal network.
This address is managed by MetalLB in L2 mode on dedicated frontend nodes.

Configuring DNAT/SNAT rules on the Edge Gateway



1. Go to “Networking” → “Edge Gateways”, open the edge gateway:

2. Go to “Services” → “NAT”:

3. Add the following rules:

The first two rules are for incoming traffic, and the third is for SSH access to the control plane node (required for installation).

4. To allow virtual machines to access the internet, configure SNAT rules as in the example:

This rule allows VMs from the “192.168.199.0/24” subnet to access the internet.

Let’s Encrypt certificate issuance

> **i** This instruction is applicable only for the `Standard` deployment layout.

When using `cert-manager` with the HTTP-01 ACME challenge type, you may need to configure Hairpin NAT (NAT loopback) on the Edge Gateway.

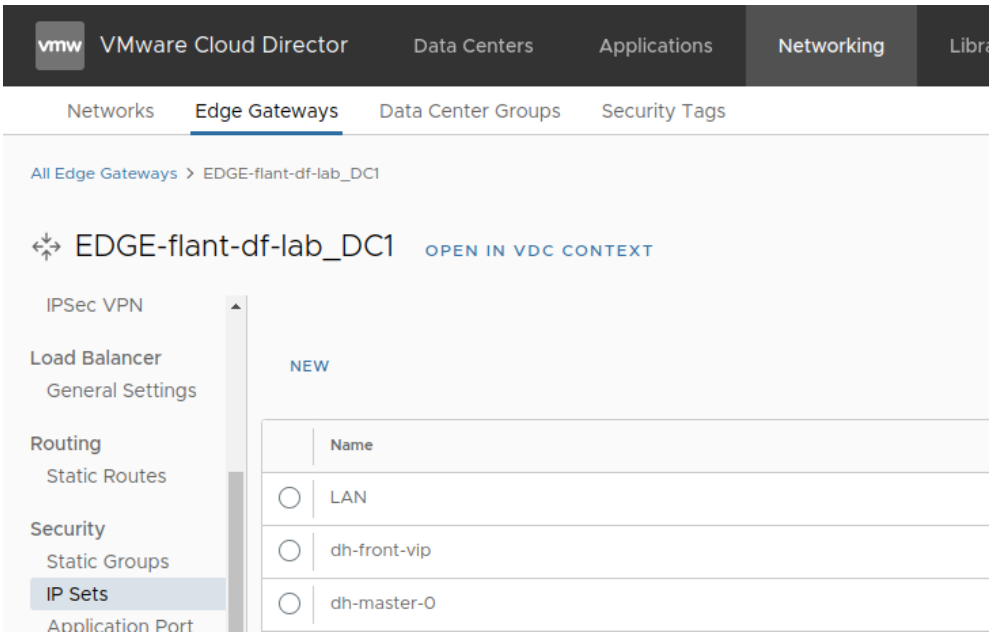
This is required when the Ingress domain name resolves to the external IP address of the Edge Gateway, while requests to that address are made from **inside** the cluster (from the node network). In this case, the traffic must be correctly routed back to the internal network to the Ingress address (for example, the MetalLB address).

This is important for issuing Let’s Encrypt certificates because cert-manager performs a preliminary self-check of the challenge URL before sending a request to the ACME provider. If the URL is not reachable from inside the cluster, certificate issuance will not start, even if the address is accessible from outside.

Example (cluster network `192.168.199.0/24`):

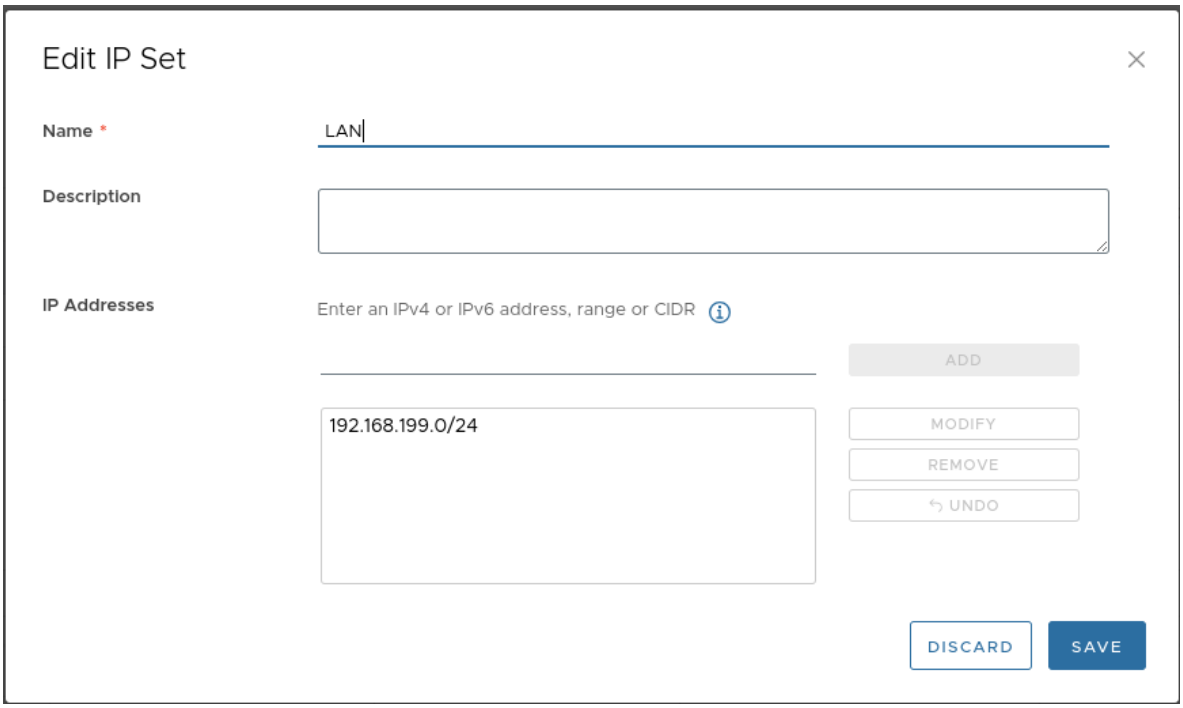
- internal node network: `192.168.199.0/24`
- external Edge Gateway IP address: `194.117.83.19`
- internal Ingress address (for example, MetalLB): `192.168.199.251`.

In this case, you must configure Hairpin NAT for traffic from the `192.168.199.0/24` network that is sent to the external IP `194.117.83.19`, with translation to the internal Ingress address `192.168.199.251`. Apply Hairpin NAT rules (DNAT and SNAT if needed) to the **local interface** of the Edge Gateway, not to the Uplink.

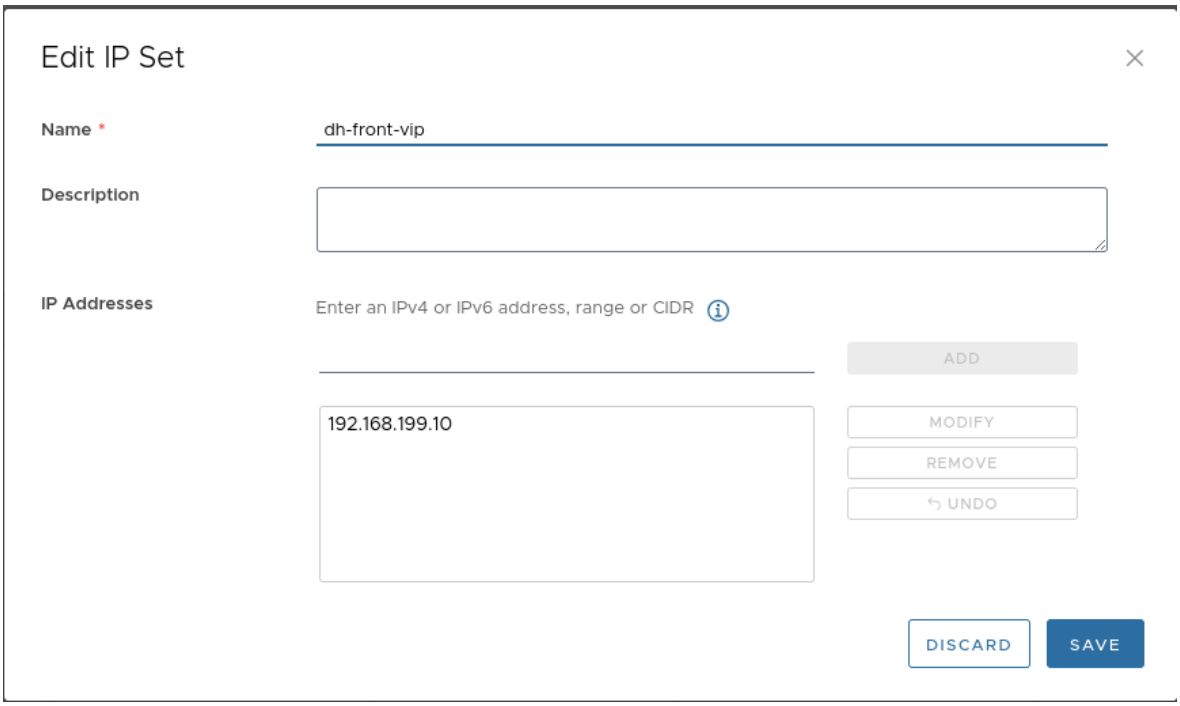


> **i** Hairpin NAT configuration may be required for Edge Gateway based on NSX-V.
>
> For NSX-T, the loopback scenario is often supported by default, but the actual behavior depends on the VMware Cloud Director configuration.

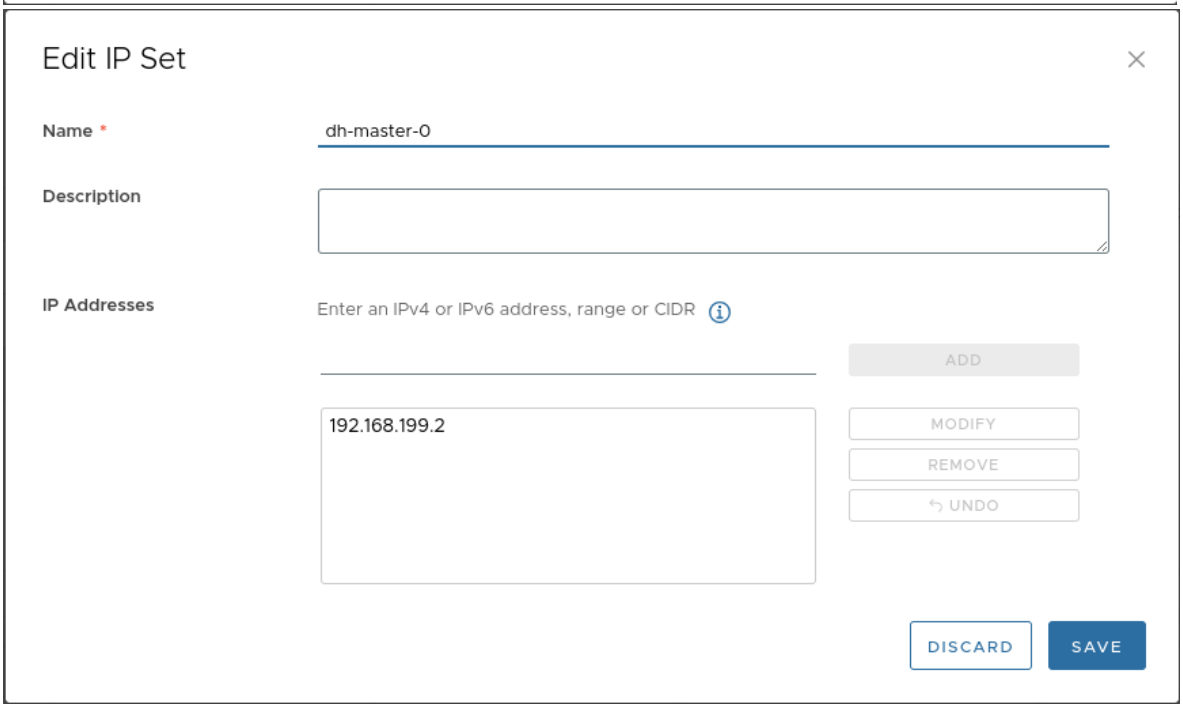
Firewall setup



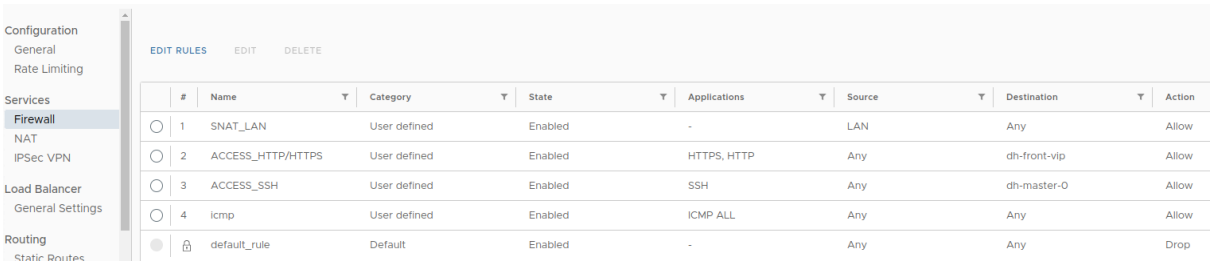
> **i** This instruction applies only to the “Standard” placement scheme.



After configuring DNAT, configure the firewall. Start by setting up IP sets.



1. Go to “Security” → “IP Sets”:



2. Create the following IP set (assuming the MetalLB address will be “.10” and the control plane node “.2”):

3. Add the following firewall rules:

Virtual machine template

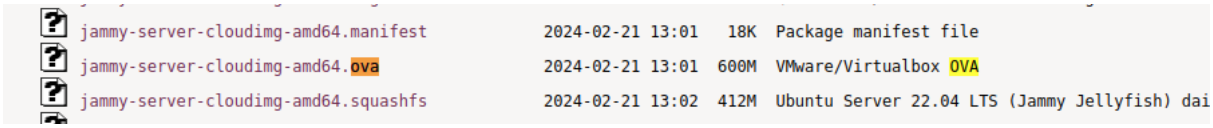
⚠ The provider has been tested only with virtual machine templates based on “Ubuntu 22.04”.

⚠ Disable vApp/Guest OS Customization (Guest Customization, vApp Customization, and similar mechanisms) for the cluster template and virtual machines in VMware Cloud Director. DP performs the initial node provisioning via `cloud-init` (OVF/VMware GuestInfo datasource). If customization is enabled, it may conflict with `cloud-init` and result in incorrect node initialization.

⚠ To use `ContainerdV2` as the container runtime on cluster nodes, the operating systems on virtual machines must meet the following requirements:

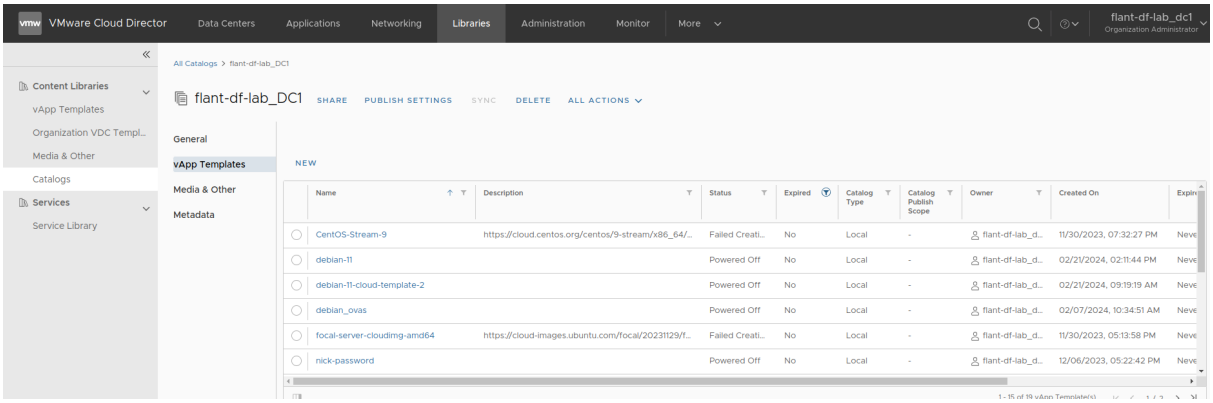
- Linux kernel version 5.8 or newer, except for the ranges 6.12.0–6.12.28 or 6.14.0–6.14.6 (these versions are affected by CVE-2025-37999 in EROFS).
- `CgroupsV2` support.
- Systemd version `244` or newer.
- `erofs` kernel module support.

For more information, see the documentation.



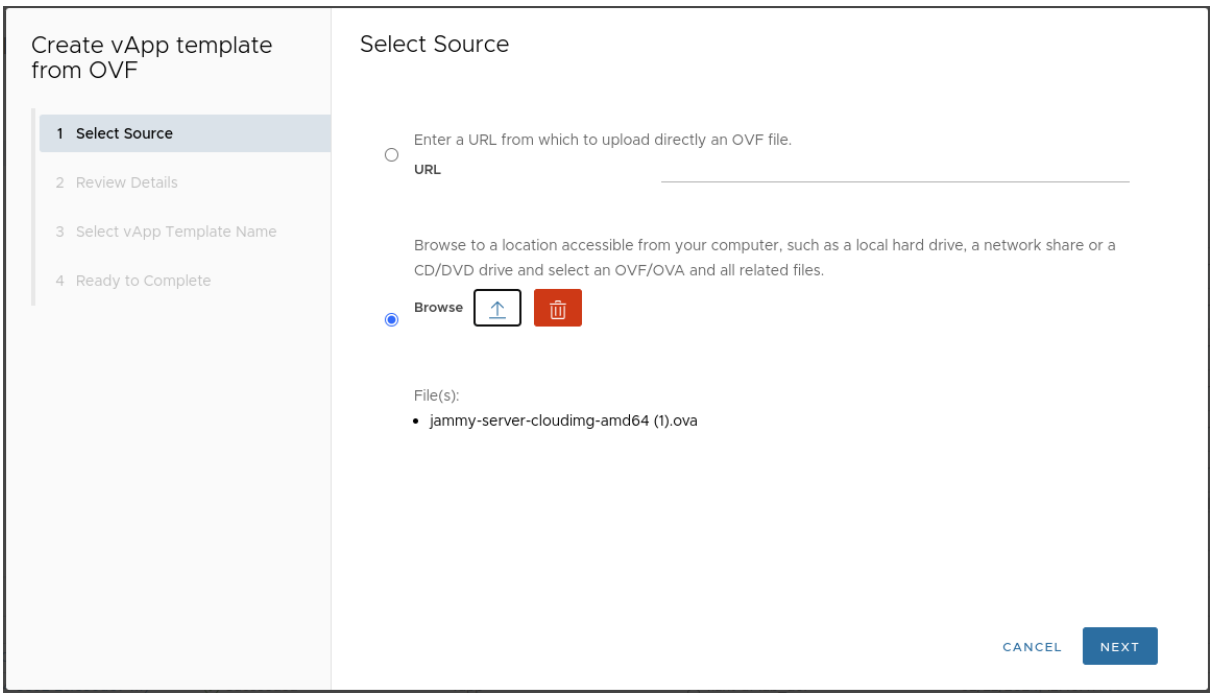
⚠ The `cloud-init` package must be installed on the VMs. After the virtual machine is started, the following services associated with this package must be started:

- `cloud-config.service`;
- `cloud-final.service`;
- `cloud-init.service`.

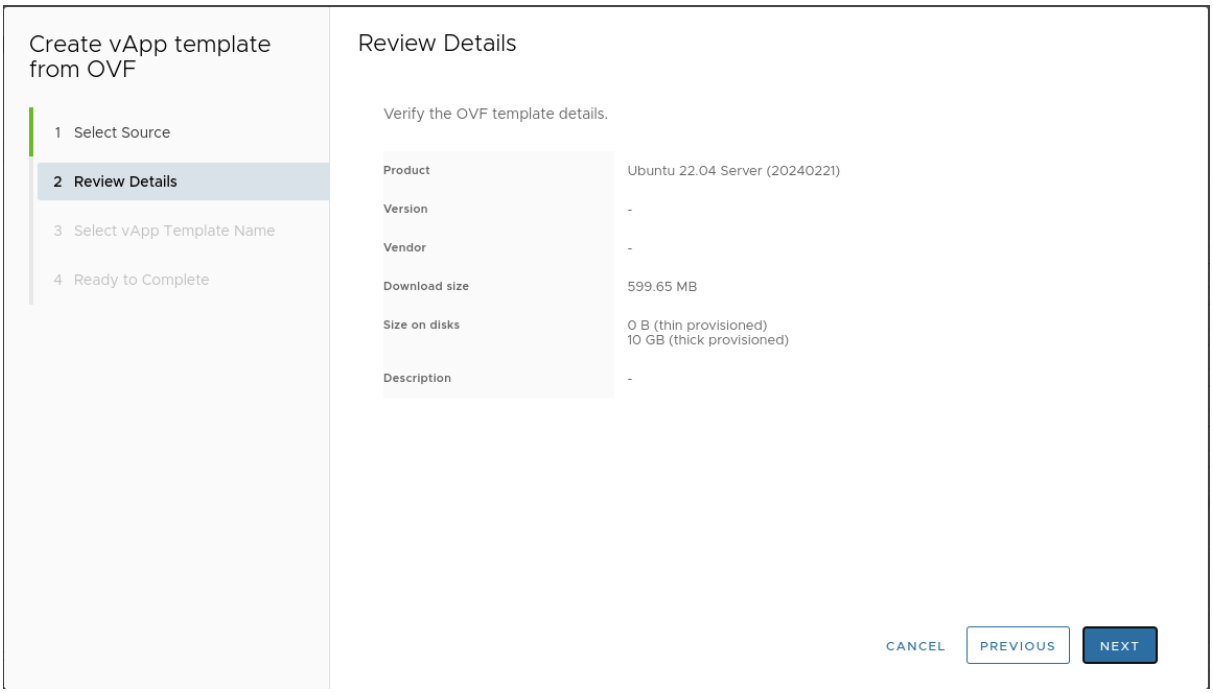


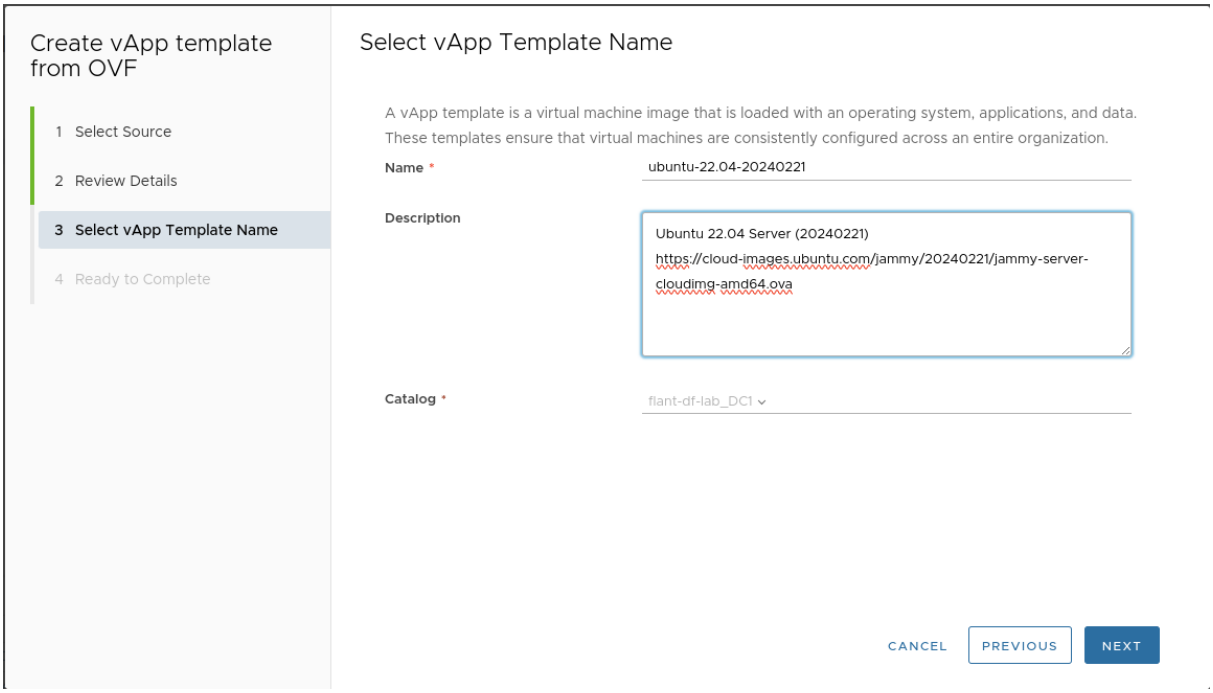
In the example, an “OVA” file provided by Ubuntu is used, with two modifications.
These modifications are required for proper provisioning of CloudPermanent nodes and to allow attaching disks created by CSI.

Preparing the template from an OVA file

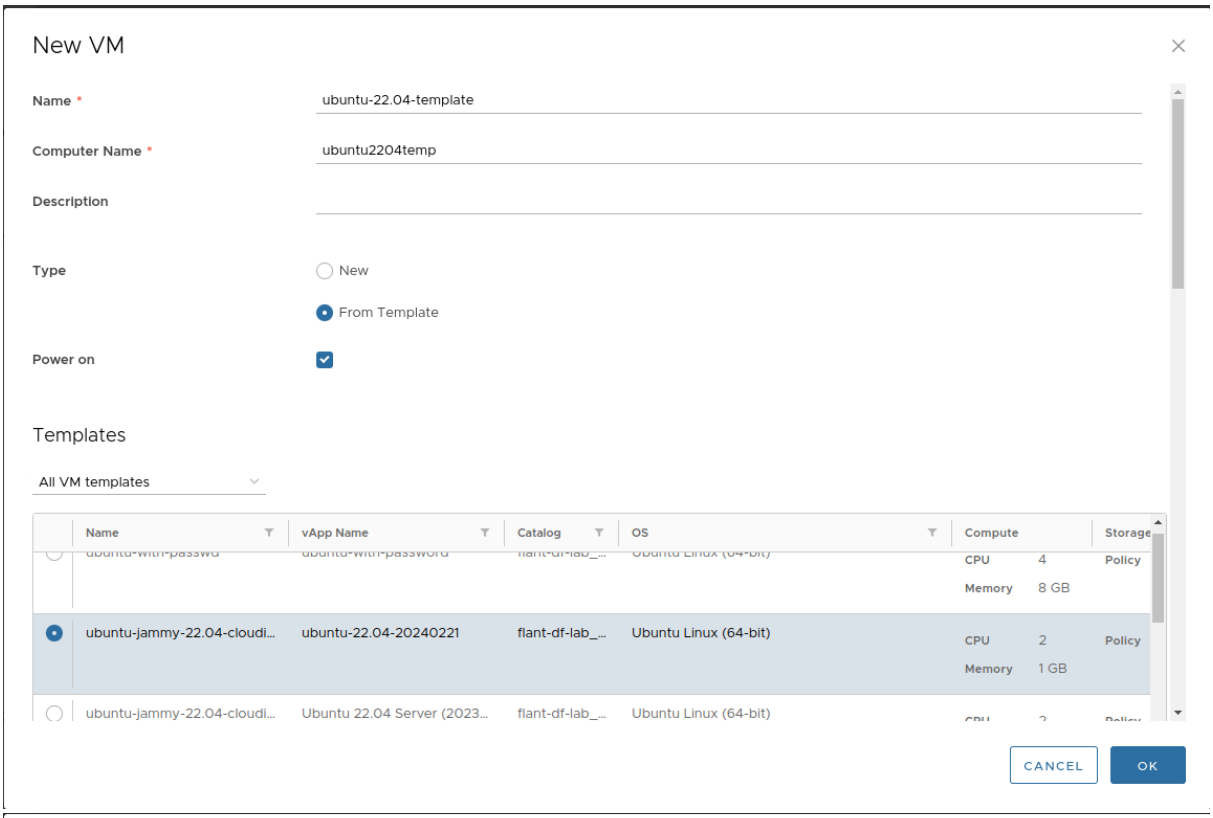


1. Download the OVA file:

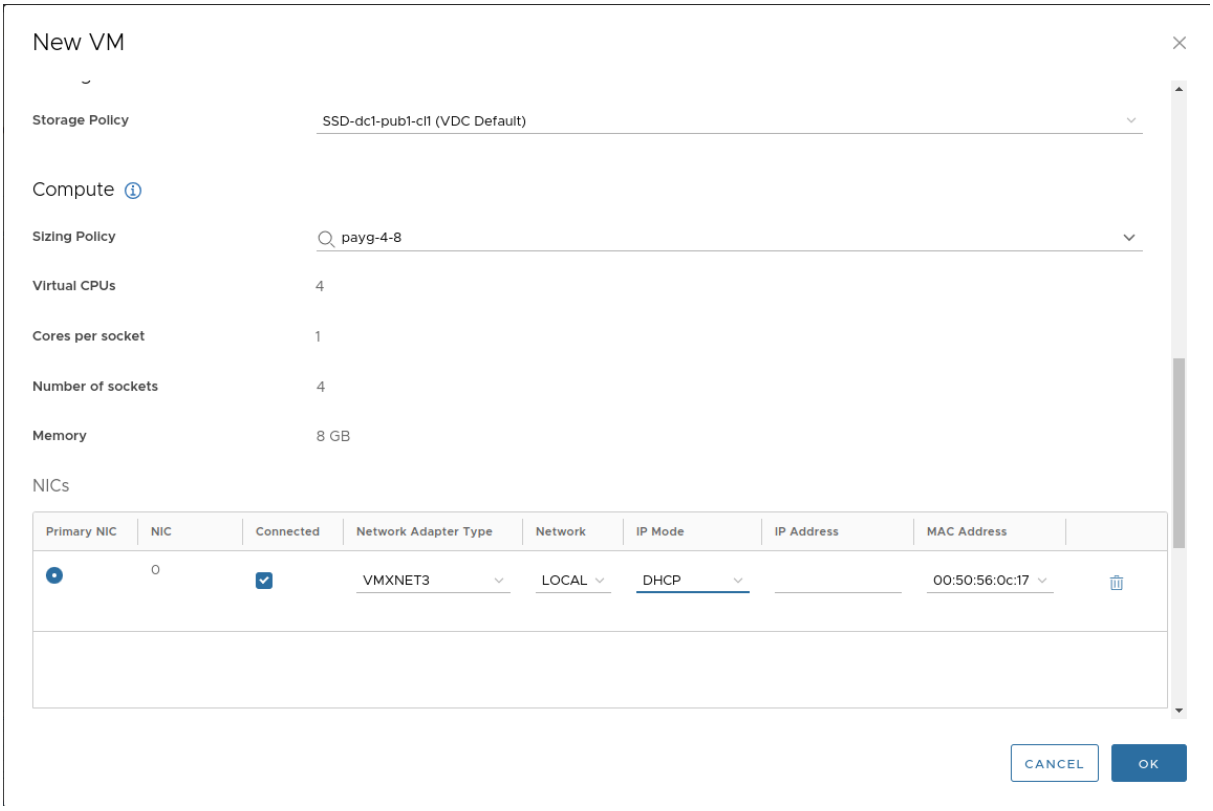


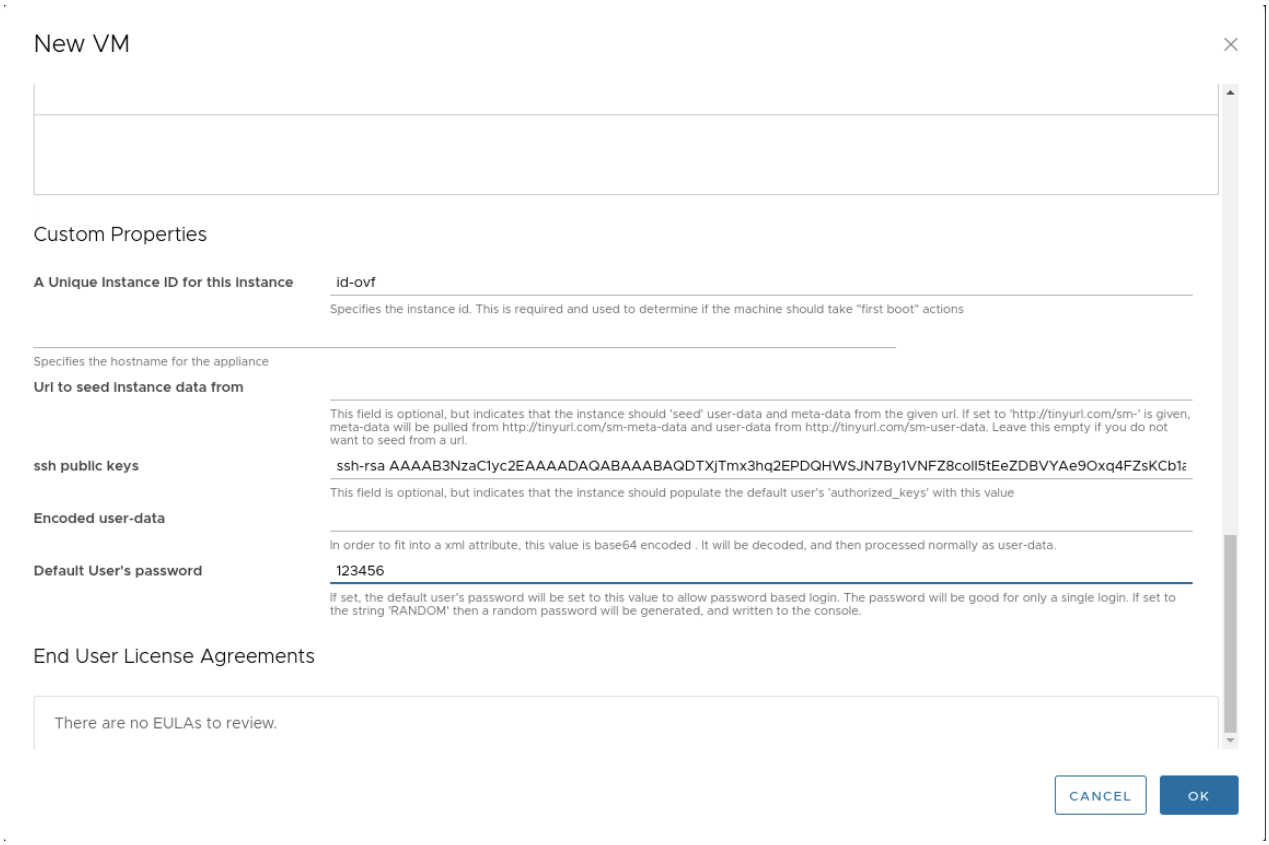


2. Go to “Libraries” → “Catalogs” → “Organization Catalog”:

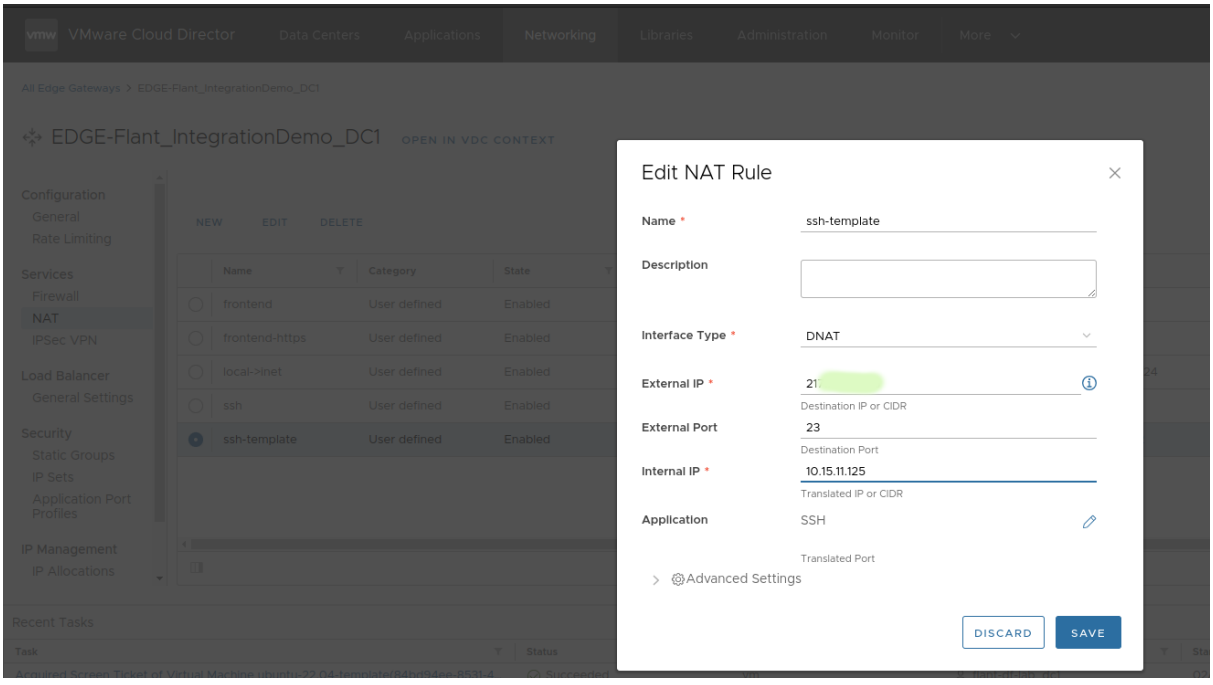


3. Upload the downloaded template to the catalog:



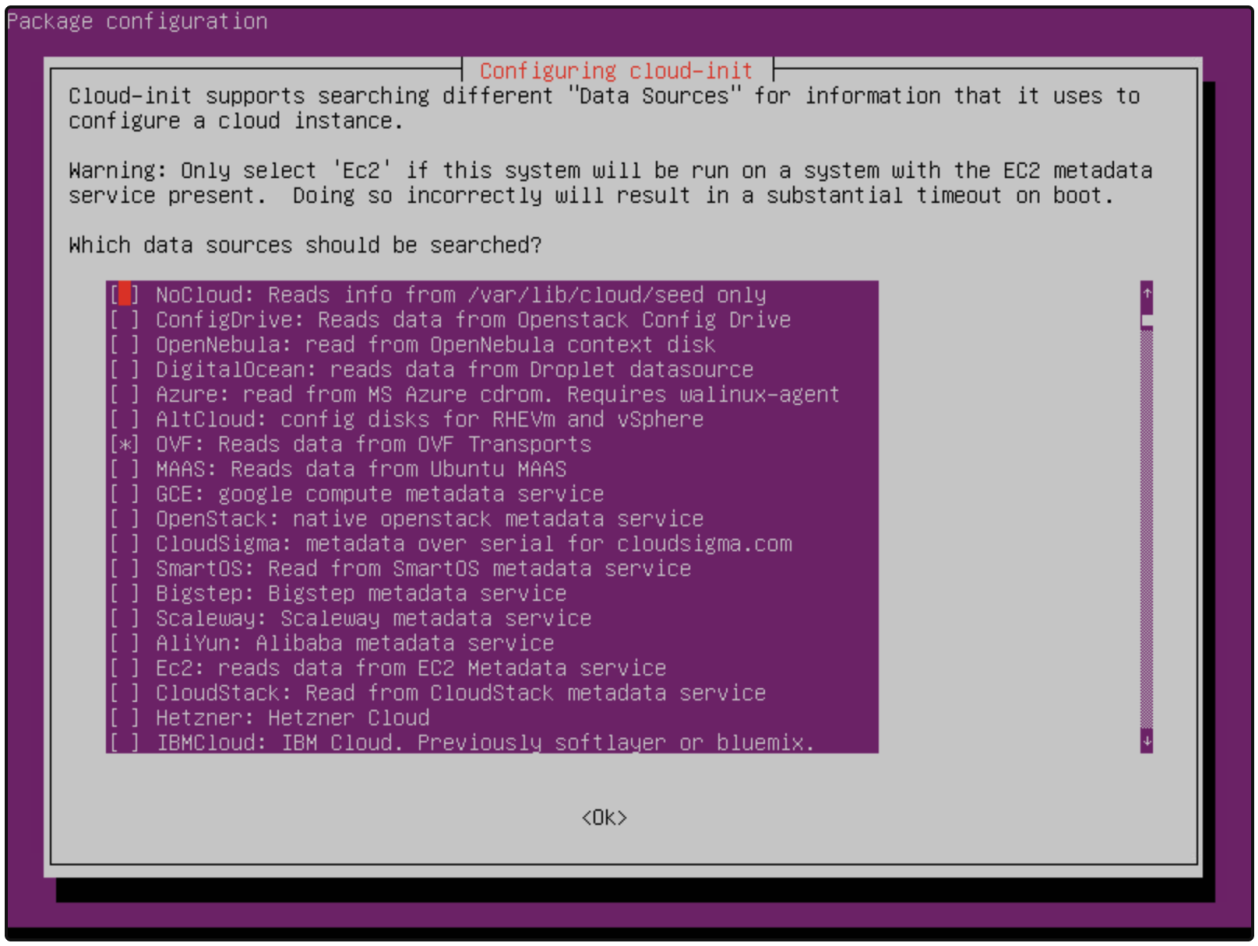


4. Create a VM from the template:



⚠ Set a default password and public key. These will be needed to log into the VM console.

To connect to the VM:



1. Start the VM.
2. Wait until it gets an IP address.
3. Forward port “22” to the VM:

Log into the VM via SSH and run:

```
rm /etc/netplan/99-netcfg-vmware.yaml
echo -e '\n[deployPkg]\nwait-cloudinit-timeout=1800\n' >> /etc/vmware-tools/tools.conf
echo 'disable_vmware_customization: true' > /etc/cloud/cloud.cfg.d/91_vmware_cust.cfg
dpkg-reconfigure cloud-init
```

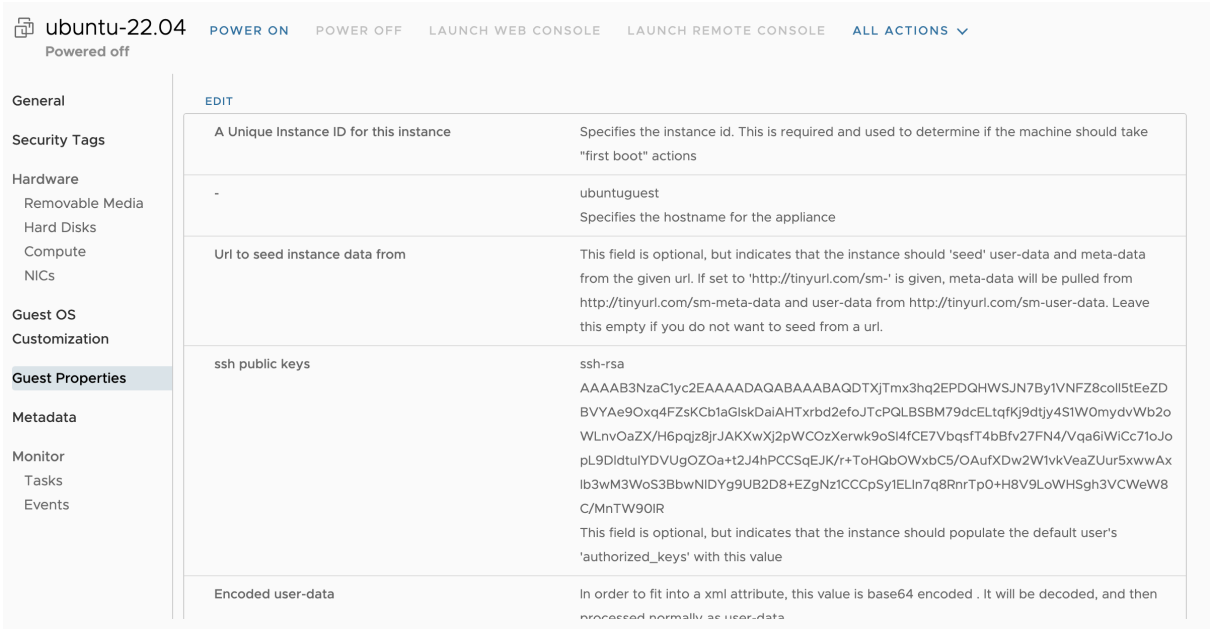
In the dialog window, leave only the checkbox for `OVF: Reads data from OVF transports`. Disable all other options:

Make sure that the `datasource_list` parameter is specified in the `cloud-init` configuration. You can verify this using the following command:

```
cat /etc/cloud/cloud.cfg.d/90_dpkg.cfg
```

If the output is empty, execute the following command:

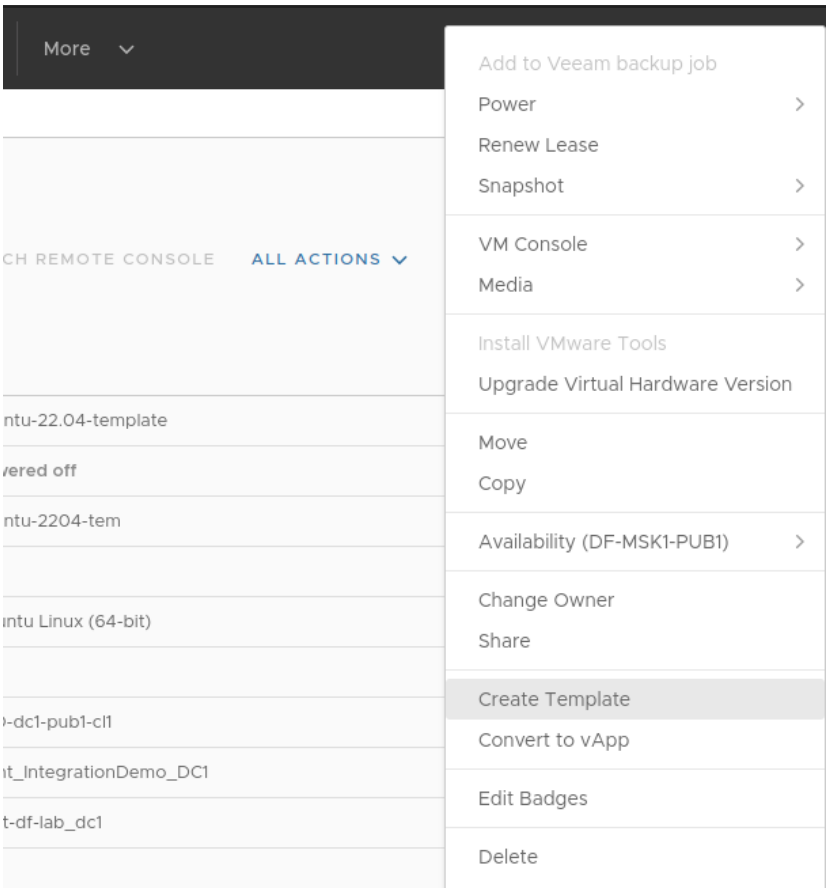
```
echo "datasource_list: [ OVF, VMware, None ]" > /etc/cloud/cloud.cfg.d/90_dpkg.cfg
```



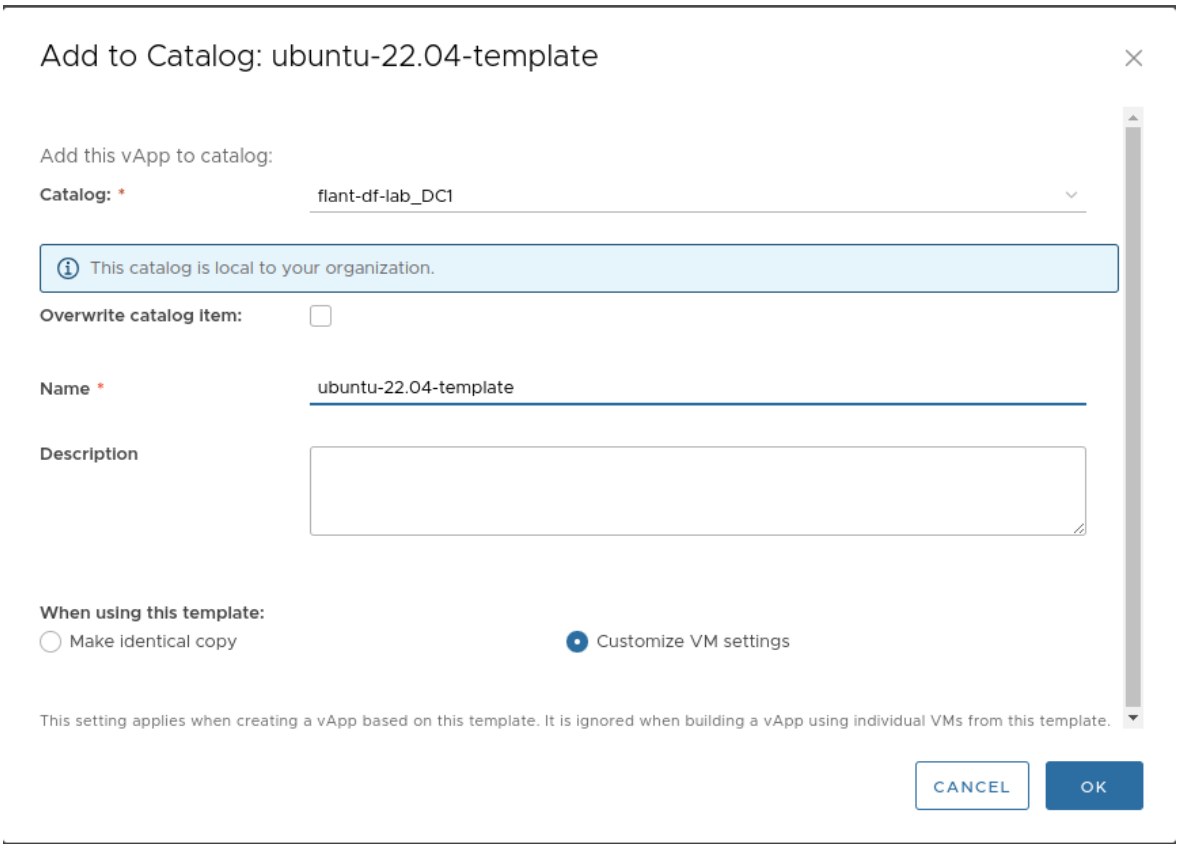
Run the remaining commands:

```
truncate -s 0 /etc/machine-id
rm /var/lib/dbus/machine-id
ln -s /etc/machine-id /var/lib/dbus/machine-id
cloud-init clean --logs --seed
passwd -d ubuntu
passwd -d root
rm /home/ubuntu/.ssh/authorized_keys
history -c

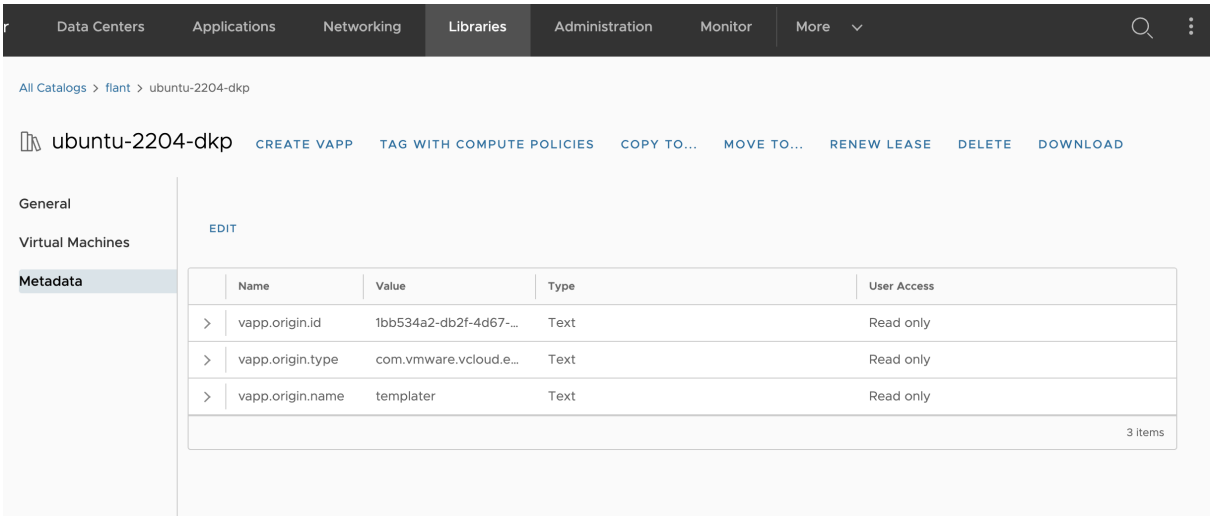
shutdown -P now
```



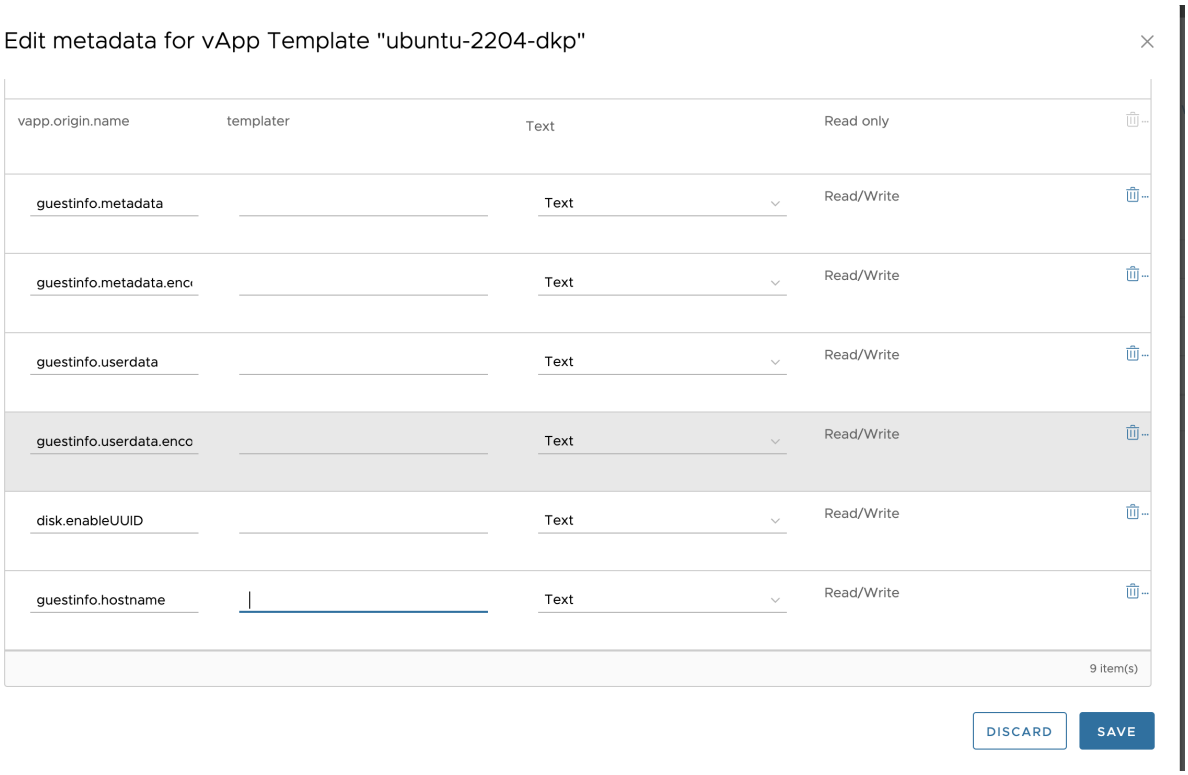
Configuring the template in VCD



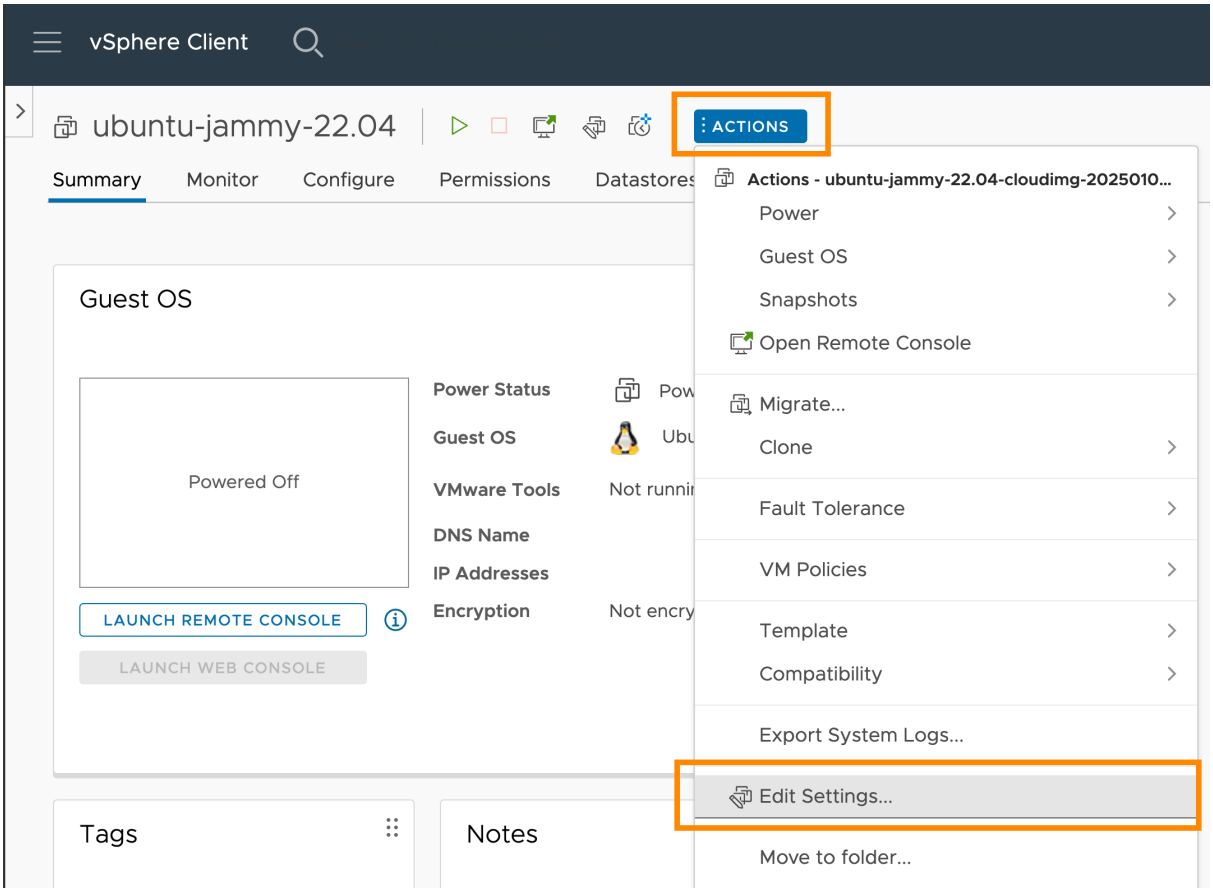
1. Power off the virtual machine and delete all filled “Guest Properties” fields:



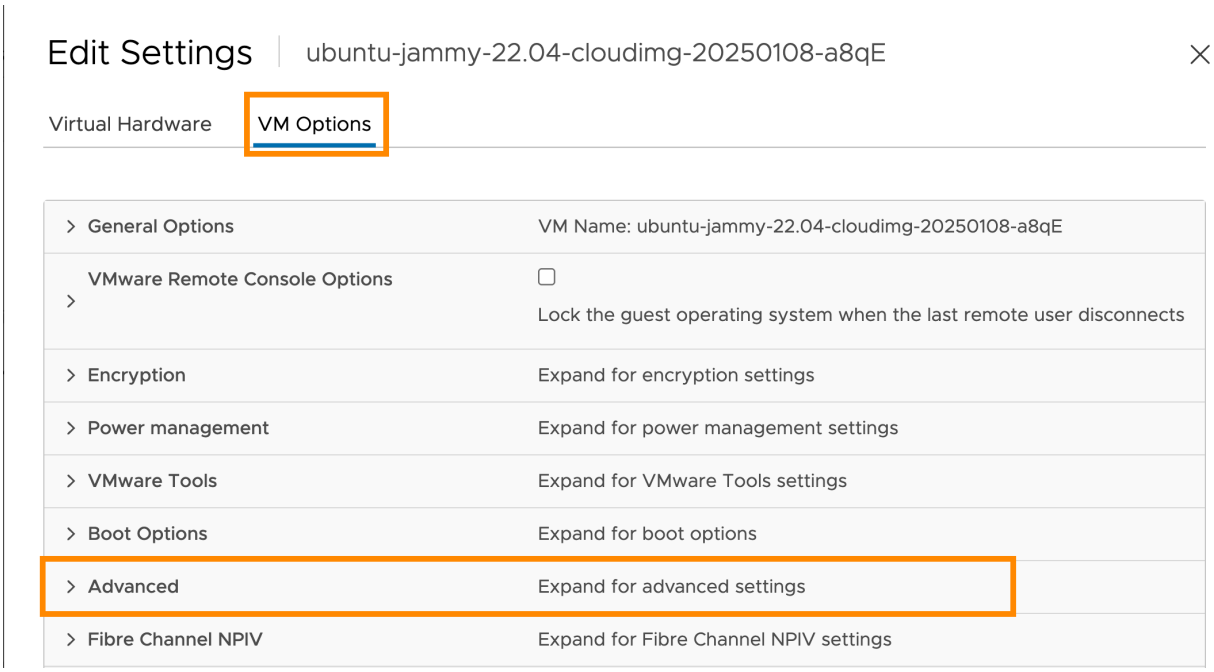
2. Create a virtual machine template:



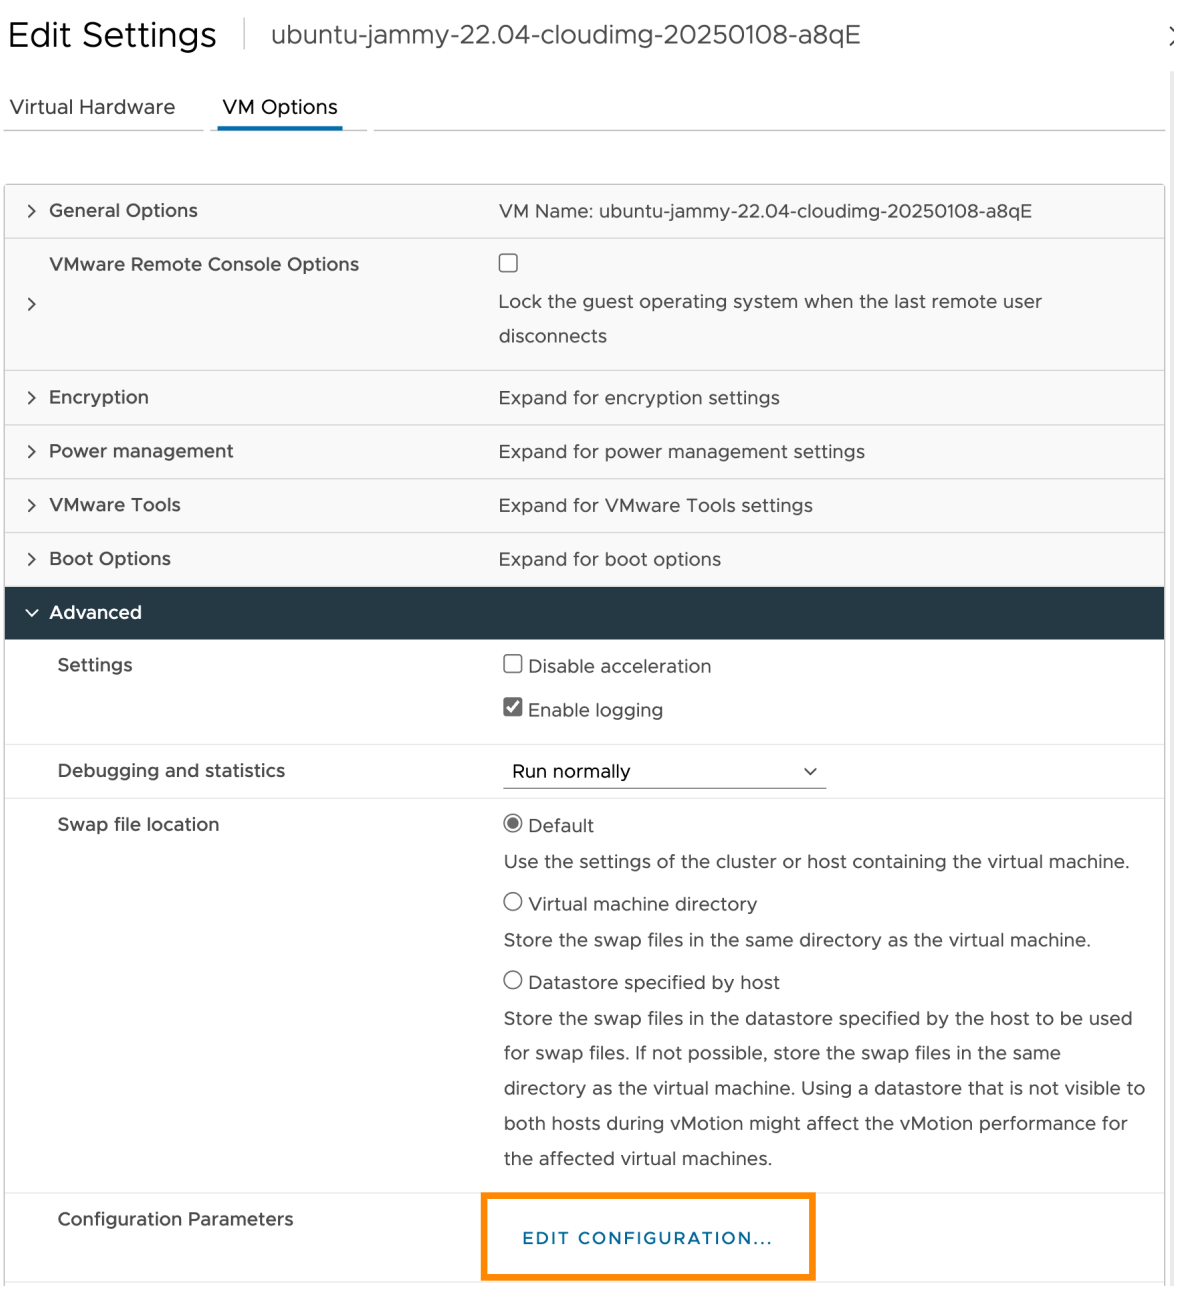
3. In the created template, go to the “Metadata” tab and add six fields:
   - `guestinfo.metadata`
   - `guestinfo.metadata.encoding`
   - `guestinfo.userdata`
   - `guestinfo.userdata.encoding`
   - `disk.enableUUID`
   - `guestinfo.hostname`



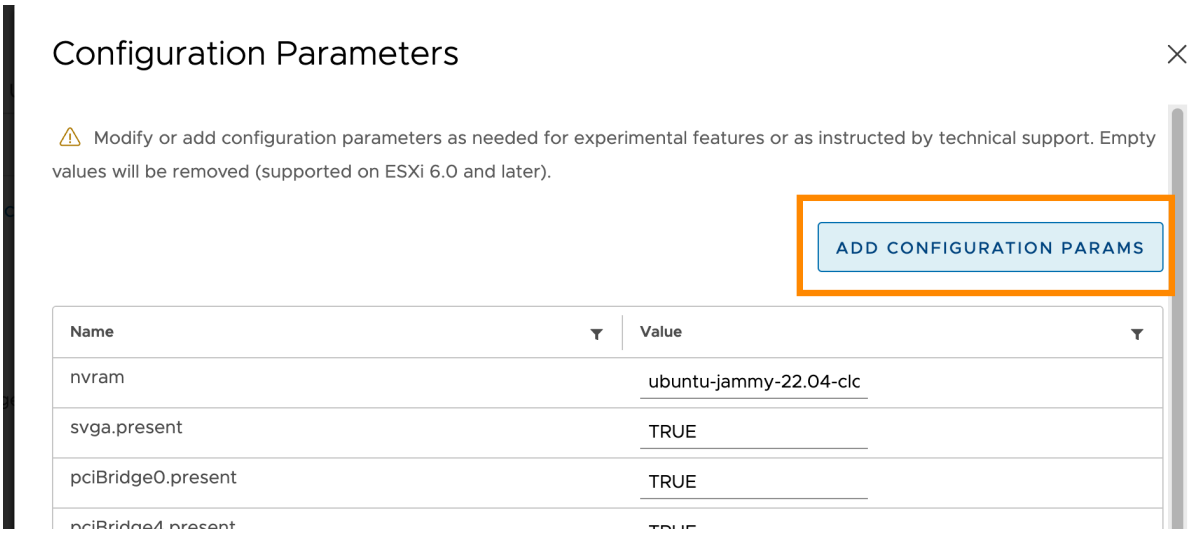
For **each** field in the add/edit form, set the following:

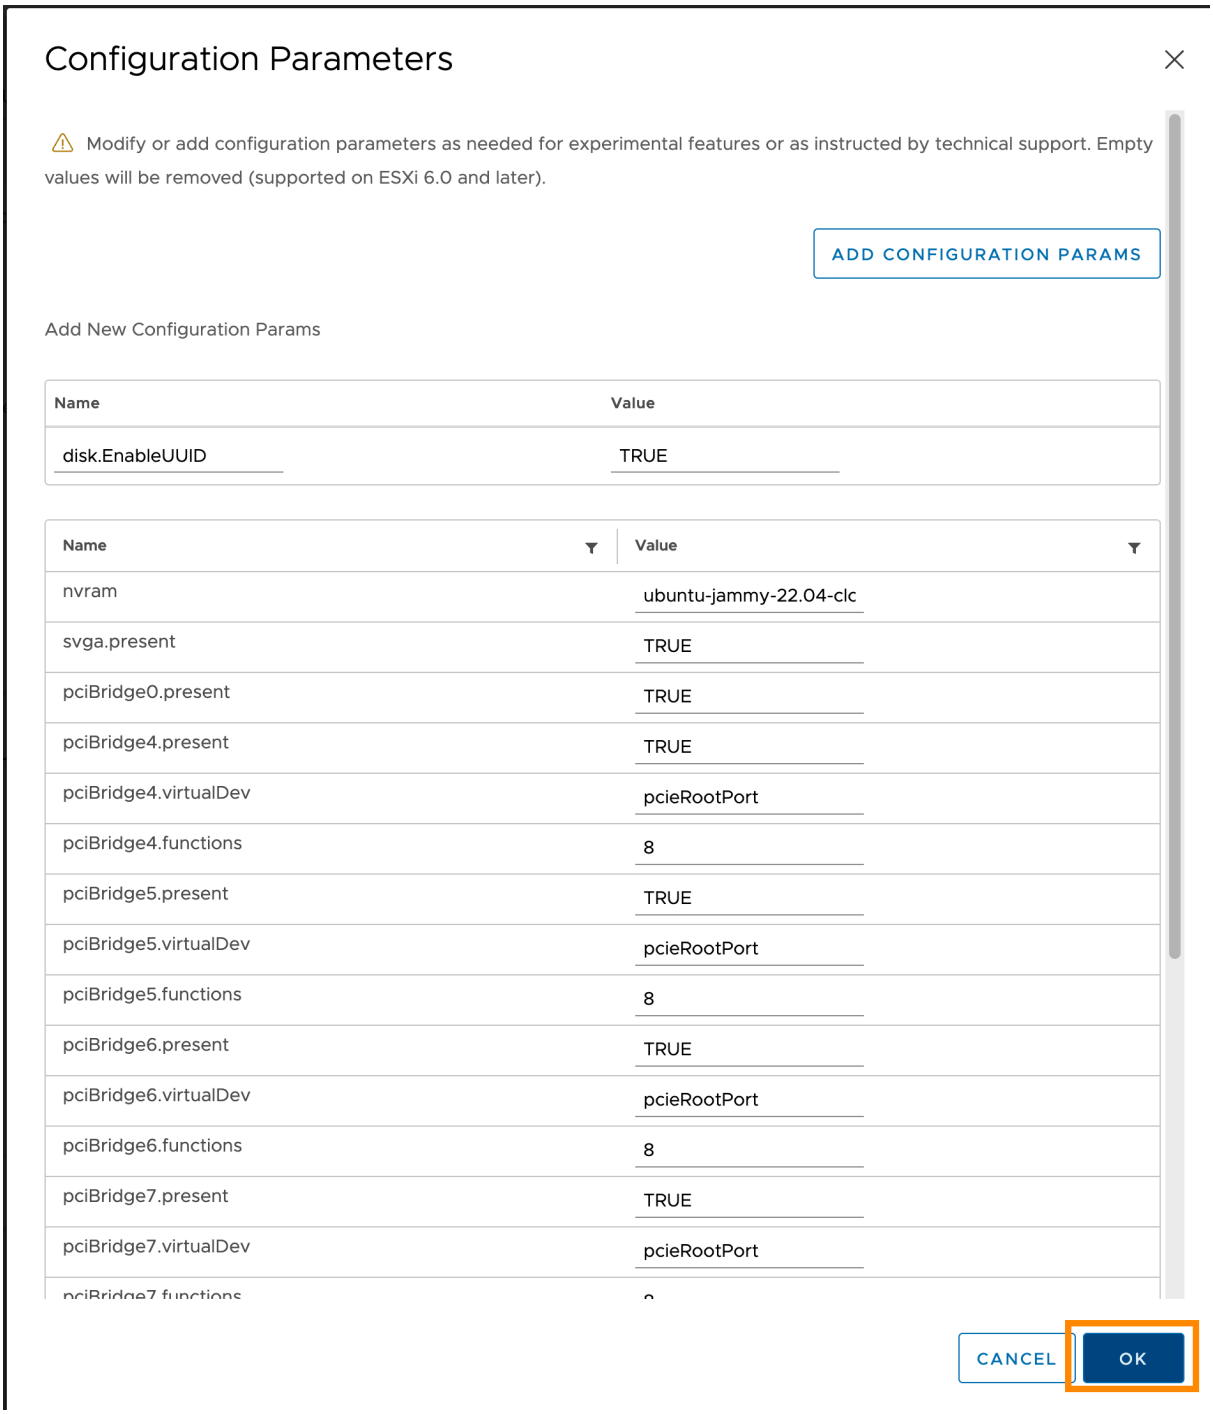


- “Type”: `Text` (text value)
- “User access”: `Read/Write`
- “Value”: A single space



> **i** The VCD UI may not save metadata with an empty value. A single space is used as a placeholder and does not affect functionality. The actual values will be populated automatically when virtual machines are created.





4. In the vCenter management panel, enable the `disk.EnableUUID` parameter for the template:

Virtual machine directory
Store the swap files in the same directory as the virtual machine.
Datastore specified by host
Store the swap files in the datastore specified by the host to be used for swap files. If not possible, store the swap files in the same directory as the virtual machine. Using a datastore that is not visible to both hosts during vMotion might affect the vMotion performance for the affected virtual machines.
Configuration Parameters
EDIT CONFIGURATION...

Replacing the OS image

Deckhouse Platform creates the nodes from a virtual machine template that is specified in the `template` parameter of the VCDInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the VCDClusterConfiguration

resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new OS image, prepare a new template based on it and follow the steps from “How do I replace the OS image in a cloud cluster?” .

Storage usage

- VCD supports CSI. Disks are created as VCD Independent Disks.
- The guest property `disk.EnableUUID` must be enabled for the VM templates in use.
- Deckhouse Platform supports disk resizing starting from version v1.59.1.

Using the LoadBalancer

- DP components support `Service` resources of type `LoadBalancer` when deployed on VMware Cloud Director (VCD).
- VMware NSX Advanced Load Balancer (ALB or Avi Networks) is used as the load balancer.
- Support is available **only** when using the `NSX-T` network virtualization platform.
- The load balancer functionality must be enabled on the Edge Gateway by your VCD provider. You can verify this under Edge Gateway → Load Balancer → General Settings — the `State` parameter must be `Active`.
- If the load balancer was enabled after the DP cluster was successfully created, the components will automatically pick up the changes within an hour (no additional actions are required).
- For each open port, a Pool + Virtual Service pair is created.
- If a firewall is in place, you must create an allow rule for the load balancer’s external IP address and the corresponding ports.

Additional resources

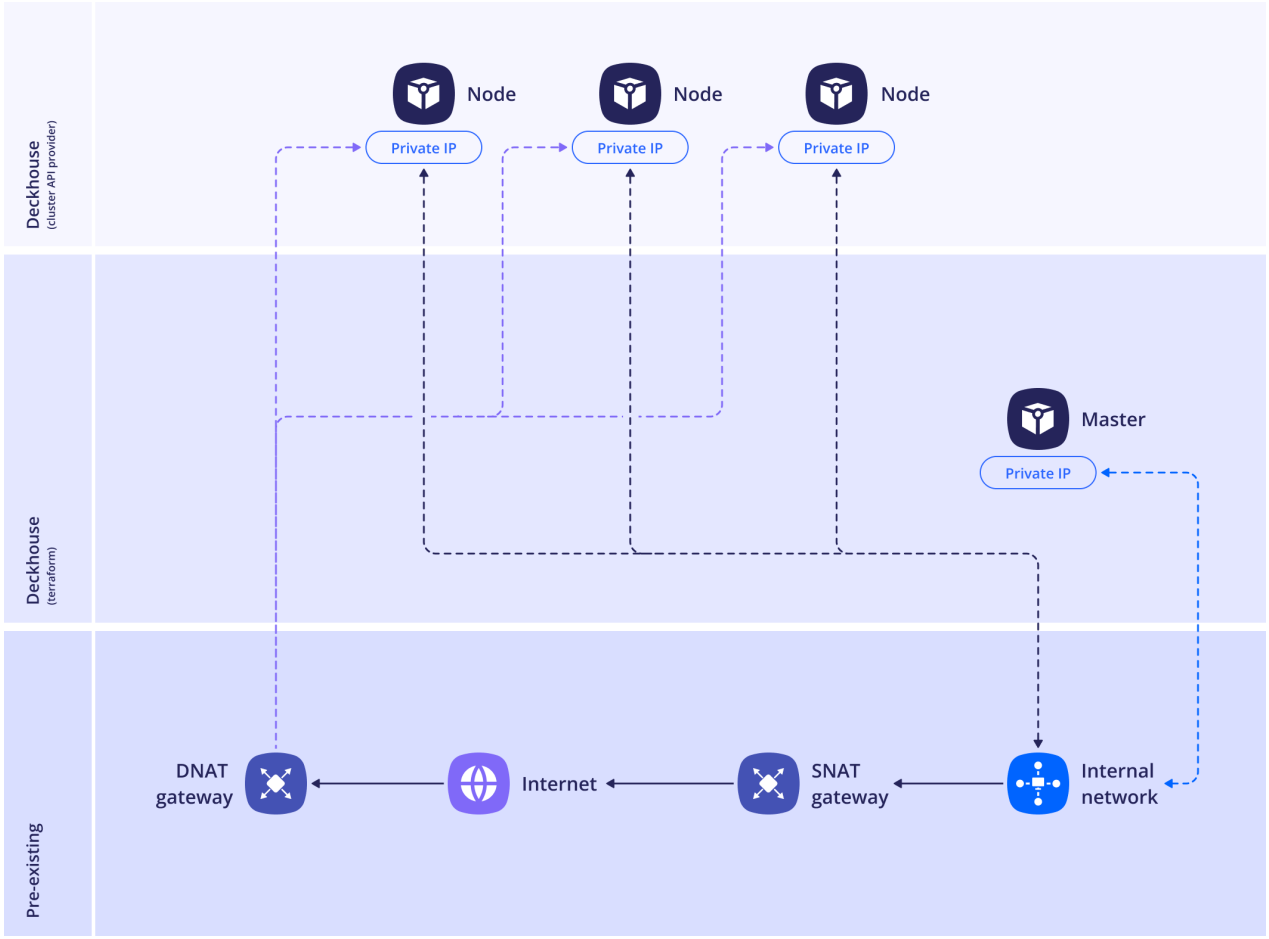
- Module `cert-manager` documentation
- Module `cloud-provider-vcd` custom resources
- Module `metallb` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in VMware Cloud Director

List of required VMware Cloud Director services

The following VMware Cloud Director service must be available for Deckhouse Platform to operate:

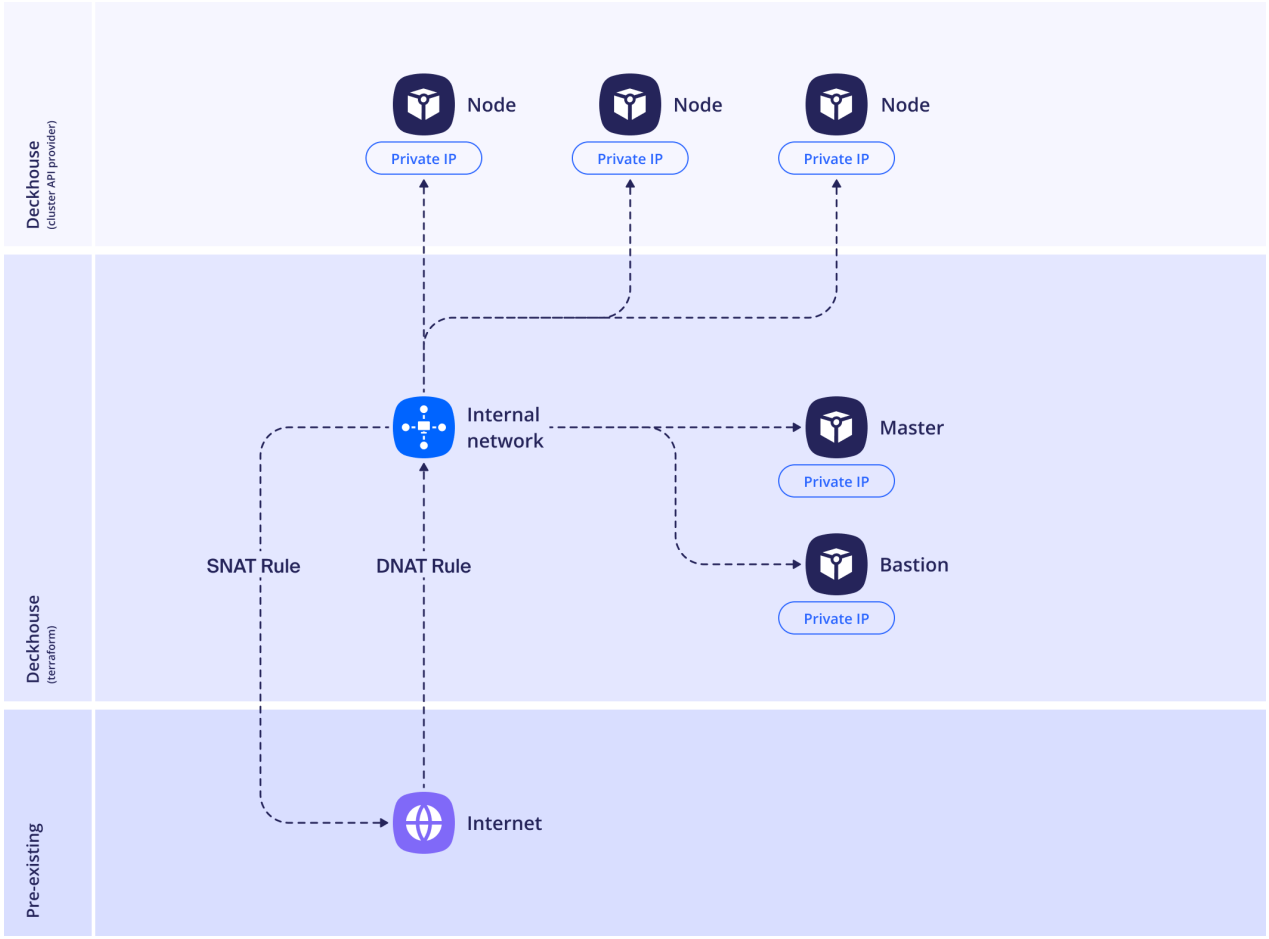


Service	API version
VMware Cloud Director API	`37.2` and later

> For VMware Cloud Director API versions earlier than `37.2`, compatibility mode for legacy API versions is used.

Layouts

Deckhouse Platform supports two layouts for deploying resources in VCD.



Standard

Example layout configuration:

```
---
apiVersion: deckhouse.io/v1alpha1
kind: VCDClusterConfiguration
layout: Standard
provider:
  server: '<SERVER>'
  username: '<USERNAME>'
  password: '<PASSWORD>'
  insecure: true
sshPublicKey: <SSH_PUBLIC_KEY>
organization: deckhouse
virtualDataCenter: MSK-1
virtualApplicationName: deckhouse
internalNetworkCIDR: 192.168.199.0/24
masterNodeGroup:
  replicas: 1
  instanceClass:
    storageProfile: "Fast vHDD"
    sizingPolicy: 4cpu8mem
    template: "catalog/Ubuntu 22.04 Server"
    mainNetwork: internal
    mainNetworkIPAddresses:
    - 192.168.199.2
```

WithNAT

When using this layout, you must confirm the type of network virtualization platform with your administrator and specify it in the `edgeGateway.type` parameter. Two options are supported: `NSX-T` and `NSX-V`.

To ensure administrative access to the cluster nodes, a bastion is deployed. The parameters for its configuration are described in the `bastion` section.

If the Edge Gateway is based on `NSX-T`, a DHCP server will be automatically enabled for the created node network. It will assign IP addresses starting from the 30th address in the subnet up to the penultimate one (before the broadcast address). The starting address of the DHCP pool can be changed using the `internalNetworkDHCPPoolStartAddress` parameter.

If `NSX-V` is used, DHCP must be configured manually. Otherwise, nodes waiting to obtain an IP address via DHCP will not be able to receive one.

⚠ It is not recommended to use dynamic addressing for the first master node together with `NSX-V`.

This layout assumes the automatic creation of the following NAT rules:

- **SNAT** — translation of internal node network addresses to the external address specified in `edgeGateway.externalIP`.
- **DNAT** — translating the external address and port, specified in the `edgeGateway.externalIP` and `edgeGateway.externalPort` properties, respectively, to the internal address of the bastion instance on port 22 using the TCP protocol for administrative access to the nodes via SSH.

⚠ If the Edge Gateway is powered by `NSX-V`, you must specify the name and type of the network to which the rule will be bound in the `edgeGateway.NSX-V.externalNetworkName` and `edgeGateway.NSX-V.externalNetworkType` properties. Usually, this is the network connected to the Edge Gateway in the `Gateway Interfaces` section and having an external IP address.

It is also possible to create firewall rules using the `createDefaultFirewallRules` property.

⚠ If the Edge Gateway is powered by `NSX-T`, existing Edge Gateway rules will be overwritten. This option is intended for scenarios where only one cluster is deployed on the Edge Gateway.

The following rules will be created:

- Allow all outgoing traffic;
- Allow incoming TCP traffic on port 22 for SSH connections to cluster nodes;
- Allow all incoming ICMP traffic;
- Allow incoming TCP and UDP traffic on ports 30000–32767 for `NodePort` services.

Example configuration for the WithNAT layout using `NSX-T`:

```
apiVersion: deckhouse.io/v1alpha1
kind: VCDClusterConfiguration
layout: WithNAT
provider:
  server: '<SERVER>'
  username: '<USERNAME>'
  password: '<PASSWORD>'
  insecure: true
sshPublicKey: <SSH_PUBLIC_KEY>
organization: deckhouse
virtualDataCenter: MSK-1
virtualApplicationName: deckhouse
internalNetworkCIDR: 192.168.199.0/24
internalNetworkDNSServers:
  - 77.88.8.8
  - 1.1.1.1
mainNetwork: internal
bastion:
  instanceClass:
    rootDiskSizeGb: 30
    sizingPolicy: 2cpu1mem
    template: "catalog/Ubuntu 22.04 Server"
    storageProfile: Fast vHDD
    mainNetworkIPAddress: 10.1.4.10
edgeGateway:
  name: "edge-gateway-01"
  type: "NSX-T"
  externalIP: 10.0.0.1
  externalPort: 10022
createDefaultFirewallRules: false
masterNodeGroup:
  replicas: 1
  instanceClass:
    storageProfile: "Fast vHDD"
    sizingPolicy: 4cpu8mem
    template: "catalog/Ubuntu 22.04 Server"
    mainNetworkIPAddresses:
    - 192.168.199.2
```

Example configuration for the WithNAT layout using `NSX-V`:

```
apiVersion: deckhouse.io/v1alpha1
kind: VCDClusterConfiguration
layout: WithNAT
provider:
  server: '<SERVER>'
  username: '<USERNAME>'
  password: '<PASSWORD>'
  insecure: true
sshPublicKey: <SSH_PUBLIC_KEY>
organization: deckhouse
virtualDataCenter: MSK-1
virtualApplicationName: deckhouse
internalNetworkCIDR: 192.168.199.0/24
internalNetworkDNSServers:
  - 77.88.8.8
  - 1.1.1.1
mainNetwork: internal
bastion:
  instanceClass:
    rootDiskSizeGb: 30
    sizingPolicy: 2cpu1mem
    template: "catalog/Ubuntu 22.04 Server"
    storageProfile: Fast vHDD
    mainNetworkIPAddress: 10.1.4.10
edgeGateway:
  name: "edge-gateway-01"
  type: "NSX-V"
  externalIP: 10.0.0.1
  externalPort: 10022
  NSX-V:
    externalNetworkName: external
    externalNetworkType: ext
createDefaultFirewallRules: true
masterNodeGroup:
  replicas: 1
  instanceClass:
    storageProfile: "Fast vHDD"
    sizingPolicy: 4cpu8mem
    template: "catalog/Ubuntu 22.04 Server"
    mainNetworkIPAddresses:
    - 192.168.199.2
```

Configuration

Integration is carried out using the VCDClusterConfiguration resource, which describes the configuration of the cloud cluster in VCD and is used by the virtualization system if the cluster's control plane is hosted there. The DP module responsible for integration is automatically configured based on the selected deployment layout.

To modify the configuration in a running cluster, execute the following command:

```
d8 -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller edit provider-cluster-configuration
```

> **i** After changing the node parameters, you must run the `dhctl converge` command for the changes to take effect.

Example configuration:

```
apiVersion: deckhouse.io/v1
kind: VCDClusterConfiguration
sshPublicKey: "<SSH_PUBLIC_KEY>"
organization: My_Org
virtualDataCenter: My_Org
virtualApplicationName: Cloud
mainNetwork: internal
layout: Standard
internalNetworkCIDR: 172.16.2.0/24
masterNodeGroup:
  replicas: 1
  instanceClass:
    template: Templates/ubuntu-focal-20.04
    sizingPolicy: 4cpu8ram
    rootDiskSizeGb: 20
    etcdDiskSizeGb: 20
    storageProfile: nvme
nodeGroups:
  - name: worker
    replicas: 1
    instanceClass:
      template: Org/Templates/ubuntu-focal-20.04
      sizingPolicy: 16cpu32ram
      storageProfile: ssd
provider:
  server: "<SERVER>"
  username: "<USERNAME>"
  password: "<PASSWORD>"
  insecure: true
```

The number of nodes to be provisioned and their parameters are defined in the NodeGroup custom resource, where you also specify the name of the instance class used for that group (the `cloudInstances.classReference` parameter). For the VCD cloud provider, the instance class is a custom resource called VCDInstanceClass, which contains the specific configuration of the VMs.

The following is the example configuration of VCDInstanceClass for ephemeral nodes of the VMware Cloud Director cloud provider.

Example configuration of VCDInstanceClass

```
apiVersion: deckhouse.io/v1
kind: VCDInstanceClass
metadata:
  name: test
spec:
  rootDiskSizeGb: 90
  sizingPolicy: payg-4-8
  storageProfile: SSD-dc1-pub1-cl1
  template: MyOrg/Linux/ubuntu2204-cloud-ova
```

Storage

A StorageClass is automatically created for each Datastore and DatastoreCluster in the zone (or zones).

You can set the name of StorageClass that will be used in the cluster by default (the `default` parameter), and filter out the unnecessary StorageClasses (the `exclude` parameter).

CSI

By default, the storage subsystem uses CNS volumes capable of on-the-fly resizing. FCD volumes are also supported, but only in the legacy mode. You can set this via the `compatibilityFlag` parameter.

Additional resources

- Module `cloud-provider-vcd` provider configuration
- Module `cloud-provider-vcd` custom resources
- Module `node-manager` custom resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in VMware vSphere

Requirements

The following prerequisites must be met for Deckhouse Platform to work correctly with VMware vSphere:

- Access to vCenter;
- A user account with the required set of privileges;
- Tags and tag categories created in vSphere;
- Networks with DHCP and Internet access;
- Shared Datastore resources available on all ESXi hosts in use;
- vSphere version `7.x` or `8.x` with support for `Online volume expansion`;
- vCenter accessible from inside the cluster from the master nodes;
- A configured Datacenter that includes the following objects:
  1. VirtualMachine template:
     - The virtual machine image must use `Virtual machines with hardware version 15 or later` — this is required for online resize support.
     - The image must include the `open-vm-tools`, `cloud-init`, and `cloud-init-vmware-guestinfo` packages if the `cloud-init` version is lower than `21.3`.
  2. Network:
     - The network must be available on all ESXi hosts where virtual machines are planned to be created.
  3. Datastore (one or more):
     - The Datastore must be connected to all ESXi hosts where virtual machines are planned to be created.
     - A tag from the category specified in the `zoneTagCategory` parameter must be assigned to the Datastore (default: `k8s-zone`). This tag defines the zone.
     - All Cluster objects within the same zone must have access to all Datastore objects in that zone.
  4. Cluster:
     - All ESXi hosts in use must be added to the Cluster.
     - A tag from the category specified in the `zoneTagCategory` parameter must be assigned to the Cluster (default: `k8s-zone`). This tag defines the zone.
     - DRS must be enabled in the Cluster. The platform does not pick a specific host when creating a virtual machine, so vSphere chooses the host.
  5. Folder for the virtual machines being created:
     - This parameter is optional.
     - By default, the root virtual machine folder is used.
  6. Role:
     - The role must include the required set of privileges.
  7. User:
     - The user must be assigned the role specified in the previous item.
- A tag from the category specified in the `regionTagCategory` parameter must be assigned to the created Datacenter (default: `k8s-region`). This tag defines the region.

VM image requirements

To create a VM template (Template), it is recommended to use a ready-made cloud image/OVA file provided by the OS vendor:

- **Ubuntu**
- **Debian**
- **CentOS**
- **Rocky Linux** (section *Generic Cloud / OpenStack*)

⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

Preparing the virtual machine image

⚠ Disable VMware Guest OS Customization (and any vApp/OS customization mechanisms, if applicable in your setup) for the template and the cluster virtual machines. DP performs the initial node configuration via `cloud-init` (VMware GuestInfo datasource). Enabled customization can conflict with `cloud-init` and lead to incorrect node initialization.

1. Install the required packages:

   If you use `cloud-init` version lower than 21.3 (VMware GuestInfo support is required):

   ```
   sudo apt-get update
   sudo apt-get install -y open-vm-tools cloud-init cloud-init-vmware-guestinfo
   ```

   If you use `cloud-init` version 21.3 or higher:

   ```
   sudo apt-get update
   sudo apt-get install -y open-vm-tools cloud-init
   ```

2. Verify that the `disable_vmware_customization: false` parameter is set in `/etc/cloud/cloud.cfg`.
3. Make sure the `default_user` parameter is specified in `/etc/cloud/cloud.cfg`. It is required to add an SSH key when the VM starts.

4. Add the VMware GuestInfo datasource — create `/etc/cloud/cloud.cfg.d/99-DataSourceVMwareGuestInfo.cfg`:

```
datasource:
  VMware:
    vmware_cust_file_max_wait: 10
```

5. Before creating the VM template, reset the `cloud-init` identifiers and state using the following commands:

```
truncate -s 0 /etc/machine-id &&
rm /var/lib/dbus/machine-id &&
ln -s /etc/machine-id /var/lib/dbus/machine-id
```

6. Clear `cloud-init` event logs:

```
cloud-init clean --logs --seed
```

⚠ After the virtual machine starts, the following services related to the packages installed during `cloud-init` preparation must be running:

- `cloud-config.service`,
- `cloud-final.service`,
- `cloud-init.service`.

To ensure that the services are enabled, use the command:

```
systemctl is-enabled cloud-config.service cloud-init.service cloud-final.service
```

Example output for enabled services:

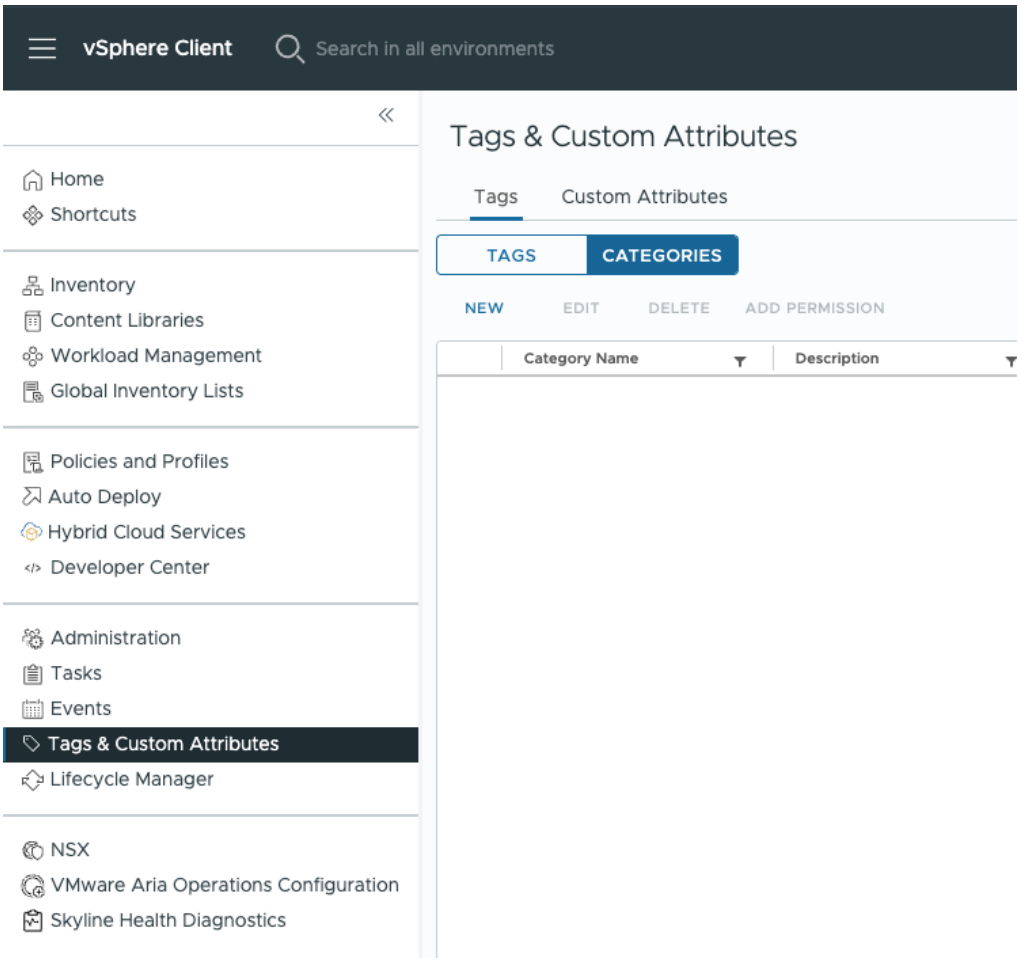
```
enabled
enabled
enabled
```

i DP creates VM disks of type `eagerZeroedThick`, but the type of disks of created VMs may be changed without notification according to the `VM Storage Policy` settings in vSphere.
For more details, see the documentation.

i DP uses the `ens192` interface as the default interface for VMs in vSphere. Therefore, when using static IP addresses in `mainNetwork`, you must create an interface named `ens192` in the OS image as the default interface.

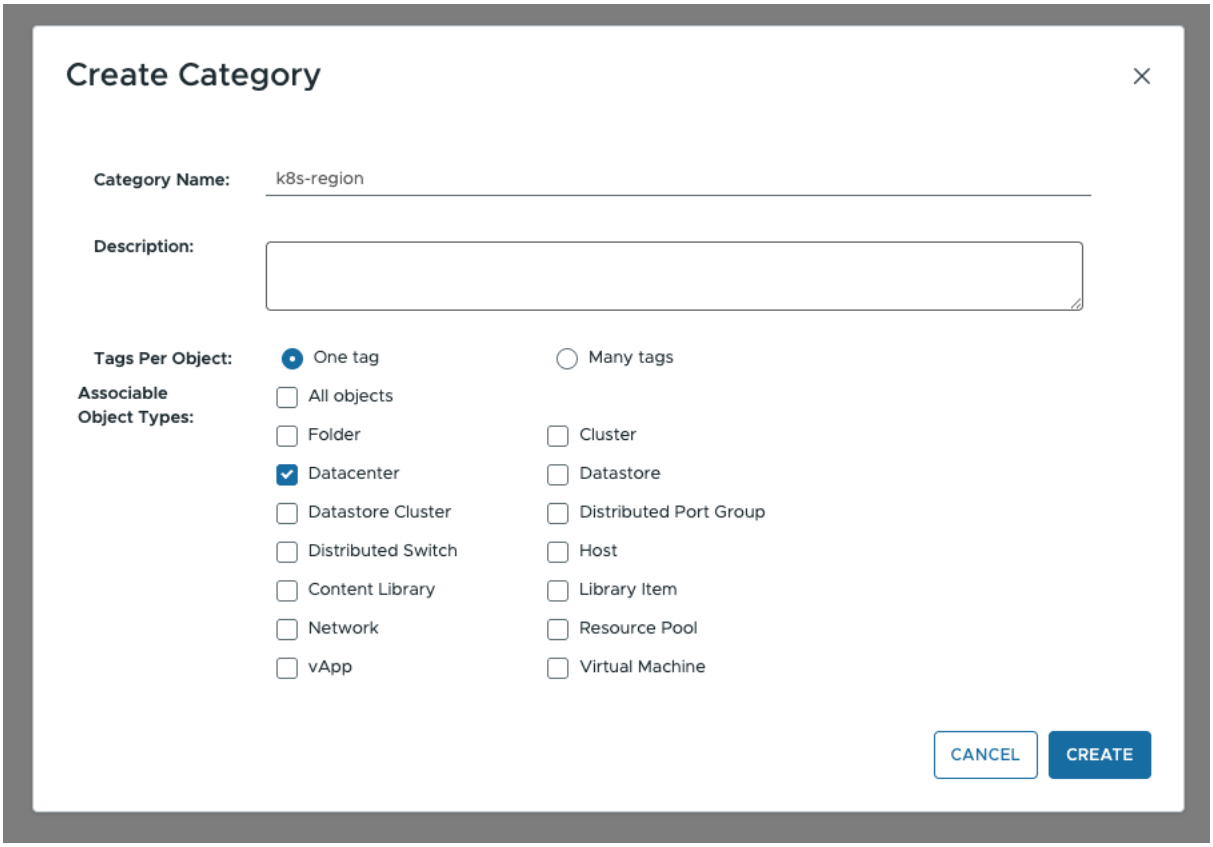
Replacing the OS image

Deckhouse Platform creates the nodes from a virtual machine template that is specified in the `template` parameter of the VsphereInstanceClass resource for `CloudEphemeral` nodes and in the `instanceClass` section of the VsphereClusterConfiguration resource for `CloudPermanent` nodes and master nodes. To move the cluster nodes to a new OS image, prepare a new template based on it and follow the steps from “How do I replace the OS image in a cloud cluster?”.



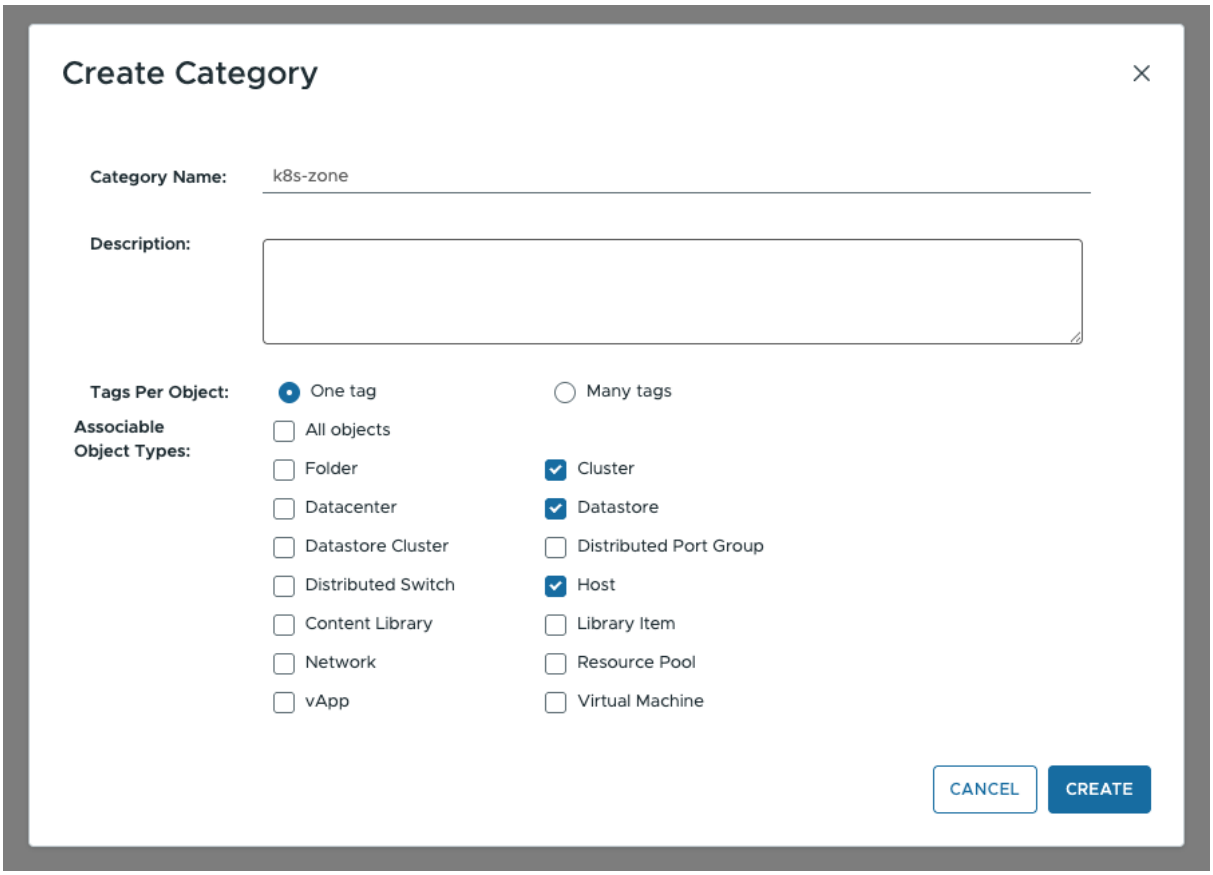
vSphere configuration

Configuration in vSphere Client

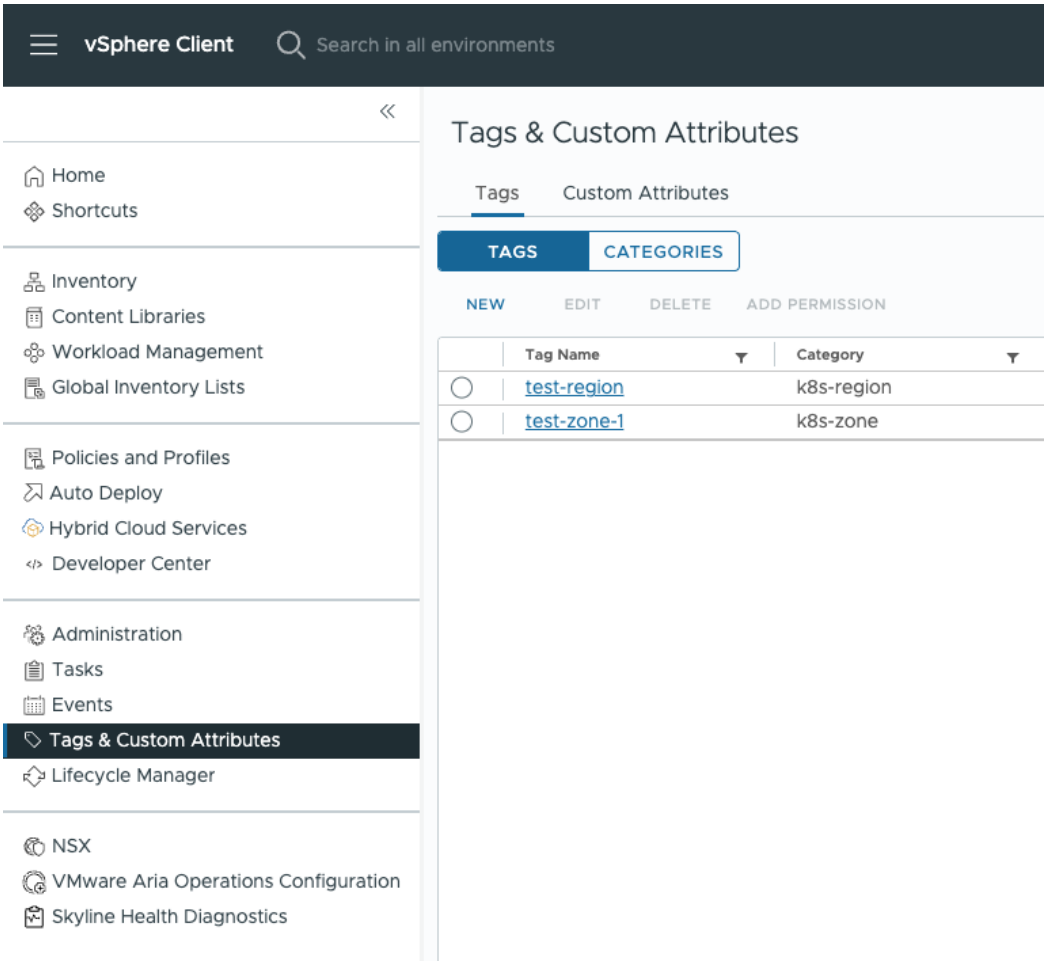


Creating tags and tag categories in vSphere Client

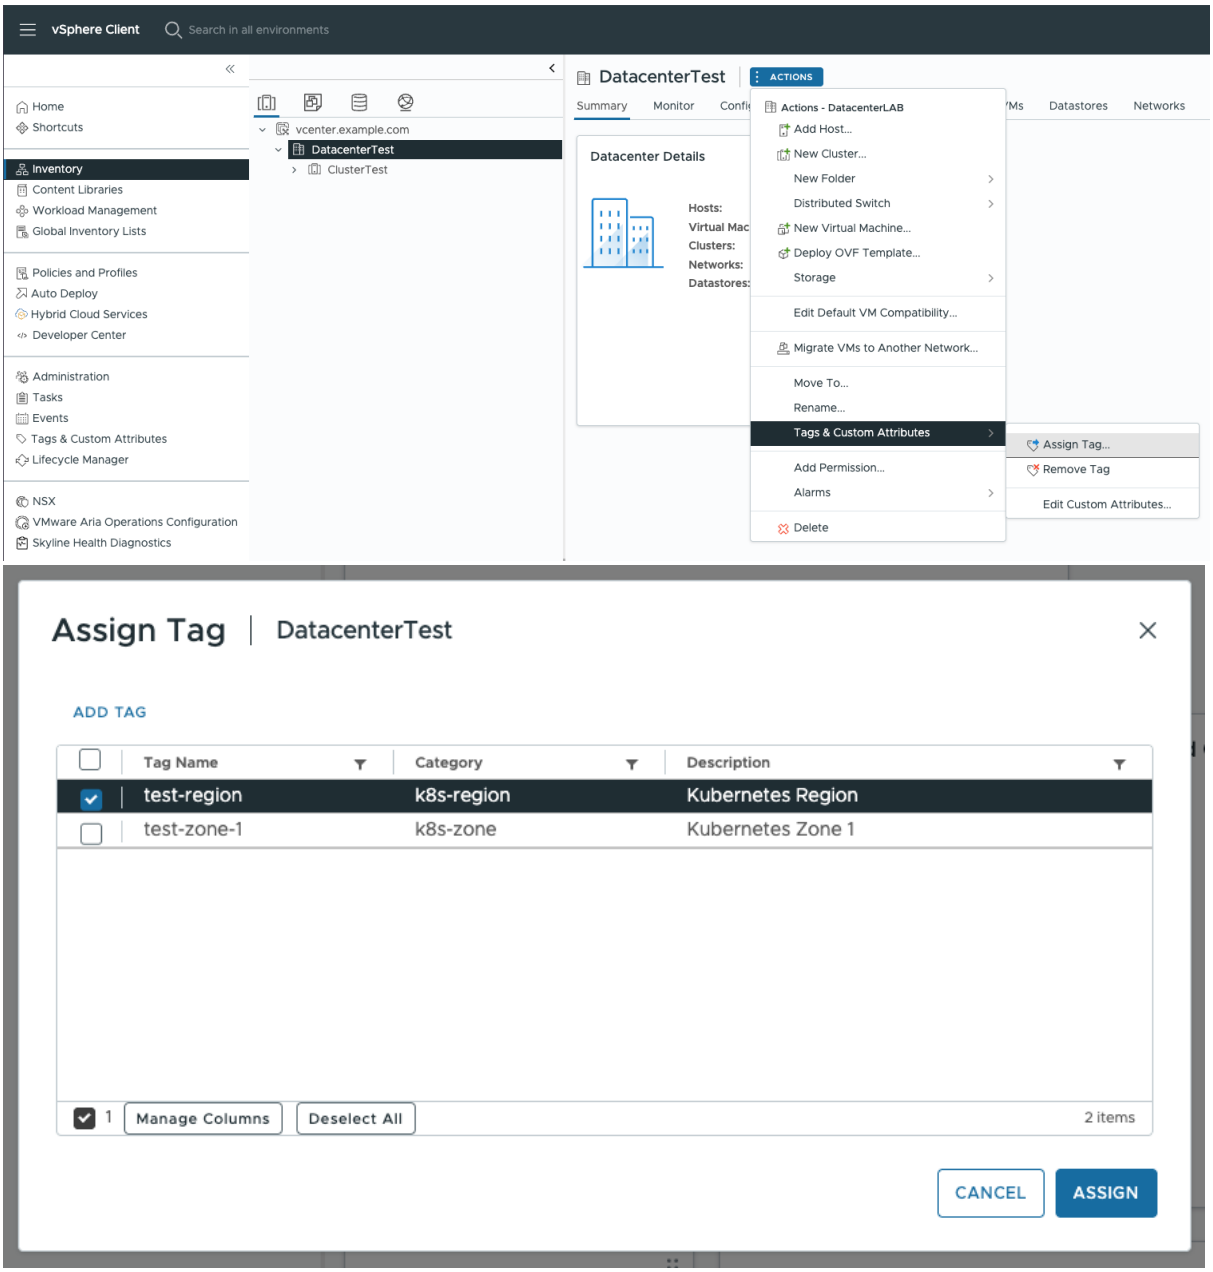
VMware vSphere does not have built-in concepts of a “region” or a “zone”. In vSphere, a Datacenter acts as a region, and a Cluster acts as a zone. Tags are used to establish this mapping.



1. Open vSphere Client and go to “Menu” → “Tags & Custom Attributes” → “Tags”.

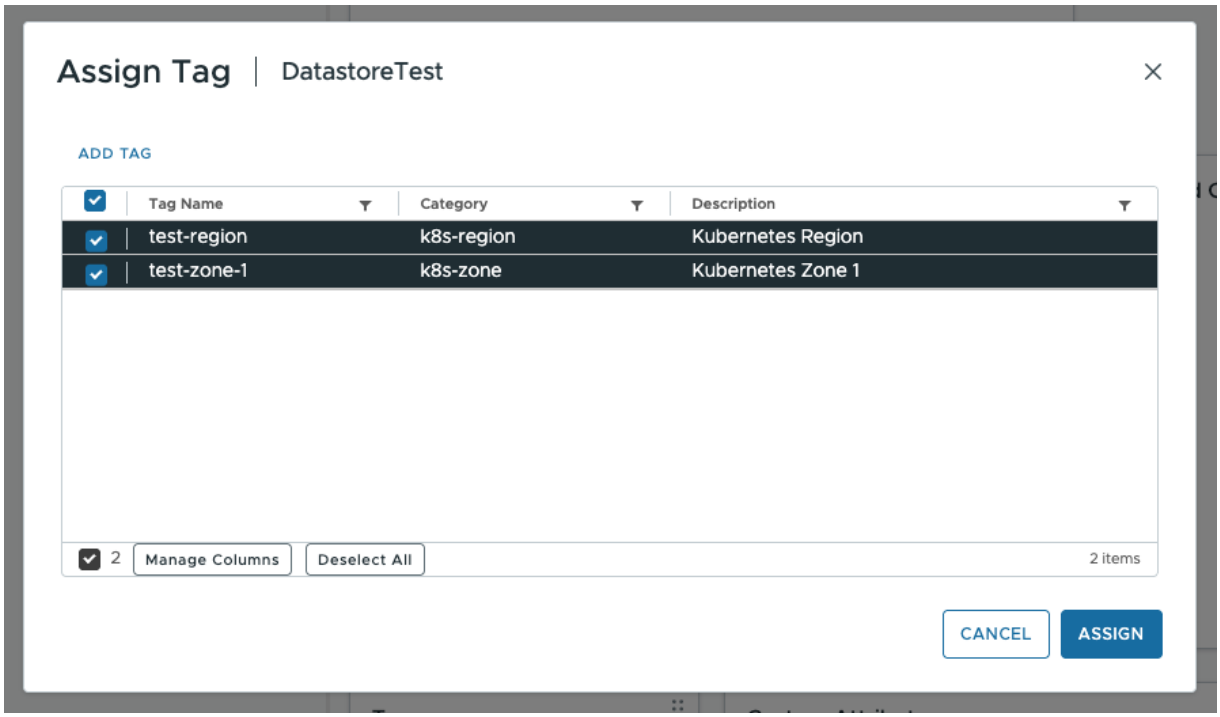


2. Open the “Categories” tab and click “NEW”. Create a category for regions (for example, `k8s-region`): set “Tags Per Object” to “One tag” and specify the applicable object types, including Datacenter.



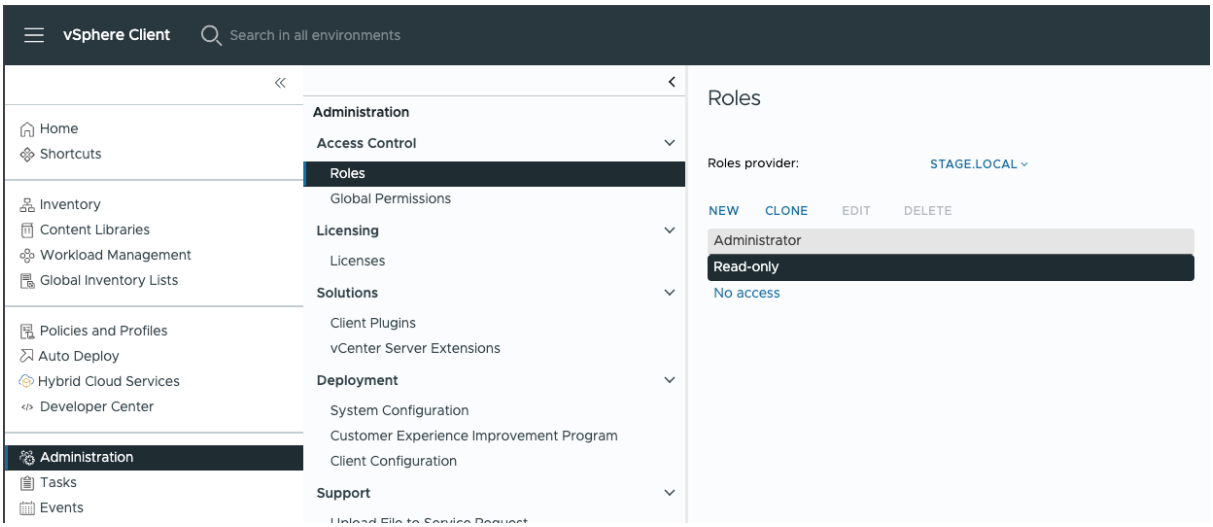
3. Create a second category for zones (for example, `k8s-zone`) with the object types Host, Cluster, and Datastore.

4. Go to the “Tags” tab and create at least one tag in the region category and one tag in the zone category (for example, `test-region`, `test-zone-1`).



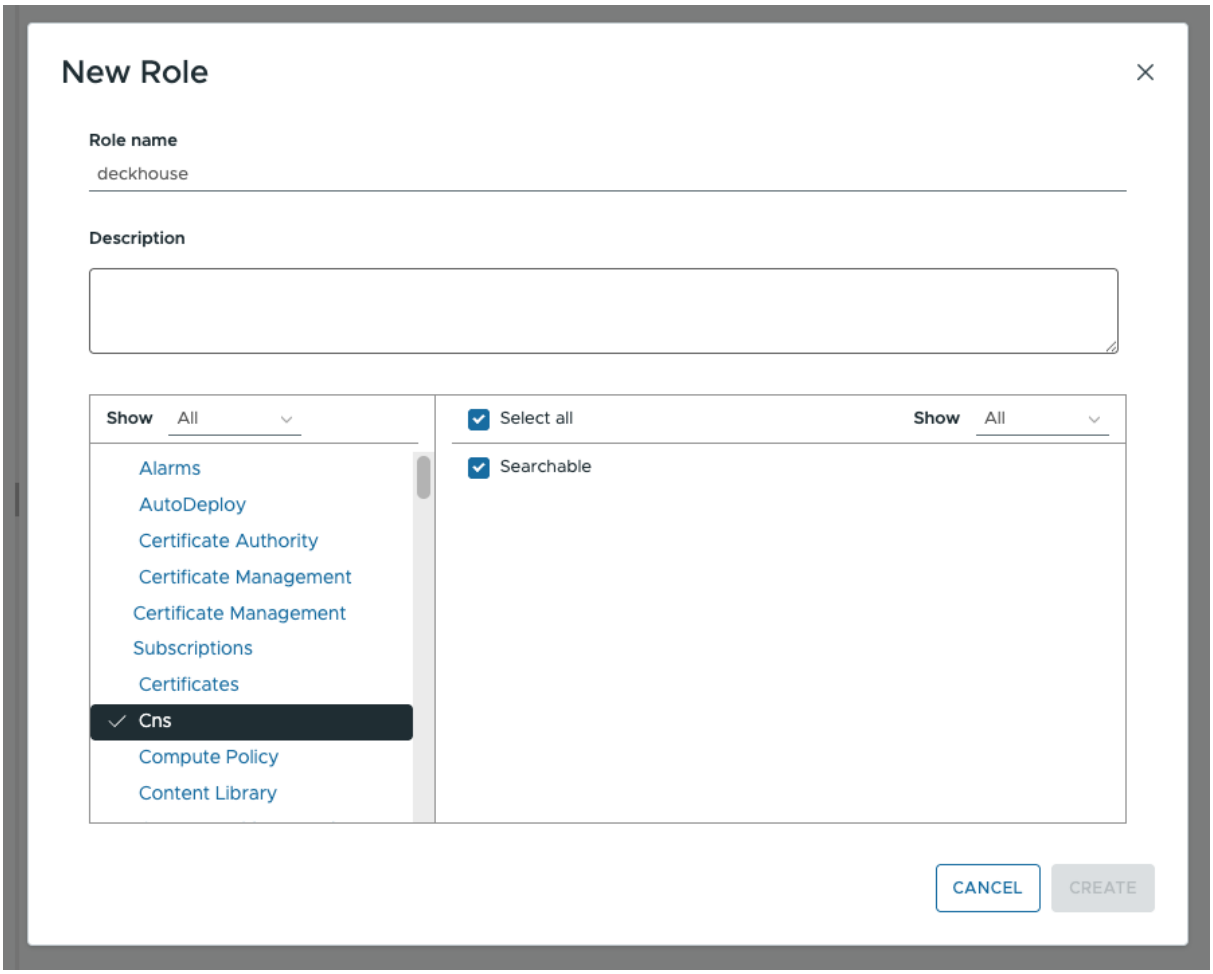
5. In the “Inventory” tab, select the target Datacenter, open the “Summary” panel, then choose “Actions” → “Tags & Custom Attributes” → “Assign Tag” and assign the region tag. Repeat this step for each Cluster that will host nodes, assigning the appropriate zone tags.

Configuring Datastore in vSphere Client

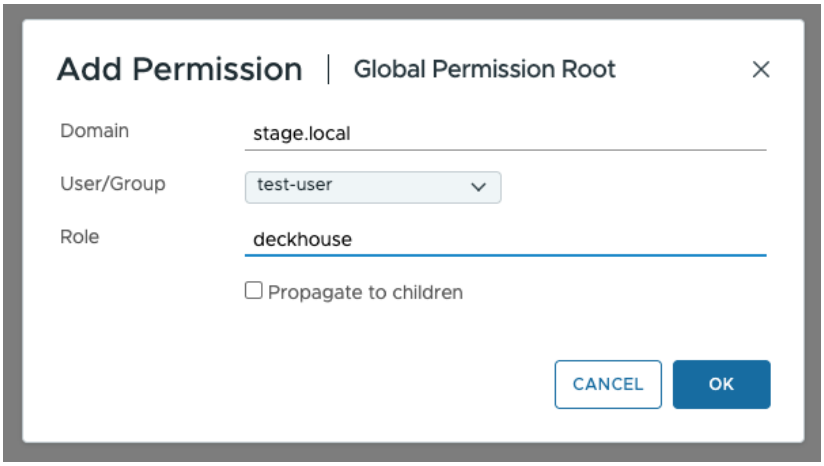


> ⚠ For dynamic provisioning of PersistentVolume, the Datastore must be available on **every** ESXi host in the zone (shared datastore).

In the “Inventory” tab, select the Datastore, open the “Summary” panel, then choose “Actions” → “Tags & Custom Attributes” → “Assign Tag”. Assign the Datastore the same region tag as the corresponding Datacenter, and the same zone tag as the corresponding Cluster.



Creating and assigning a role in vSphere Client



1. Go to “Menu” → “Administration” → “Access Control” → “Roles”.

2. Click “NEW”, enter a role name (for example, `deckhouse`), and add the privileges from the list.

3. Assign the role to the Deckhouse service account: go to “Menu” → “Administration” → “Access Control” → “Global Permissions”, click “ADD”, and select the user and the `deckhouse` role.

Configuration with govc

Installing govc

To continue configuring vSphere, install the govc CLI utility.

After installation, set the environment variables required to connect to `vCenter`.

⚠ Make sure to specify the username together with the domain, for example: `username@domain.local`.

```
export GOVC_URL=example.com
export GOVC_USERNAME=<username>@vsphere.local
export GOVC_PASSWORD=<password>
export GOVC_INSECURE=1
```

Creating tags and tag categories with govc

VMware vSphere does not have built-in concepts of a “region” or a “zone”. In vSphere, a Datacenter acts as a region, and

a Cluster acts as a zone. Tags are used to establish this mapping.

Create tag categories with the following commands:

```
govc tags.category.create -d "Kubernetes Region" k8s-region
govc tags.category.create -d "Kubernetes Zone" k8s-zone
```

Create tags in each category. If you intend to use multiple “zones” (Cluster), create a tag for each one of them:

```
govc tags.create -d "Kubernetes Region" -c k8s-region test-region
govc tags.create -d "Kubernetes Zone Test 1" -c k8s-zone test-zone-1
govc tags.create -d "Kubernetes Zone Test 2" -c k8s-zone test-zone-2
```

Attach the “region” tag to Datacenter:

```
govc tags.attach -C k8s-region test-region /<DATACENTER_NAME>
```

Attach “zone” tags to the Cluster objects:

```
govc tags.attach -C k8s-zone test-zone-1 /<DATACENTER_NAME>/host/<CLUSTER_NAME_1>
govc tags.attach -C k8s-zone test-zone-2 /<DATACENTER_NAME>/host/<CLUSTER_NAME_2>
```

Datastore configuration with govc

⚠ For dynamic PersistentVolume provisioning, a Datastore must be available on **each** ESXi host (shared datastore).

Assign the “region” and “zone” tags to the Datastore objects to automatically create a StorageClass in the Kubernetes cluster:

```
govc tags.attach -C k8s-region test-region /<DATACENTER_NAME>/datastore/<DATASTORE_NAME_1>
govc tags.attach -C k8s-zone test-zone-1 /<DATACENTER_NAME>/datastore/<DATASTORE_NAME_1>

govc tags.attach -C k8s-region test-region /<DATACENTER_NAME>/datastore/<DATASTORE_NAME_2>
govc tags.attach -C k8s-zone test-zone-2 /<DATACENTER_NAME>/datastore/<DATASTORE_NAME_2>
```

Creating and assigning a role with govc

i We’ve intentionally skipped User creation since there are many ways to authenticate a user in the vSphere.

The role described below includes the privileges from the list of required privileges section. If you need a more granular Role, please contact your Deckhouse support.

Create a role with the required privileges:

```
govc role.create deckhouse \
    Cns.Searchable \
    Datastore.AllocateSpace Datastore.Browse Datastore.FileManagement \
    Folder.Create Folder.Delete Folder.Move Folder.Rename \
    Global.GlobalTag Global.SystemTag \
    InventoryService.Tagging.AttachTag InventoryService.Tagging.CreateCategory \
    InventoryService.Tagging.CreateTag InventoryService.Tagging.DeleteCategory \
    InventoryService.Tagging.DeleteTag InventoryService.Tagging.EditCategory \
    InventoryService.Tagging.EditTag InventoryService.Tagging.ModifyUsedByForCategory \
    InventoryService.Tagging.ModifyUsedByForTag InventoryService.Tagging.ObjectAttachable \
    Network.Assign \
    Resource.AssignVMToPool Resource.CreatePool Resource.DeletePool Resource.EditPool Resource.RenamePool \
    StorageProfile.View \
    System.Anonymous System.Read System.View \
    VApp.ApplicationConfig VApp.AssignResourcePool VApp.AssignVM VApp.Create VApp.Delete \
    VApp.ExtractOvfEnvironment VApp.Import VApp.InstanceConfig VApp.PowerOff VApp.PowerOn VApp.ResourceConfig \
    VirtualMachine.Config.AddExistingDisk VirtualMachine.Config.AddNewDisk VirtualMachine.Config.AddRemoveDevice \
    VirtualMachine.Config.AdvancedConfig VirtualMachine.Config.Annotation VirtualMachine.Config.CPUCount \
    VirtualMachine.Config.ChangeTracking VirtualMachine.Config.DiskExtend VirtualMachine.Config.DiskLease \
    VirtualMachine.Config.EditDevice VirtualMachine.Config.ManagedBy VirtualMachine.Config.Memory \
    VirtualMachine.Config.QueryUnownedFiles VirtualMachine.Config.RawDevice VirtualMachine.Config.ReloadFromPath \
    VirtualMachine.Config.RemoveDisk VirtualMachine.Config.Rename VirtualMachine.Config.ResetGuestInfo \
    VirtualMachine.Config.Resource VirtualMachine.Config.Settings VirtualMachine.Config.SwapPlacement \
    VirtualMachine.Config.UpgradeVirtualHardware \
    VirtualMachine.GuestOperations.Query \
    VirtualMachine.Interact.AnswerQuestion VirtualMachine.Interact.DeviceConnection \
    VirtualMachine.Interact.GuestControl VirtualMachine.Interact.PowerOff VirtualMachine.Interact.PowerOn \
    VirtualMachine.Interact.Reset VirtualMachine.Interact.SetCDMedia VirtualMachine.Interact.ToolsInstall \
    VirtualMachine.Inventory.Create VirtualMachine.Inventory.CreateFromExisting VirtualMachine.Inventory.Delete \
    VirtualMachine.Inventory.Move \
    VirtualMachine.Provisioning.Clone VirtualMachine.Provisioning.Customize VirtualMachine.Provisioning.DeployTemplate \
    VirtualMachine.Provisioning.GetVmFiles VirtualMachine.Provisioning.PutVmFiles VirtualMachine.Provisioning.ReadCustSpecs
\
    VirtualMachine.State.CreateSnapshot VirtualMachine.State.RemoveSnapshot VirtualMachine.State.RenameSnapshot
```

Assign the role to a user on the vCenter object.

⚠ Make sure to specify the username together with the domain, for example: `username@domain.local`.

```
govc permissions.set -principal <username>@vsphere.local -role deckhouse /
```

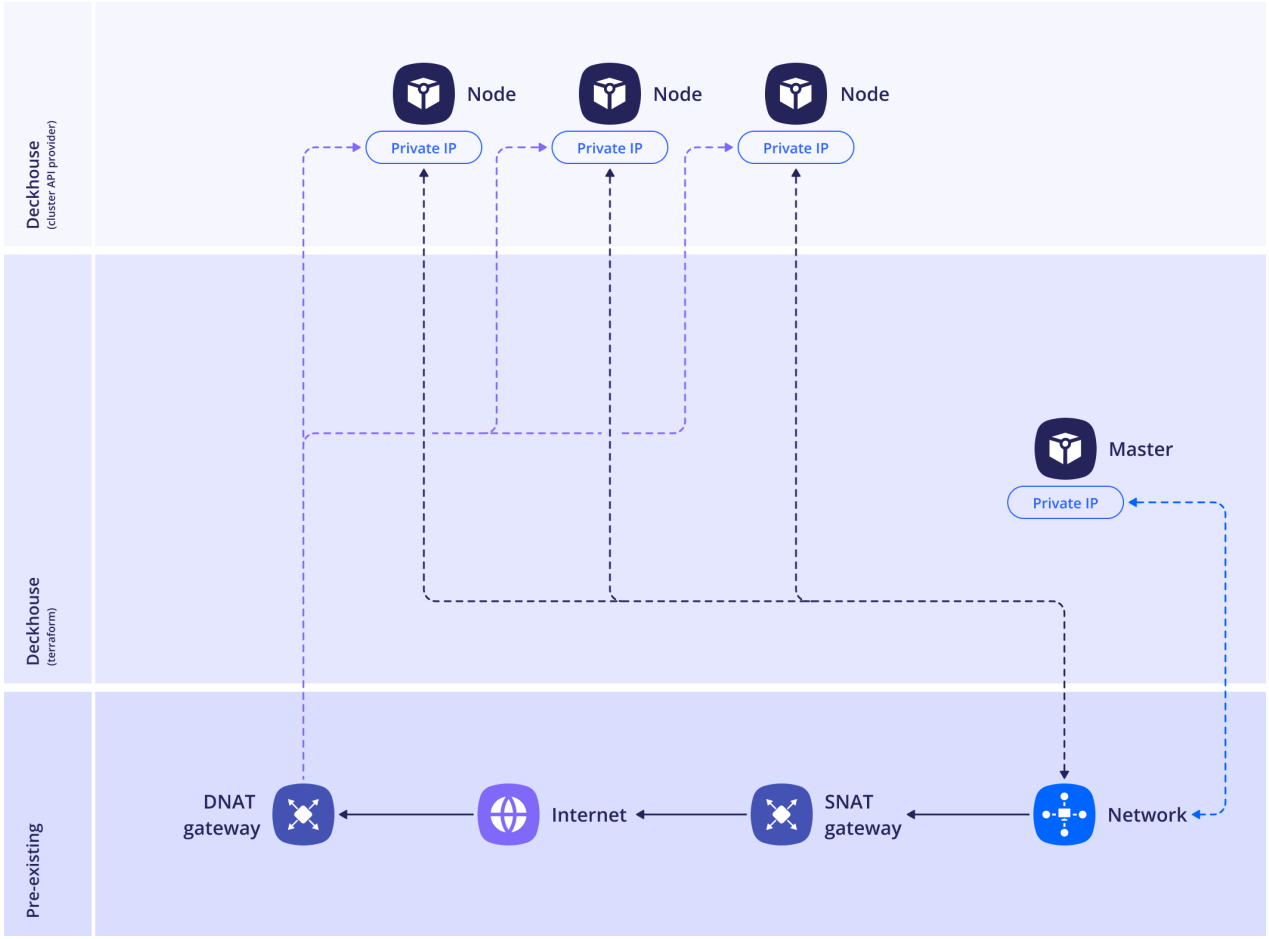
i For more detailed permission configuration, refer to the official documentation.

Additional resources

- Module `cloud-provider-vsphere` documentation

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.



Layouts and configuration in VMware vSphere

Standard

The Standard layout is intended for deploying a cluster within the vSphere infrastructure with full control over resources, networking, and storage.

Key features:

- Uses a vSphere Datacenter as a `region`.
- Uses a vSphere Cluster as a `zone`.
- Supports multiple zones and node placements across zones.
- Supports using different datastores for disks and volumes.
- Supports network connectivity including additional network isolation (for example, MetalLB + BGP).

Example configuration:

```
apiVersion: deckhouse.io/v1
kind: VsphereClusterConfiguration
layout: Standard
provider:
  server: '<SERVER>'
  username: '<USERNAME>'
  password: '<PASSWORD>'
vmFolderPath: dev
regionTagCategory: k8s-region
zoneTagCategory: k8s-zone
region: X1
internalNetworkCIDR: 192.168.199.0/24
masterNodeGroup:
  replicas: 1
  zones:
    - ru-central1-a
    - ru-central1-b
  instanceClass:
    numCPUs: 4
    memory: 8192
    template: dev/golden_image
    datastore: dev/lun_1
    mainNetwork: net3-k8s
nodeGroups:
  - name: khm
    replicas: 1
    zones:
      - ru-central1-a
    instanceClass:
      numCPUs: 4
      memory: 8192
      template: dev/golden_image
      datastore: dev/lun_1
      mainNetwork: net3-k8s
sshPublicKey: "<SSH_PUBLIC_KEY>"
zones:
  - ru-central1-a
  - ru-central1-b
```

Required parameters for the VsphereClusterConfiguration resource:

- `region`: Tag assigned to the Datacenter object.
- `zoneTagCategory` and `regionTagCategory`: Tag categories used to identify regions and zones.
- `internalNetworkCIDR`: Subnet for assigning internal IP addresses.
- `vmFolderPath`: Path to the folder where cluster virtual machines will be placed.
- `sshPublicKey`: Public SSH key used to access the nodes.
- `zones`: List of zones available for node placement.

i All nodes placed in different zones must have access to shared datastores with matching zone tags.

List of required privileges

i To create a role and assign it to a user, refer to Configuration in vSphere Client and Configuration with govc sections.

A detailed list of privileges required for Deckhouse Platform to work in vSphere:

Privilege category in UI	Privileges in UI	Privileges in API	Purpose in Deckhouse

—	— (assigned by default when creating a role)	`System.Anonymous`
		`System.Read`
		`System.View`
			Basic access to vSphere Inventory objects required for all Deckhouse vSphere integration components.

Cns	Searchable	`Cns.Searchable`	Search and mapping of Container Native Storage objects when the CSI driver works with Kubernetes volumes.

Privilege category in UI	Privileges in UI	Privileges in API	Purpose in Deckhouse

Datastore	Allocate space,
	Browse datastore,
	Low level file operations
		`Datastore.AllocateSpace`
		`Datastore.Browse`
		`Datastore.FileManagement`
			Disk provisioning when creating virtual machines and ordering `PersistentVolumes` in the cluster.

Folder	Create folder,
	Delete folder,
	Move folder,
	Rename folder
		`Folder.Create`
		`Folder.Delete`
		`Folder.Move`
		`Folder.Rename`
			Grouping a Deckhouse Platform cluster in a single `Folder` in vSphere Inventory.

Global	Global tag, System tag	`Global.GlobalTag` `Global.SystemTag`	Access to global and system tags used by Deckhouse Platform when working with vSphere objects.

vSphere Tagging	Assign or Unassign vSphere Tag,
	Assign or Unassign vSphere Tag on Object,
	Create vSphere Tag,
	Create vSphere Tag Category,
	Delete vSphere Tag,
	Delete vSphere Tag Category,
	Edit vSphere Tag,
	Edit vSphere Tag Category,
	Modify UsedBy Field for Category,
	Modify UsedBy Field for Tag
		`InventoryService.Tagging.AttachTag`
		`InventoryService.Tagging.ObjectAttachable`
		`InventoryService.Tagging.CreateTag`
		`InventoryService.Tagging.CreateCategory`
		`InventoryService.Tagging.DeleteTag`
		`InventoryService.Tagging.DeleteCategory`
		`InventoryService.Tagging.EditTag`
		`InventoryService.Tagging.EditCategory`
		`InventoryService.Tagging.ModifyUsedByForCategory`
		`InventoryService.Tagging.ModifyUsedByForTag`
			Deckhouse Platform uses tags to identify the `Datacenter`, `Cluster`, and `Datastore` objects available to it, as well as to identify the virtual machines under its control.

Network	Assign network	`Network.Assign`	Connecting networks and port groups to Deckhouse Platform cluster virtual machines.

Resource	Assign virtual machine to resource pool,
	Create resource pool,
	Modify resource pool,
	Remove resource pool,
	Rename resource pool
		`Resource.AssignVMToPool`
		`Resource.CreatePool`
		`Resource.DeletePool`
		`Resource.EditPool`
		`Resource.RenamePool`
			Placement of Deckhouse Platform cluster virtual machines into the target resource pool and management of this pool.

VM Storage Policies (*Profile-driven Storage Privileges* in vSphere 7)	View VM storage policies (*Profile-driven storage view* in vSphere 7)	`StorageProfile.View`	Viewing storage policies used when creating virtual machines and dynamically provisioning volumes in the cluster.

vApp	Add virtual machine,
	Assign resource pool,
	Create,
	Delete,
	Import,
	Power Off,
	Power On,
	View OVF Environment,
	vApp application configuration,
	vApp instance configuration,
	vApp resource configuration
		`VApp.ApplicationConfig`
		`VApp.AssignResourcePool`
		`VApp.AssignVM`
		`VApp.Create`
		`VApp.Delete`
		`VApp.ExtractOvfEnvironment`
		`VApp.Import`
		`VApp.InstanceConfig`
		`VApp.PowerOff`
		`VApp.PowerOn`
		`VApp.ResourceConfig`
			Managing operations related to deployment and configuration of vApp and OVF templates used when creating virtual machines.

Privilege category in UI	Privileges in UI	Privileges in API	Purpose in Deckhouse

Virtual Machine > Change Configuration	Add existing disk,
	Add new disk,
	Add or remove device,
	Advanced configuration,
	Set annotation,
	Change CPU count,
	Toggle disk change tracking,
	Extend virtual disk,
	Acquire disk lease,
	Modify device settings,
	Configure managedBy,
	Change Memory,
	Query unowned files,
	Configure Raw device,
	Reload from path,
	Remove disk,
	Rename,
	Reset guest information,
	Change resource,
	Change Settings,
	Change Swapfile placement,
	Upgrade virtual machine compatibility
		`VirtualMachine.Config.AddExistingDisk`
		`VirtualMachine.Config.AddNewDisk`
		`VirtualMachine.Config.AddRemoveDevice`
		`VirtualMachine.Config.AdvancedConfig`
		`VirtualMachine.Config.Annotation`
		`VirtualMachine.Config.CPUCount`
		`VirtualMachine.Config.ChangeTracking`
		`VirtualMachine.Config.DiskExtend`
		`VirtualMachine.Config.DiskLease`
		`VirtualMachine.Config.EditDevice`
		`VirtualMachine.Config.ManagedBy`

		`VirtualMachine.Interact.GuestControl`
		`VirtualMachine.Interact.PowerOff`
		`VirtualMachine.Interact.PowerOn`
		`VirtualMachine.Interact.Reset`
		`VirtualMachine.Interact.SetCDMedia`
		`VirtualMachine.Interact.ToolsInstall`
			Managing virtual machine power state, device connections, and interaction with the guest operating system.

Privilege category in UI	Privileges in UI	Privileges in API	Purpose in Deckhouse

Virtual Machine > Provisioning	Clone virtual machine,
	Customize guest,
	Deploy template,
	Allow virtual machine download,
	Allow virtual machine files upload,
	Read customization specifications
		`VirtualMachine.Provisioning.Clone`
		`VirtualMachine.Provisioning.Customize`
		`VirtualMachine.Provisioning.DeployTemplate`
		`VirtualMachine.Provisioning.GetVmFiles`
		`VirtualMachine.Provisioning.PutVmFiles`
		`VirtualMachine.Provisioning.ReadCustSpecs`
			Cloning virtual machine templates, customizing them, and deploying them when creating Deckhouse Platform cluster nodes.

Virtual Machine > Snapshot Management	Create snapshot,
	Remove Snapshot,
	Rename Snapshot
		`VirtualMachine.State.CreateSnapshot`
		`VirtualMachine.State.RemoveSnapshot`
		`VirtualMachine.State.RenameSnapshot`
			Managing snapshots of virtual machines and volumes in scenarios where this functionality is used by platform components.

Additional resources

- Module `cloud-provider-vsphere` provider configuration

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage and load balancing in VMware vSphere

Storage

The following storage types are used in VMware vSphere for Kubernetes cluster data:

- **Datastores**: Used to store the root disks of virtual machines;
- **CNS disks (Container Native Storage)**: Used for automatic creation of PersistentVolumes via CSI.

Deckhouse Platform (DP) automatically creates a StorageClass for each Datastore and DatastoreCluster that is tagged as a `zone`.

You can specify:

- The default StorageClass name (`default`).
- Exclusions via the `exclude` field in a form of a list of names or patterns for StorageClasses that should not be created.

Example configuration using ModuleConfig:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-vsphere
spec:
  version: 2
  enabled: true
  settings:
    storageClass:
      default: fast-lun102
      exclude:
        - ".*-lun101-.*"
        - slow-lun103
```

Resizing a volume (PVCs)

DP supports Online Resize PersistentVolume starting with vSphere 7.0U2. However, due to CSI and vSphere API specifics, additional steps are required after resizing a PVC:

1. Run `d8 k cordon <node_name>`.
2. Delete the Pod that uses the PVC.
3. Wait for the resize operation to complete:
   - Ensure the PVC no longer has the `Resizing` condition.
   - It’s safe to ignore the `FileSystemResizePending` status.
4. Run `d8 k uncordon <node_name>`.

Load balancing

Options for organizing incoming traffic load balancing:

1. **Via an external load balancer**. If your infrastructure includes an external load balancer (for example, NSX-T), you can route traffic directly to the cluster's frontend nodes.
2. **Via MetalLB**. For fault-tolerant load balancing within the cluster, it is recommended that you use MetalLB in BGP mode. In this case:
   - Frontend nodes receive two network interfaces.
   - A dedicated VLAN is required for BGP traffic.
   - The network must provide DHCP and internet access.
   - IP addresses and BGP router ASNs must be specified.
   - A pool of IP addresses to be announced must be defined.

> **i** Make sure there is connectivity between BGP routers and frontend nodes in the dedicated VLAN.

CSI

The storage subsystem uses CNS disks by default, with support for online resizing.
Legacy mode with FCD disks is also supported. The subsystem behavior is configured via the `compatibilityFlag` parameter.

Important information on PVC size expansion

Due to specifics of the CSI volume-resizer and vSphere API, after increasing a PVC size, you must perform the following steps:

1. On the node hosting the Pod, run `d8 k cordon <node_name>`.
2. Delete the Pod.
3. Ensure the resize operation completed successfully — the PVC **must not** have the `Resizing` condition.

   > **i** The `FileSystemResizePending` condition is not an issue.

4. On the node hosting the Pod, run `d8 k uncordon <node_name>`

Datastore configuration

> **i** You can also tag **Datastore** objects through the **VMware vSphere Client** — follow Datastore configuration in the connection and authorization guide. The steps below use **`govc` only**.

> ⚠ For dynamic `PersistentVolume` provisioning, a `Datastore` must be available on **each** ESXi host (shared datastore).

For PersistentVolume to function correctly, the datastore must be accessible from all ESXi hosts.

Assign tags:

```
govc tags.attach -C k8s-region test-region /<DatacenterName>/datastore/<DatastoreName1>
govc tags.attach -C k8s-zone test-zone-1 /<DatacenterName>/datastore/<DatastoreName1>

govc tags.attach -C k8s-region test-region /<DatacenterName>/datastore/<DatastoreName2>
govc tags.attach -C k8s-zone test-zone-2 /<DatacenterName>/datastore/<DatastoreName2>
```

Additional resources

- Module `cloud-provider-vsphere` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integration with VMware vSphere services

Deckhouse Platform integrates with VMware vSphere infrastructure and uses VsphereInstanceClass resources to describe the specifications of virtual machines created as part of the Kubernetes cluster.

Key features:

- Provisioning and removal of virtual machines via the vCenter API.
- Node placement across multiple clusters (`zones`) and datacenters (`region`).
- Use of VM templates with `cloud-init`.
- Support for networks with DHCP, static addressing, and additional interfaces.
- Storage management: provisioning root disks and PVCs based on Datastore or CNS disks.
- Support for incoming traffic load balancing:
  - Via external load balancers.

- Via MetalLB (in BGP mode).

> **i** DP supports hybrid integration with VMware vSphere. For configuration details, see Hybrid cluster with vSphere section.

vSphere resource management

Removing CloudPermanent nodes in vSphere

Nodes of the `CloudPermanent` type are created based on the node group configuration specified in the `nodeGroups` section of the VsphereClusterConfiguration resource.

The `replicas` parameter defines the required number of virtual machines in the group. After the configuration is changed, run the `dhctl converge` command to start Terraform and bring the state of virtual machines in VMware vSphere in line with the specified number of replicas.

To reduce the number of nodes in a group, decrease the `replicas` value and run `dhctl converge`.

> **⚠** Do not remove the group definition from the `nodeGroups` section while the value of the `replicas` parameter is greater than zero.
>
> If the group definition is removed before the number of replicas is reduced to zero, the Terraform state may become inconsistent with the state of virtual machines and disks in VMware vSphere. As a result, a subsequent `dhctl converge` run may fail and require manual state recovery.

Reducing the number of nodes

To reduce the number of nodes in a `CloudPermanent` group:

1. Open the vSphere configuration for editing:

   ```
   d8 system edit provider-cluster-configuration
   ```

2. In the `nodeGroups` section, find the required group and decrease the value of the `replicas` parameter to the required number of nodes.

   For example, to reduce the number of nodes in the `worker` group from three to two, set `replicas: 2`:

   ```
   nodeGroups:
   - name: worker
     replicas: 2
     zones:
     - zone-a
     instanceClass:
       numCPUs: 4
       memory: 8192
       template: Templates/ubuntu-24.04
       datastore: datastore-1
       mainNetwork: network-1
   ```

   Save the changes.

3. In the DP installer container, apply the updated configuration:

   ```
   dhctl converge \
     --ssh-host <MASTER-NODE-IP-ADDRESS> \
     --ssh-user <USERNAME> \
     --ssh-agent-private-keys /tmp/.ssh/<PRIVATE-SSH-KEY-NAME>
   ```

   > **i** Use an installer container of the same edition and version as the cluster.

4. Wait for `dhctl converge` to complete and check the number of nodes in the group:

   ```
   d8 k get nodes -l node.deckhouse.io/group=<GROUP-NAME>
   ```

Completely removing a node group

A `CloudPermanent` group must be removed in two stages. First, reduce the number of replicas to zero and wait for the nodes and virtual machines to be removed. You can then remove the group definition from the vSphere configuration.

To completely remove a `CloudPermanent` group:

1. Open the vSphere configuration for editing:

```
d8 system edit provider-cluster-configuration
```

2. In the `nodeGroups` section, find the group to be removed and set `replicas: 0`. Do not remove the group definition at this stage. For example:

   ```
   nodeGroups:
   - name: worker
     replicas: 0
     zones:
     - zone-a
     instanceClass:
       numCPUs: 4
       memory: 8192
       template: Templates/ubuntu-24.04
       datastore: datastore-1
       mainNetwork: network-1
   ```

   Save the changes.

3. In the DP installer container, apply the updated configuration:

   ```
   dhctl converge \
     --ssh-host <MASTER-NODE-IP-ADDRESS> \
     --ssh-user <USERNAME> \
     --ssh-agent-private-keys /tmp/.ssh/<PRIVATE-SSH-KEY-NAME>
   ```

4. Wait for `dhctl converge` to complete successfully and make sure that no nodes remain in the group:

   ```
   d8 k get nodes -l node.deckhouse.io/group=<GROUP-NAME>
   ```

   The command must not return any nodes from the group being removed.

   Also use vSphere Client to make sure that the virtual machines associated with the group have been removed.

5. Open the cloud provider configuration again:

   ```
   d8 system edit provider-cluster-configuration
   ```

6. Remove the group definition from the `nodeGroups` section and save the changes.
7. Apply the configuration again:

   ```
   dhctl converge \
     --ssh-host <MASTER-NODE-IP-ADDRESS> \
     --ssh-user <USERNAME> \
     --ssh-agent-private-keys /tmp/.ssh/<PRIVATE-SSH-KEY-NAME>
   ```

8. Make sure that the NodeGroup object has been removed:

   ```
   d8 k get nodegroup <GROUP-NAME>
   ```

   The command must return a message stating that the requested resource was not found.

- Module `cloud-provider-vsphere` custom resources
- Module `cloud-provider-vsphere` provider configuration

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Connection and authorization in zVirt

For Deckhouse Platform to create virtual machines in zVirt, assign the required roles to the zVirt user, prepare a cloud image of the operating system and a virtual machine template, and pass the user login and password in the credentials Secret.

Requirements

Deckhouse Platform requires the following to work with zVirt:

- A working zVirt installation with an accessible API
- zVirt version `4.0`–`4.4`

- A user with the permissions listed in the “User permissions” section
- A storage domain with an uploaded cloud image of the operating system
- A virtual machine template prepared from the cloud image

⚠ The provider supports working with only one disk in the virtual machine template. Make sure the template contains only one disk.

User permissions

Deckhouse Platform does not require the `SuperUser` role for the zVirt user. It is enough to assign the following predefined zVirt roles to the user on the objects the cluster works with:

Role	Object	Purpose
`UserVmManager`	zVirt cluster from the `clusterID` parameter	Creating, starting, stopping, and deleting node virtual machines, creating their network interfaces, attaching and detaching disks
`UserTemplateBasedVm`	Virtual machine template	Creating virtual machines from the template
`DiskOperator`	Storage domains that contain the template disk and where disks for etcd and cluster volumes are created	Creating, resizing, attaching, detaching, and deleting disks
`VnicProfileUser`	vNIC profile	Creating a virtual machine network interface from the vNIC profile
`TagManager`	Entire system (system permission)	Creating the cluster tag and assigning it to virtual machines of CloudEphemeral nodes

The `TagManager` role is assigned only on the entire system, because zVirt checks the tag management permission at this level.

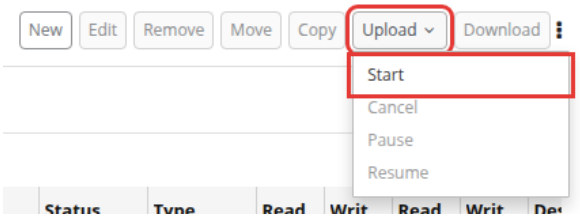
⚠ The `TagManager` role is administrative. With it, the user can view all objects via the zVirt API but can modify only the objects on which the roles from the table are assigned to the user.

zVirt assigns some roles to the Everyone group by default, so you do not need to assign them to the user separately:

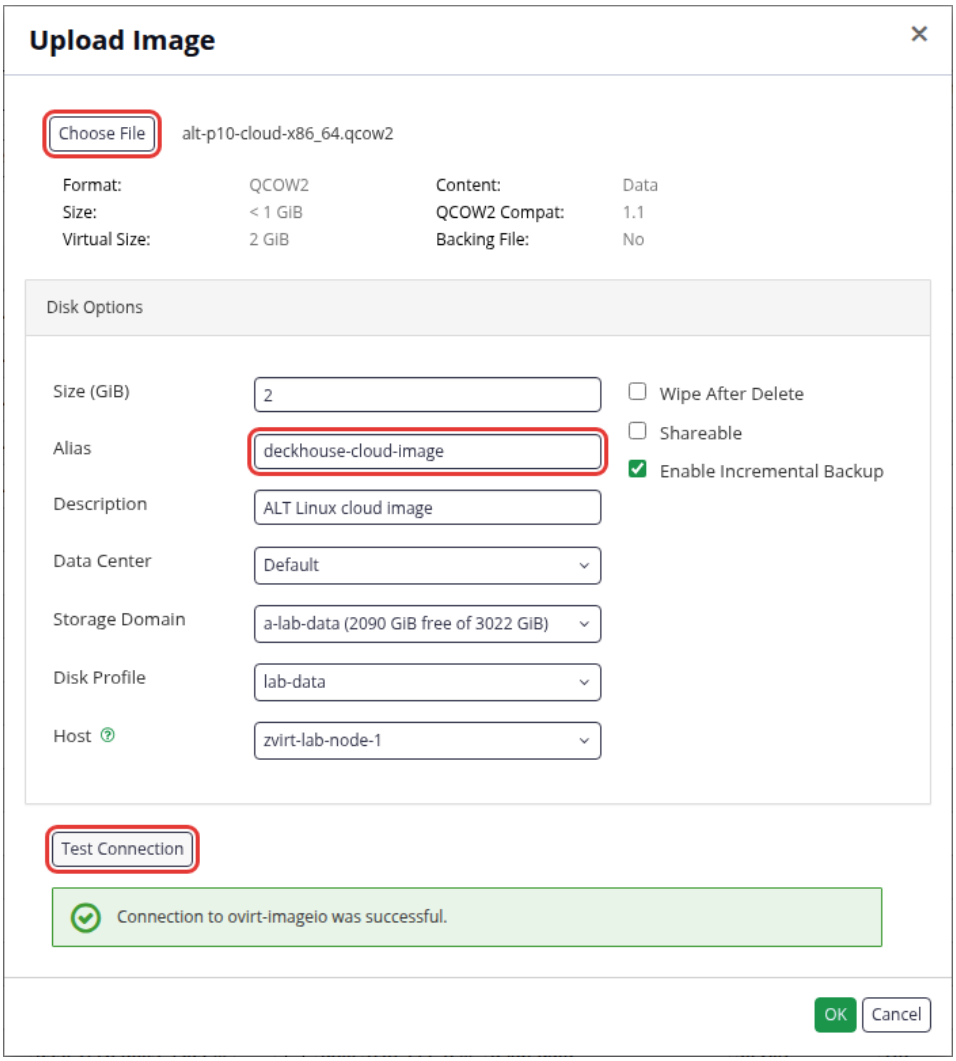
- `UserTemplateBasedVm` on a template created with the “Allow all users to access this Template” checkbox selected
- `VnicProfileUser` on a public vNIC profile
- `CpuProfileOperator` on the cluster CPU profile
- `DiskProfileUser` on the disk profiles of storage domains

If these permissions were removed in your zVirt installation, assign the roles to the user.

To assign a role on an object:



1. Open the object in the zVirt Administration Portal, for example, a cluster in the “Compute → Clusters” section.
2. Go to the “Permissions” tab and click “Add”.
3. Select the user and the role and save the permission.

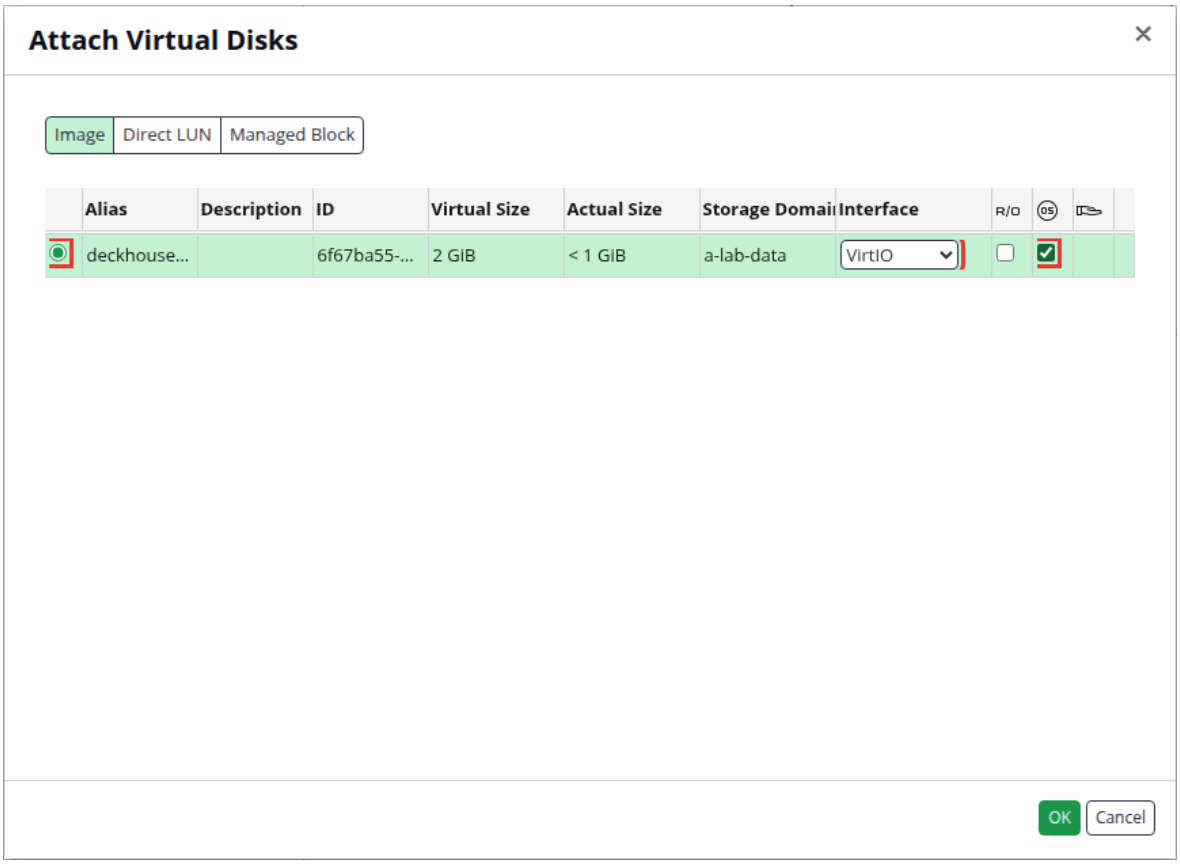


Assign the `TagManager` role in the “Administration → Configure” section on the “System Permissions” tab.

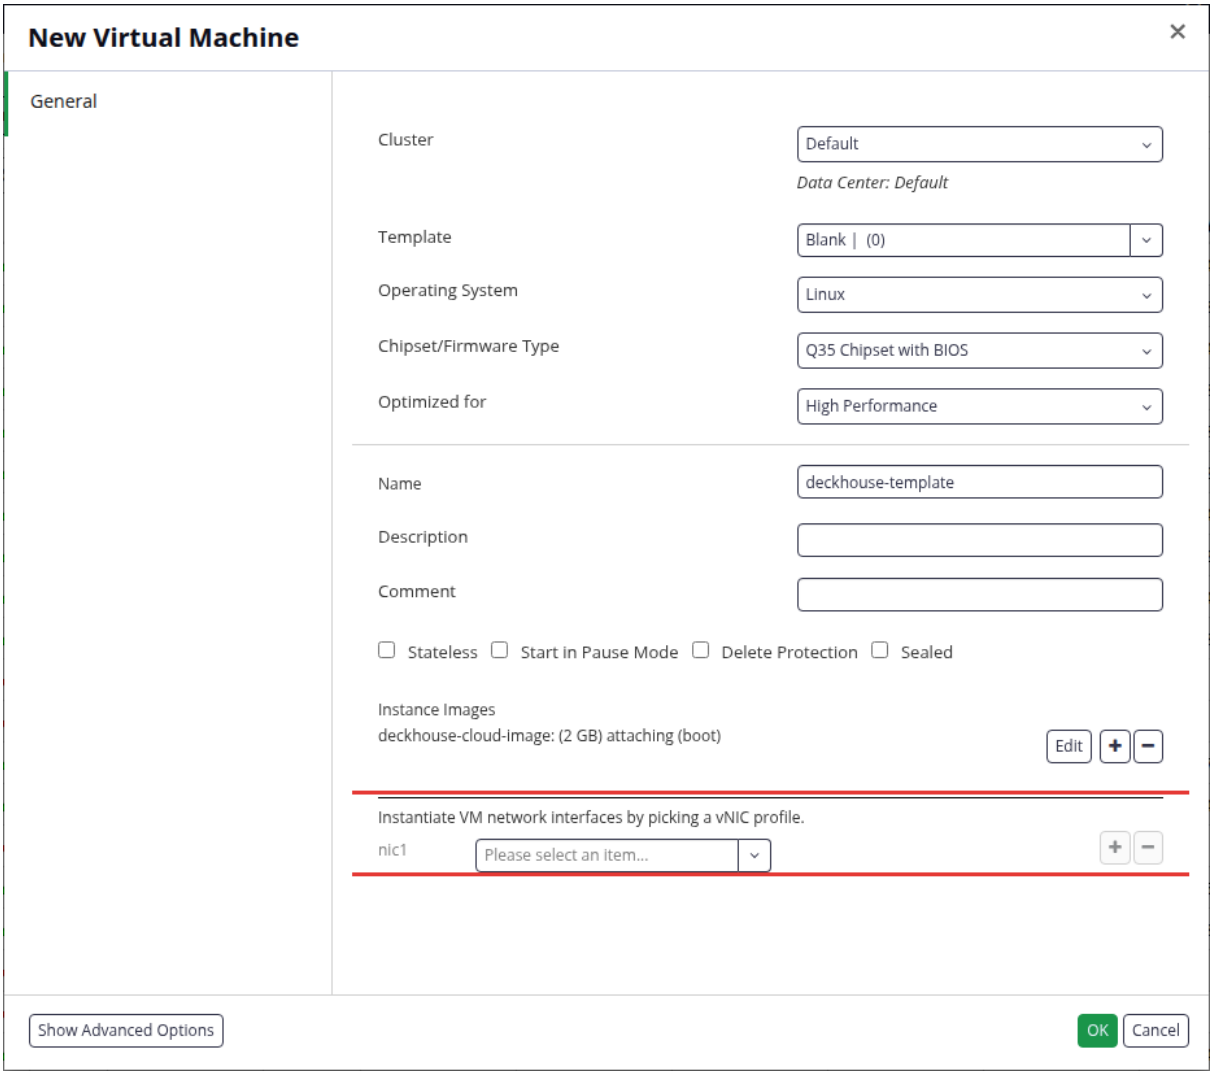
Preparing a cloud image

The cloud image of the operating system (OS) is uploaded to the zVirt disk storage. To upload the image:

1. Open the zVirt Administration Portal and go to the “Storage → Disks” section.
2. Upload the OS cloud image (for example, `.qcow2` or `.img`) to the storage.

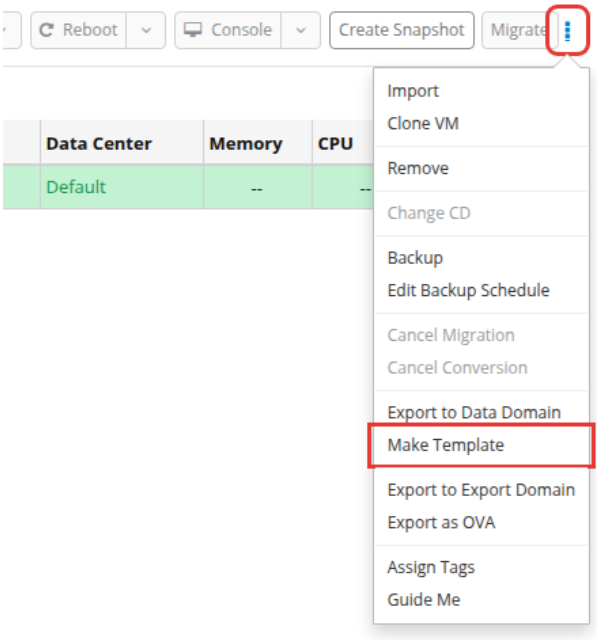


3. Wait for the upload to complete. The disk must get the `OK` status.

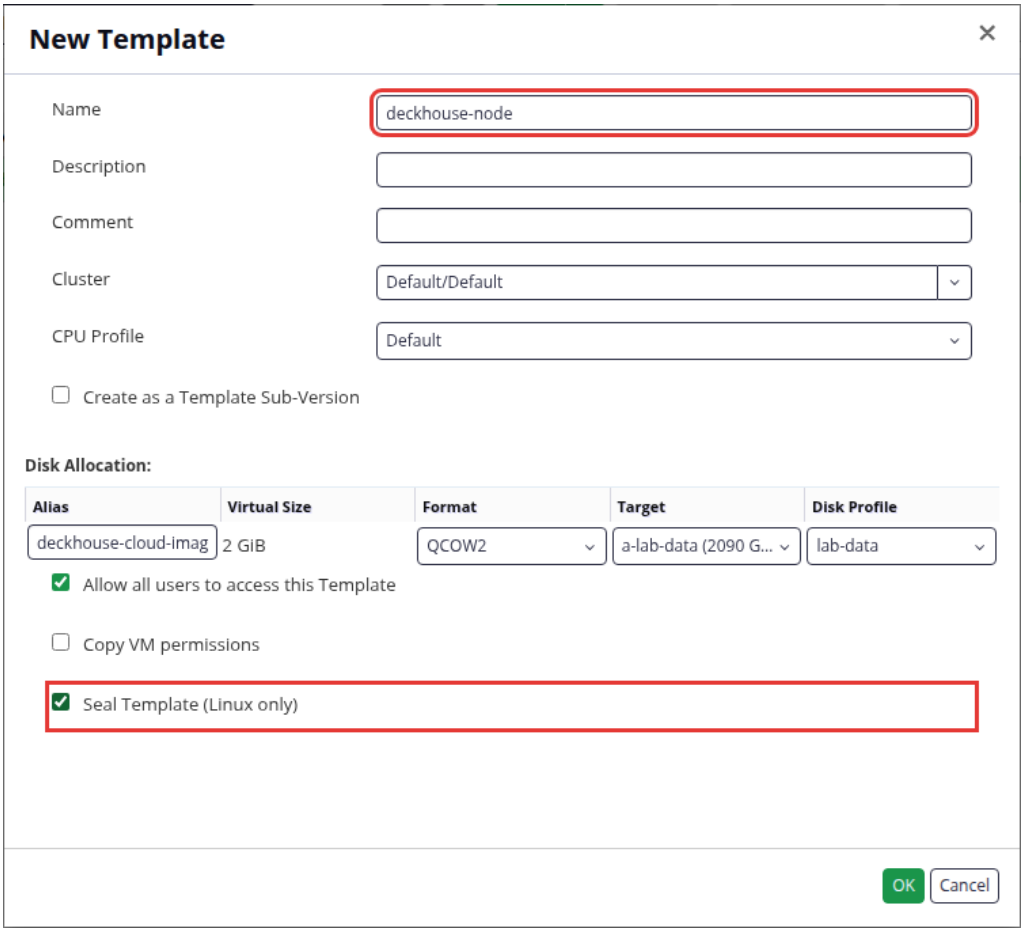


Preparing a virtual machine template

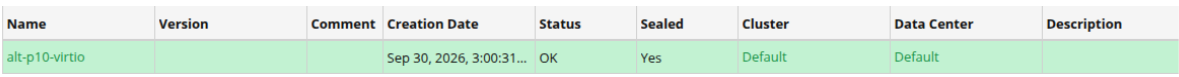
The template is created from a virtual machine (VM) with the OS cloud image attached. To prepare the template:



1. Open the “Compute → Virtual Machines” section and create a VM.
2. Set the following parameters:
   - “Template”: `Blank`.
   - “Operating System”: The OS of the uploaded cloud image.
   - “Optimized for”: “High Performance”.
   - “Instance Images”: Click “Attach”, select the uploaded cloud image, select the checkbox in the “OS” column to make the disk bootable, and select the “VirtIO” interface.



3. Do not add network interfaces. Deckhouse Platform creates a network interface when it creates a VM for a node.



4. Leave the other parameters at their defaults and create the VM.
5. After the VM is created, select it in the list, open the additional actions menu (⋮), and select “Make Template”.

6. Specify the template name and enable the “Seal Template (Linux only)” parameter.

7. Make sure the template is displayed in the “Compute → Templates” section.

Replacing the OS image

The `template` parameter of ZvirtInstanceClass defines the image for `CloudEphemeral` nodes. With a ModuleConfig-based provider configuration, this parameter also defines the image for `CloudPermanent` nodes and master nodes.

With a ZvirtClusterConfiguration-based configuration, the image for `CloudPermanent` nodes and master nodes is set by `template` in `nodeGroups[].instanceClass` and `masterNodeGroup.instanceClass`, respectively.

The replacement procedure is described in “How do I replace the OS image in a cloud cluster?”.

Credentials Secret

The zVirt user login and password are stored in a separate Secret rather than in the ModuleConfig. The `cloud-provider-zvirt` module reads it and passes the credentials to its components that access the zVirt API.

The Secret is created during cluster installation together with the other resources of the initial configuration. The Secret must meet the following requirements:

- The name is `d8-credentials` and the namespace is `d8-cloud-provider-zvirt`.
- The type is `cloud-provider.deckhouse.io/credentials`.
- The `authScheme` field is set to `userPassword`.
- The `identity` field contains the zVirt user login.
- The `secret` field contains the zVirt user password.

```
apiVersion: v1
kind: Secret
metadata:
  name: d8-credentials
  namespace: d8-cloud-provider-zvirt
type: cloud-provider.deckhouse.io/credentials
stringData:
  authScheme: userPassword
  identity: <USERNAME>
  secret: <PASSWORD>
```

Replace `<USERNAME>` and `<PASSWORD>` with the zVirt user login and password.

A Secret that does not meet these requirements fails the check both during cluster installation and when applied in a running cluster.

To change the credentials, update the `identity` and `secret` fields:

```
d8 k -n d8-cloud-provider-zvirt edit secret d8-credentials
```

In clusters migrated to ModuleConfig, the login and password are moved to this Secret from the `provider.username` and `provider.password` parameters of the ZvirtClusterConfiguration resource.

Additional resources

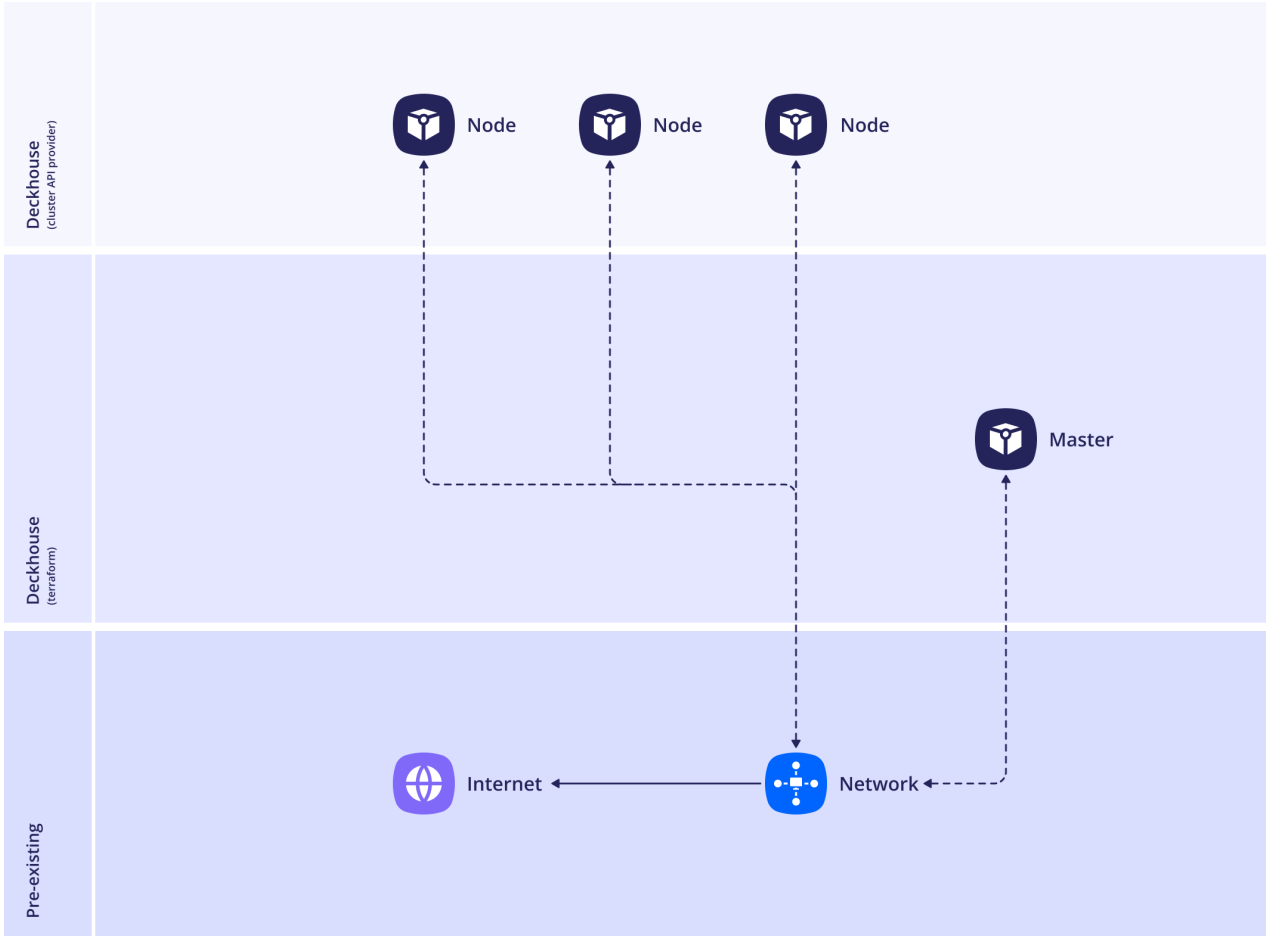
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Layouts and configuration in zVirt



Layouts

The layout defines how cluster nodes are placed in the zVirt infrastructure. Only the Standard layout is supported. The layout is set with the `layout` parameter in the ModuleConfig resource of the `cloud-provider-zvirt` module.

Standard

In the Standard layout, all cluster nodes are created in a single zVirt cluster. Key features of the layout:

- Virtual machines are created in the zVirt cluster set with the `clusterID` parameter.
- The zVirt cluster must have shared storage domains available to all its hosts and CPUs of the same type.
- Virtual machines are cloned from a template prepared from a cloud image.
- The virtual machine network interface is created from the vNIC profile set with the `vnicProfileID` parameter of the ZvirtInstanceClass resource.
- Deckhouse Platform creates and deletes the node virtual machines via the zVirt API.

Example of the layout configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-zvirt
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        server: <ZVIRT_API_URL>
        clusterID: <CLUSTER_ID>
    nodes:
      parameters:
        layout: Standard
        sshPublicKey: <SSH_PUBLIC_KEY>
```

Configuration

The zVirt cloud provider parameters are set in four resources:

- The ModuleConfig of the `cloud-provider-zvirt` module sets the layout, the zVirt API connection parameters, and the zVirt cluster to create virtual machines in.
- The `d8-credentials` Secret in the `d8-cloud-provider-zvirt` namespace stores the zVirt user login and password in the format covered in the “Credentials Secret” section.
- ZvirtInstanceClass describes the virtual machine parameters.
- NodeGroup describes the node groups and references the instance class. Master nodes are described by the `master` node group with the `CloudPermanent` type.

To change the provider settings in a running cluster, edit the ModuleConfig:

```
d8 k edit mc cloud-provider-zvirt
```

To apply the changes to the master nodes and the nodes of CloudPermanent groups, run the following command:

```
dhctl converge
```

⚠ If the cluster was installed with the ZvirtClusterConfiguration schema, it must be migrated to the ModuleConfig-based configuration. Until the migration is complete, the `D8CloudProviderZvirtMigrationPending` alert may fire and Deckhouse Platform updates may be blocked.

The migration procedure is described in “How to migrate a cloud provider to ModuleConfig-based configuration?”.

Configuration example

Below is a minimal configuration of a cluster with the Standard layout, one master node, and one group of worker nodes:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-zvirt
spec:
  version: 2
  enabled: true
  settings:
    provider:
      parameters:
        server: <ZVIRT_API_URL>
        clusterID: <CLUSTER_ID>
    nodes:
      parameters:
        layout: Standard
        sshPublicKey: <SSH_PUBLIC_KEY>
---
apiVersion: v1
kind: Secret
metadata:
  name: d8-credentials
  namespace: d8-cloud-provider-zvirt
type: cloud-provider.deckhouse.io/credentials
stringData:
  authScheme: userPassword
  identity: <USERNAME>
  secret: <PASSWORD>
---
apiVersion: deckhouse.io/v1
kind: ZvirtInstanceClass
metadata:
  name: master
spec:
  numCPUs: 4
  memory: 8192
  rootDiskSizeGb: 50
  etcdDiskSizeGb: 10
  template: <TEMPLATE_NAME>
  vnicProfileID: <VNIC_PROFILE_ID>
  storageDomainID: <STORAGE_DOMAIN_ID>
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: master
spec:
  nodeType: CloudPermanent
  cloudInstances:
    classReference:
      kind: ZvirtInstanceClass
      name: master
    minPerZone: 1
    maxPerZone: 1
---
apiVersion: deckhouse.io/v1
kind: ZvirtInstanceClass
metadata:
  name: worker
spec:
  numCPUs: 4
  memory: 8192
  template: <TEMPLATE_NAME>
```

```
  vnicProfileID: <VNIC_PROFILE_ID>
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: ZvirtInstanceClass
      name: worker
    minPerZone: 1
    maxPerZone: 3
```

Where:

- `ZVIRT API URL`: URL of the zVirt API endpoint (the `server` parameter), for example, `https://zvirt.example.com/ovirt-engine/api`.
- `CLUSTER ID`: ID of the zVirt cluster to create virtual machines in (the `clusterID` parameter).
- `SSH PUBLIC_KEY`: Public SSH key for accessing the nodes (the `sshPublicKey` parameter).
- `USERNAME` and `PASSWORD`: zVirt user login and password for the credentials Secret.
- `TEMPLATE_NAME`: Name of the virtual machine template prepared as described in the “Preparing a virtual machine template” section.
- `VNIC PROFILE ID`: ID of the vNIC profile used to create the virtual machine network interface.
- `STORAGE_DOMAIN_ID`: ID of the zVirt storage domain to create the etcd disk in.

The number of master nodes is set with the `minPerZone` parameter of the `master` node group. In the ZvirtInstanceClass resource of the `master` group, set the `etcdDiskSizeGb` and `storageDomainID` parameters, which set the size and the storage domain of a separate disk for etcd. The `etcdDiskSizeGb` parameter cannot be set in the instance classes of other CloudPermanent groups.

If the zVirt API uses a self-signed certificate, pass the CA certificate in the `caBundle` parameter or set the `insecure` parameter to `true`.

The other parameters are described in the module settings and in the ZvirtInstanceClass resource description.

> **i** The `clusterID`, `vnicProfileID`, and `storageDomainID` values can be obtained via the zVirt API or the Administration Portal. Getting the vNIC profile ID via the API is described in the “How to get the vNIC profile ID?” section.

Static network configuration of nodes

Nodes whose group has no static network configuration get their network settings over DHCP. To assign static IP addresses to the nodes of CloudPermanent groups, set the `customNetworkConfigs` parameter in the `nodes.parameters` section of the ModuleConfig resource. The parameter key sets the node group name, and the value sets the network interface configuration of the nodes in this group.

Example of the static network configuration for the `master` group of three nodes:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-zvirt
spec:
  version: 2
  settings:
    nodes:
      parameters:
        customNetworkConfigs:
          master:
            networkInterfaceName: enp1s0
            networkInterfaceAddresses:
              - 192.168.1.10
              - 192.168.1.11
              - 192.168.1.12
            networkInterfaceNetmask: 255.255.255.0
            networkInterfaceGateway: 192.168.1.1
            dnsServers:
              - 192.168.1.2
```

Addresses from the `networkInterfaceAddresses` list are assigned to the group nodes in order, one address per node, so specify an address for each node of the group. Duplicate addresses in the list are not allowed.

⚠ If you change the network settings of existing nodes in the `customNetworkConfigs` parameter, `dhctl converge` recreates the virtual machines of these nodes.

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage and load balancing in zVirt

Storage

The `cloud-provider-zvirt` module provisions zVirt disks for cluster volumes via the `csi.ovirt.org` CSI driver. Volumes are requested with standard PersistentVolumeClaim resources using the StorageClasses the module creates.

StorageClasses for storage domains

For each active zVirt storage domain, the module creates a StorageClass whose name is derived from the storage domain name. Letters in the name are converted to lowercase, spaces are replaced with hyphens, and the other characters except Latin letters, digits, hyphens, and dots are removed. Hyphens and dots at the beginning and end of the name are also removed.

The created StorageClasses have the following properties:

- The disk for a volume is created in the storage domain the StorageClass corresponds to.
- Space for the disk is allocated in full at once (thin provisioning is not used).
- A volume is created when the workload that uses it is scheduled to a node (`volumeBindingMode: WaitForFirstConsumer`).
- The volume size can be increased (`allowVolumeExpansion: true`).

If the global `defaultClusterStorageClass` parameter is not set and the cluster has no other default StorageClass, the alphabetically first StorageClass of the module becomes the default StorageClass.

To prevent the module from creating StorageClasses for some storage domains, list the names of these StorageClasses in the `excludedStorageClasses` parameter of the ModuleConfig resource. Each item of the list is a regular expression matched against the whole StorageClass name.

Example of excluding StorageClasses:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-zvirt
spec:
  version: 2
  settings:
    storage:
      parameters:
        excludedStorageClasses:
          - hostedstorage
          - backup-.*
```

In the example, the module does not create the `hostedstorage` StorageClass and the StorageClasses whose names start with `backup-`.

To disable disk provisioning in the cluster, set the `storage.disabled` parameter to `true`. In this case, the module does not deploy the CSI driver and does not create StorageClasses.

Virtual machine disks

The root disk of a virtual machine is created when the template is cloned, and then it is resized to the value of the `rootDiskSizeGb` parameter of the ZvirtInstanceClass resource.

On master nodes, a separate disk is created for etcd. Its size is set with the `etcdDiskSizeGb` parameter, and the storage domain is set with the `storageDomainID` parameter of the ZvirtInstanceClass resource of the `master` group. The storage domain must be available in the zVirt cluster set with the `clusterID` parameter.

Load balancing

The `cloud-provider-zvirt` module does not create load balancers for Service objects of the `LoadBalancer` type. To accept incoming traffic, use one of the following options:

- An external load balancer, for example, a hardware or software one, that forwards traffic to ports `80` and `443` of the cluster frontend nodes.
- The `metallb` module in L2 mode that announces load balancer IP addresses in the node network.

For L2 mode, allocate an IP address range in the network the frontend nodes are connected to via the vNIC profile from the `vnicProfileID` parameter. Addresses from this range must not be assigned by the network DHCP server. A configuration example is described in the “Example of metallb usage in L2 LoadBalancer mode” section.

> **i** Operation of the `metallb` module in BGP mode in zVirt is not guaranteed and depends on the network infrastructure.

Additional resources

Integration with zVirt services

Deckhouse Platform integrates with the zVirt infrastructure and creates virtual machines for cluster nodes based on the definitions in the ZvirtInstanceClass resource.

Key features

The integration with zVirt provides the following features:

- Creating and deleting virtual machines in zVirt when node groups (NodeGroup) are created and scaled.
- Cloning virtual machines from a prepared template based on a cloud image with `cloud-init`.
- Creating the virtual machine network interface from a vNIC profile automatically.
- Getting node network settings over DHCP or the static network configuration for the nodes of CloudPermanent groups.
- Provisioning volumes via the CSI driver and StorageClasses for zVirt storage domains.
- Removing from the cluster the nodes whose virtual machines no longer exist in zVirt.

Additional resources

- Module `cloud-provider-zvirt` custom resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Hybrid clusters

A hybrid cluster is a static Deckhouse Platform (DP) cluster extended with nodes placed in the infrastructure of a supported provider, such as Yandex Cloud, VMware Cloud Director or VMware vSphere.

In this scenario, the control plane and the initial cluster nodes remain part of the static DP cluster, while additional nodes are added through the corresponding provider module. These nodes can be created automatically through the provider API or connected manually if the virtual machines were created in advance.

This approach allows you to expand an existing static cluster without creating a separate Kubernetes cluster: increase compute capacity, place some workloads in another infrastructure, or gradually migrate services there. Applications still use a single Kubernetes control plane: the same API, shared resources, and unified mechanisms for scheduling, monitoring, updates, and operations.

Hybrid integration is performed on top of an already deployed static DP cluster (`clusterType: Static`). Then the corresponding cloud provider module is enabled, allowing DP to obtain information about the external infrastructure and create or connect additional nodes.

Depending on the provider, nodes can be added automatically through the provider API or connected manually by running a bootstrap script on pre-created virtual machines.

The general principles of hybrid integration are described on this page. The procedure for preparing the infrastructure and adding nodes depends on the provider being used and is described in separate guides:

- Yandex Cloud;
- VMware Cloud Director;
- VMware vSphere.

NodeGroup types

In a hybrid scenario, DP uses the following NodeGroup types:

- `CloudEphemeral` — nodes that DP creates and deletes automatically through the configured cloud provider API.
- `CloudStatic` — nodes that are created manually by the user or by external tools in the same cloud infrastructure for which cloud provider integration is configured. CSI runs on such nodes, and the Node object is managed by cloud-controller-manager: it is automatically enriched with zone and region information based on provider data.

Ways to add nodes

Nodes from the provider infrastructure can be connected in the following ways:

- **Automatic creation of cloud nodes**. DP creates virtual machines through the provider API. VM parameters are described by the `*InstanceClass` resource, while the required number of nodes and placement zones are defined by the NodeGroup resource with the `CloudEphemeral` type.
- **Connecting manually created cloud nodes using a bootstrap script**. A virtual machine is created in advance by the user in the provider infrastructure, after which a DP bootstrap script is run on it to connect the node to the cluster. This scenario uses a NodeGroup with the `CloudStatic` type. Such a node is managed by the corresponding provider's cloud-controller-manager.

This section describes the general network requirements for hybrid clusters. Provider-specific requirements, including network parameters, virtual machine templates, credentials, placement parameters, and ways to add nodes, are described in separate guides for Yandex Cloud, VCD, and vSphere.

General network requirements

Two-way network connectivity sufficient for DP and Kubernetes components must be configured between the nodes of the initial static cluster and the connected nodes placed in the provider infrastructure.

Connectivity must provide:

- access from connected nodes to the Kubernetes API of the initial cluster;
- access from connected nodes to DNS servers;
- access from connected nodes to the container image registry and other external services required to download images and packages;
- access from the control plane and system components to the connected nodes for kubelet, networking components, monitoring, and Kubernetes service operations;
- access from DP components that interact with the provider infrastructure to the corresponding provider API.

The full list of required connections is provided in the Network interaction section, and access restriction recommendations are provided in the Configuring network policies section.

Additionally, it is recommended to check:

- routing between the networks of the initial static cluster and the connected nodes in both directions;
- consistent MTU values across the entire network path, especially when tunnels are used;
- traffic encapsulation parameters when using Cilium, including `tunnelMode`, if traffic filtering is applied between sites.

Specific requirements for networks, subnets, virtual machine templates, credentials, and additional parameters depend on the infrastructure provider being used and are described in the "Prerequisites" section for the corresponding provider.

Additional resources

- Global custom resources
- Module `cni-cilium` parameters
- Module `node-manager` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>

Hybrid cluster with Yandex Cloud

The following describes the process of adding nodes from Yandex Cloud to an existing static Deckhouse Platform cluster.

Integration with Yandex Cloud uses the `cloud-provider-yandex` module. It provides interaction between DP and the Yandex Cloud API, retrieval of information about cloud infrastructure, creation of virtual machines, work with network parameters, and connection of nodes to an existing cluster.

This section describes two ways to add nodes:

- **Automatic node creation in Yandex Cloud**. DP creates virtual machines through the Yandex Cloud API. VM parameters are defined by the YandexInstanceClass resource, and the required number of nodes and placement zones are defined by the NodeGroup resource with the `CloudEphemeral` type.
- **Connecting manually created nodes through a bootstrap script**. A virtual machine is created by the user in advance and connected to the cluster using the DP bootstrap script. This scenario uses NodeGroup with the `CloudStatic` type.

Prerequisites

Before you begin, make sure that the following conditions are met:

- The cluster was created with the `clusterType: Static` parameter, and its nodes meet the minimum system requirements.
- "Network connectivity" is configured between the network of static nodes and the Yandex Cloud VPC. Yandex Cloud nodes added to the cluster have access to the Kubernetes API, DNS, and the required addresses according to the

"Network interaction" and "Network policy configuration" sections. When using Cilium with pod traffic tunneling, the `tunnelMode` mode is selected according to the network connectivity between sites.
- The requirements from the "Connection and authorization in Yandex Cloud" section are met:
  - A service account is prepared.
  - A folder where resources will be created is selected.
  - The required roles and access to the VPC being used are configured.

Adding automatically created nodes

To run the preparation commands, you need the Yandex Cloud CLI (`yc`). You can use it on the administrator's workstation. The `yc` CLI is not required on the cluster master node: only the prepared manifests need to be applied in the cluster.

1. Get the identifiers of the cloud and folder where nodes will be created:

   ```
   yc resource-manager cloud list
   yc resource-manager folder list
   ```

2. Specify the obtained identifiers in variables:

   ```
   export CLOUD_ID="<CLOUD_ID>"
   export FOLDER_ID="<FOLDER_ID>"
   ```

   Where:

   - `CLOUD ID` — Yandex Cloud cloud ID;
   - `FOLDER_ID` — ID of the folder where resources will be created.

3. Get the identifiers of the network, subnet, and zone where nodes will be created:

   ```
   yc vpc network list --folder-id "$FOLDER_ID"
   yc vpc subnet list --folder-id "$FOLDER_ID"
   yc compute zone list
   ```

4. Specify the obtained values in variables:

   ```
   export NETWORK_ID="<NETWORK_ID>"
   export SUBNET_ID="<SUBNET_ID>"
   export ZONE="<ZONE>"
   export ROUTE_TABLE_ID="<ROUTE_TABLE_ID>"
   ```

   Where:

   - `NETWORK ID` — VPC network ID;
   - `SUBNET_ID` — ID of the subnet where nodes will be created;
   - `ZONE` — availability zone that corresponds to the selected subnet, for example `ru-central1-a`;
   - `ROUTE TABLE ID` — ID of the route table attached to the subnet. It is shown in the `ROUTE TABLE ID` column of the `yc vpc subnet list` output.

   For details, see "Connecting and authorizing in Yandex Cloud".

5. Create a service account in the required Yandex Cloud folder and assign permissions to it:

   ```
   yc iam service-account create \
     --name dkp-hybrid \
     --folder-id "$FOLDER_ID"

   export SA_ID="$(yc iam service-account get \
     --name dkp-hybrid \
     --folder-id "$FOLDER_ID" \
     --format json | jq -r .id)"

   yc resource-manager folder add-access-binding "$FOLDER_ID" \
     --role editor \
     --subject "serviceAccount:${SA_ID}"

   yc resource-manager folder add-access-binding "$FOLDER_ID" \
     --role vpc.admin \
     --subject "serviceAccount:${SA_ID}"
   ```

   The `editor` role is required to create and manage cloud resources, and the `vpc.admin` role grants access to VPC network resources.

6. Create a service account key and save it to a JSON file:

   ```
   yc iam key create \
     --service-account-id "$SA_ID" \
     --output dkp-hybrid-sa-key.json
   ```

Save the service account JSON key to the `SERVICE_ACCOUNT_JSON` environment variable in single-line format:

```
export SERVICE_ACCOUNT_JSON="$(jq -c . dkp-hybrid-sa-key.json)"
```

7. Save the administrator's public SSH key to the `SSH_PUBLIC_KEY` environment variable:

   ```
   export SSH_PUBLIC_KEY="$(cat ~/.ssh/id_rsa.pub)"
   ```

   If you use another key, specify its path instead of `~/.ssh/id_rsa.pub`.

   ⚠ The `SSH_PUBLIC_KEY` variable must contain the administrator's public SSH key that will be used to access the nodes being created. Do not use the public key from the service account JSON file.

8. Get the ID of the operating system image that will be used to create virtual machines and save it to the `IMAGE_ID` environment variable:

   ```
   export IMAGE_ID="$(yc compute image get-latest-from-family ubuntu-2404-lts \
     --folder-id standard-images \
     --format json | jq -r .id)"
   ```

   ⚠ The `IMAGE_ID` variable must contain the OS image ID in Yandex Cloud. Do not use an existing virtual machine ID or a service account key ID.

9. Specify the CIDR of the network where Yandex Cloud nodes will be placed:

   ```
   export NODE_NETWORK_CIDR="<NODE_NETWORK_CIDR>"
   ```

   `NODE_NETWORK_CIDR` is the CIDR that includes the internal IP addresses of Yandex Cloud nodes. For a single zone, it usually matches the CIDR of the selected subnet. For example, if nodes are created in the `10.128.0.0/24` subnet, specify `10.128.0.0/24`. You can get the subnet CIDR with the following command:

   ```
   yc vpc subnet list --folder-id "$FOLDER_ID"
   ```

10. Create the ModuleConfig manifest for the `cloud-provider-yandex` module. For example, `yandex-module-config.yaml`:

    ```
    cat > yandex-module-config.yaml <<EOF
    apiVersion: deckhouse.io/v1alpha1
    kind: ModuleConfig
    metadata:
      name: cloud-provider-yandex
    spec:
      version: 2
      enabled: true
      settings:
        provider:
          parameters:
            cloudID: ${CLOUD_ID}
            folderID: ${FOLDER_ID}
        nodes:
          parameters:
            layout: WithoutNAT
            nodeNetworkCIDR: ${NODE_NETWORK_CIDR}
            sshPublicKey: '${SSH_PUBLIC_KEY}'
            existingNetworkID: ${NETWORK_ID}
            existingRouteTableID: ${ROUTE_TABLE_ID}
            existingZoneToSubnetIDMap:
              ${ZONE}: ${SUBNET_ID}
            zones:
              - ${ZONE}
    EOF
    ```

    The manifest automatically uses the values of the environment variables set in the previous steps: `CLOUD_ID`, `FOLDER_ID`, `NODE_NETWORK_CIDR`, `SSH_PUBLIC_KEY`, `NETWORK_ID`, `ZONE`, and `SUBNET_ID`.

    The `existingNetworkID`, `existingZoneToSubnetIDMap`, and `existingRouteTableID` parameters describe the Yandex Cloud resources that already exist, because in a hybrid cluster DP does not create the network, the subnets, or the route table. The route table is required because the cloud controller manager creates the pod subnet routes in it and does not start with an empty value.

    The layout is set by the `layout` parameter. The available layouts are described in "Configuration and layouts".

11. Copy the `yandex-module-config.yaml` file to the cluster master node. Apply the manifest:

    ```
    d8 k apply -f yandex-module-config.yaml
    ```

    While DP is enabling the module, the validating webhooks of DP and the provider may be unavailable, and the command fails with `failed calling webhook`. This state is temporary, repeat the command in half a minute. The same applies to the next step with the Secret.

12. Wait until the module creates the `d8-cloud-provider-yandex` namespace:

    ```
    d8 k get namespace d8-cloud-provider-yandex
    ```

13. Create the Secret with the service account key:

    ```
    d8 k create -f - <<EOF
    apiVersion: v1
    kind: Secret
    metadata:
      name: d8-credentials
      namespace: d8-cloud-provider-yandex
    type: cloud-provider.deckhouse.io/credentials
    stringData:
      authScheme: serviceAccount
      secret: '${SERVICE_ACCOUNT_JSON}'
    EOF
    ```

    The Secret format is described in “Credentials Secret”.

14. Wait until the `cloud-provider-yandex` module is enabled and the YandexInstanceClass resource appears:

    ```
    d8 k get module cloud-provider-yandex -o wide
    d8 k get crd yandexinstanceclasses.deckhouse.io
    ```

15. Create a file with YandexInstanceClass and NodeGroup manifests. For example, `yandex-instanceclass-nodegroup.yaml`:

    ```
    apiVersion: deckhouse.io/v1
    kind: YandexInstanceClass
    metadata:
      name: yc-worker
    spec:
      cores: 4
      memory: 8192
      diskSizeGB: 50
      diskType: network-ssd
      mainSubnet: <SUBNET_ID>
    ---
    apiVersion: deckhouse.io/v1
    kind: NodeGroup
    metadata:
      name: yc-worker
    spec:
      nodeType: CloudEphemeral
      cloudInstances:
        classReference:
          kind: YandexInstanceClass
          name: yc-worker
        minPerZone: 1
        maxPerZone: 1
        zones:
          - ru-central1-a
    ```

    Where:

    - YandexInstanceClass describes the parameters of the virtual machine that will be created in Yandex Cloud;
    - `mainSubnet` — ID of the subnet from which the created nodes must have access to the static cluster nodes;
    - NodeGroup describes the node group that DP must maintain in the cluster;
    - `nodeType: CloudEphemeral` means that nodes will be created automatically through the cloud provider;
    - `cloudInstances.zones` must contain zones from the `zones` list in the module settings.

    In the `WithoutNAT` layout, the created nodes get a public IP address. To keep the nodes of the group on internal addresses only, set the `assignPublicIPAddress: false` parameter in the YandexInstanceClass and provide the nodes with another way out to the internet, for example through a subnet NAT gateway.

16. Apply the manifest:

```
d8 k apply -f yandex-instanceclass-nodegroup.yaml
```

After the manifest is applied, DP will start creating a virtual machine in Yandex Cloud through machine-controller-manager.

17. Check that the node appears in the cluster:

    ```
    d8 k get nodes -o wide
    ```

    Example expected output:

    ```
    NAME                                STATUS   ROLES                  AGE   VERSION    INTERNAL-
    IP
    static-master-0                     Ready    control-plane,master   1h    v1.33.10
    10.128.0.15
    yc-worker-f3564dca-7fc59-s2w5d      Ready    yc-worker              10m   v1.33.10
    10.128.0.21
    ```

18. To diagnose the state and troubleshoot possible issues, check the machine-controller-manager logs:

    ```
    d8 k -n d8-cloud-instance-manager get machinedeployments.machine.sapcloud.io -o wide
    d8 k -n d8-cloud-instance-manager get machinesets.machine.sapcloud.io -o wide
    d8 k -n d8-cloud-instance-manager get machines.machine.sapcloud.io -o wide
    d8 k -n d8-cloud-instance-manager logs deploy/machine-controller-manager --tail=200
    ```

Adding manually created nodes through a bootstrap script

Before you begin, make sure that the following conditions are met:

- The `cloud-provider-yandex` module is enabled:

  ```
  d8 k get module cloud-provider-yandex -o wide
  ```

- The `cloud-provider-yandex` module components are in the `Running` state:

  ```
  d8 k -n d8-cloud-provider-yandex get pods -o wide
  ```

- A virtual machine that will be connected to the cluster has been created in Yandex Cloud.
- The virtual machine is connected to the Yandex Cloud network and subnet used for hybrid integration with the cluster.
- The virtual machine has a network interface in the Yandex Cloud VPC network and subnet used for hybrid integration with the cluster. The IP address of this interface must belong to the CIDR specified in `nodeNetworkCIDR` and be reachable from the static cluster nodes.
- The virtual machine name in Yandex Cloud matches the hostname inside the operating system.
- One of the package managers (`apt`/`apt-get`, `yum`, or `rpm`) for a supported OS is installed on the virtual machine.

1. Check the virtual machine metadata in Yandex Cloud.

   The VM metadata must have `cloud-init` configured with the user that will be used for SSH connection.

   Example metadata:

   ```
   #cloud-config
   datasource:
     Ec2:
       strict_id: false
   ssh_pwauth: no
   users:
     - name: <USER>
       sudo: ALL=(ALL) NOPASSWD:ALL
       shell: /bin/bash
       ssh_authorized_keys:
         - <SSH_PUBLIC_KEY>
   ```

   Where:

   - `<USER>`: Username for SSH access to the virtual machine.
   - `<SSH_PUBLIC_KEY>`: Administrator’s public SSH key.

2. On the master node, create a file with the NodeGroup manifest and specify the node group name. In this example and the following steps, the `yc-manual` name is used. For example, `yandex-manual-nodegroup.yaml`:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: yc-manual
spec:
  nodeType: CloudStatic
EOF
```

3. Make sure that the NodeGroup has been created and synchronized:

   ```
   d8 k get nodegroup yc-manual
   d8 k describe nodegroup yc-manual
   ```

   Example expected output:

   ```
   NAME        TYPE          READY   NODES   UPTODATE   INSTANCES   DESIRED   MIN   MAX   STANDBY
   STATUS   AGE   SYNCED
   yc-manual   CloudStatic   0       0       0
   1m    True
   ```

4. On the master node, get the bootstrap script for the created NodeGroup:

   ```
   NODE_GROUP=yc-manual

   d8 k -n d8-cloud-instance-manager get secret manual-bootstrap-for-${NODE_GROUP} \
     -o jsonpath='{.data.bootstrap\.sh}' > ${NODE_GROUP}-bootstrap.b64
   ```

5. Copy the bootstrap script to the VM being connected. If SSH access to the VM is available from the master node, run the following on the master node:

   ```
   scp ${NODE_GROUP}-bootstrap.b64 <USER>@<NODE_PUBLIC_OR_INTERNAL_IP>:/tmp/bootstrap.b64
   ```

   > **i** To copy and run the bootstrap script, use the user specified in the VM metadata.

   If SSH access to the VM is available only from the administrator’s workstation, first copy the file from the master node to the workstation, and then from the workstation to the VM:

   ```
   scp <MASTER_USER>@<MASTER_IP>:/root/${NODE_GROUP}-bootstrap.b64 ./bootstrap.b64
   scp ./bootstrap.b64 <USER>@<NODE_PUBLIC_OR_INTERNAL_IP>:/tmp/bootstrap.b64
   ```

   Where:

   - `<MASTER_USER>`: User for SSH access to the master node.
   - `<MASTER_IP>`: IP address of the master node.
   - `<USER>`: User on the VM being connected.
   - `<NODE_PUBLIC_OR_INTERNAL_IP>`: Public or internal IP address of the VM being connected.

6. On the VM being connected, decode the bootstrap script, set permissions, and run it:

   ```
   base64 -d /tmp/bootstrap.b64 > /tmp/bootstrap.sh
   chmod +x /tmp/bootstrap.sh

   sudo bash /tmp/bootstrap.sh
   ```

   After the bootstrap script is started, it will install the required components, configure the container runtime and kubelet, and connect the node to the cluster.

7. On the master node, check that the new node has appeared:

   ```
   d8 k get nodes -o wide
   ```

   Example expected output:

   ```
   NAME                    STATUS   ROLES       AGE   VERSION    INTERNAL-IP   EXTERNAL-IP
   static-master-0         Ready    master      1h    v1.33.10   10.128.0.15   <none>
   yandex-worker-hybrid    Ready    yc-manual   5m    v1.33.10   10.128.0.17   <PUBLIC_IP>
   ```

8. If connection fails, check the NodeGroup status, events, and component logs:

```
d8 k get nodegroup yc-manual
d8 k describe nodegroup yc-manual
d8 k describe node yandex-worker-hybrid
d8 k -n d8-cloud-instance-manager logs deploy/machine-controller-manager --tail=200
```

Hybrid cluster with VCD

The following describes the process of adding nodes from VMware Cloud Director (VCD) to an existing static Deckhouse Platform (DP) cluster.

Integration with VCD uses the `cloud-provider-vcd` module. It provides interaction between DP and VMware Cloud Director, creation and deletion of virtual machines, retrieval of information about the VCD infrastructure, and integration with StorageClass and other provider capabilities.

This section describes two ways to add nodes:

- **Automatic node creation in VCD**. DP creates virtual machines through the VCD API. VM parameters are defined by the VCDInstanceClass resource, and the required number of nodes is defined by the NodeGroup resource with the `CloudEphemeral` type.
- **Connecting manually created nodes through a bootstrap script**. A virtual machine is created by the user in advance and connected to the cluster using the DP bootstrap script. This scenario uses the NodeGroup resource with the `CloudStatic` type.

Prerequisites for VCD

Before you begin, make sure that the following conditions are met:

- The cluster was created with the `clusterType: Static` parameter.
- Network connectivity is configured between the network of static nodes and the network of virtual machines in VCD. VCD nodes added to the cluster have access to the Kubernetes API, DNS, and the required addresses according to the Network interaction and Network policy configuration sections. When using Cilium with pod traffic tunneling, the `tunnelMode` mode is selected according to the network connectivity between sites.
- The requirements from the Connection and authorization in VMware vCloud Director section are met:
  - A tenant with allocated resources is configured in VCD.
  - A VCD account with a static password and administrator permissions is prepared.
  - A working network with an enabled DHCP server is configured in VCD.
  - The required VCD resources are prepared: VDC, vApp, templates, policies, and other parameters.

Adding automatically created nodes

1. Create a file with a ModuleConfig resource. For example, `cloud-provider-vcd-mc.yaml`:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: cloud-provider-vcd
   spec:
     version: 1
     enabled: true
     settings:
       mainNetwork: <NETWORK_NAME>
       organization: <ORGANIZATION>
       virtualDataCenter: <VDC_NAME>
       virtualApplicationName: <VAPP_NAME>
       sshPublicKey: <SSH_PUBLIC_KEY>
       provider:
         server: <API_URL>
         username: <USER_NAME>
         password: <PASSWORD>
         insecure: false
   ```

   Where:

   - `mainNetwork`: Name of the network where cloud nodes will be placed in VCD.
   - `organization`: Organization name in VCD.
   - `virtualDataCenter`: Virtual Data Center name in VCD.

- `virtualApplicationName`: Name of the vApp where nodes will be created, for example `dkp-vcd-app`.
- `sshPublicKey`: Public SSH key for accessing the nodes.
- `provider.server`: VCD API URL.
- `provider.username`: VCD username.
- `provider.password`: VCD user password.
- `provider.insecure`: Set to `true` if VCD uses a self-signed TLS certificate.

If a token is used for authentication, specify `apiToken` instead of `username` and `password`:

```
provider:
  server: <API_URL>
  apiToken: <API_TOKEN>
  insecure: false
```

2. Apply the ModuleConfig:

```
d8 k apply -f cloud-provider-vcd-mc.yaml
d8 k get mc cloud-provider-vcd
```

3. Make sure that all pods in the `d8-cloud-provider-vcd` namespace are in the `Running` state:

```
d8 k get pods -n d8-cloud-provider-vcd
```

4. Make sure that StorageClasses for VCD have been created in the cluster:

```
d8 k get sc
```

5. Create a file with the VCDInstanceClass and NodeGroup resources. For example, `vcd-instanceclass-nodegroup.yaml`:

```
---
apiVersion: deckhouse.io/v1
kind: VCDInstanceClass
metadata:
  name: worker
spec:
  rootDiskSizeGb: 50
  sizingPolicy: <SIZING_POLICY>
  storageProfile: <STORAGE_PROFILE>
  template: <VAPP_TEMPLATE>
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: VCDInstanceClass
      name: worker
    maxPerZone: 2
    minPerZone: 1
  nodeTemplate:
    labels:
      node-role/worker: ""
```

6. Apply the manifest:

```
d8 k apply -f vcd-instanceclass-nodegroup.yaml
```

After the manifest is applied, DP will start creating virtual machines in VCD managed by the `node-manager` module.

7. Make sure that the required number of nodes has appeared in the cluster:

```
d8 k get nodes -o wide
```

8. If VM creation fails, check the Machine and MachineSet objects and the machine-controller-manager logs:

```
d8 k -n d8-cloud-instance-manager get machinesets,machines -o wide
d8 k -n d8-cloud-instance-manager logs deploy/machine-controller-manager --tail=200
```

Adding manually created nodes through a bootstrap script

Before you begin, make sure that the following conditions are met:

- The `cloud-provider-vcd` module is enabled:

```
d8 k get module cloud-provider-vcd -o wide
```

- The `cloud-provider-vcd` module components are in the `Running` state:

```
d8 k -n d8-cloud-provider-vcd get pods -o wide
```

- StorageClasses for VCD have been created in the cluster:

```
d8 k get sc
```

- A virtual machine that will be connected to the cluster has been created in VCD.
- The virtual machine name in VCD matches the hostname inside the operating system.
- The following value is set in the VM advanced parameters in VCD:

```
disk.EnableUUID = TRUE
```

- The virtual machine is connected to the VCD network used as the main network for the cluster's cloud nodes. Usually, this is the network specified in the `mainNetwork` parameter of the `cloud-provider-vcd` configuration or in the VCDInstanceClass being used.
- One of the package managers (`apt`/`apt-get`, `yum`, or `rpm`) for a supported OS is installed on the virtual machine.

1. Create a file with a NodeGroup resource and the CloudStatic node type. For example, `cloud-static-nodegroup.yaml`:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: cloud-static
spec:
  nodeType: CloudStatic
```

2. Make sure that the NodeGroup has been created and synchronized:

```
d8 k get nodegroup cloud-static
```

   Example expected output:

```
NAME           TYPE          READY   NODES   UPTODATE   INSTANCES   DESIRED   MIN   MAX
STANDBY   STATUS   AGE   SYNCED
cloud-static   CloudStatic   0       0       0
1m    True
```

3. Get the bootstrap script for the created NodeGroup:

```
NODE_GROUP=cloud-static

d8 k -n d8-cloud-instance-manager get secret manual-bootstrap-for-${NODE_GROUP} \
  -o jsonpath='{.data.bootstrap\.sh}' > bootstrap.b64
```

4. Copy the bootstrap script to the virtual machine being connected:

```
scp bootstrap.b64 <USER>@<NODE_IP>:/tmp/bootstrap.b64
```

5. Connect to the virtual machine over SSH:

```
ssh <USER>@<NODE_IP>
```

6. On the virtual machine, set permissions and run the bootstrap script:

```
base64 -d /tmp/bootstrap.b64 > /tmp/bootstrap.sh
chmod +x /tmp/bootstrap.sh

sudo bash /tmp/bootstrap.sh
```

   After the bootstrap script is started, it will install the required components, configure the container runtime and kubelet, and connect the node to the cluster.

7. On the master node, check that the new node has appeared:

```
d8 k get nodes -o wide
```

Example expected output:

```
NAME                      STATUS   ROLES          AGE   VERSION    INTERNAL-IP
static-master-0           Ready    master         1h    v1.33.10   192.168.240.138
cloud-static-worker-0     Ready    cloud-static   5m    v1.33.10   192.168.240.151
```

Hybrid cluster with vSphere

The following describes the process of adding nodes from vSphere to an existing static Deckhouse Platform (DP) cluster.

Integration with vSphere uses the `cloud-provider-vsphere` module. It provides interaction between DP and vCenter, retrieval of information about virtual machines, work with placement parameters, and integration with vSphere infrastructure capabilities.

This section describes two ways to add nodes:

- **Automatic node creation in vSphere**. DP creates virtual machines through the vSphere API. VM parameters are defined by the VsphereInstanceClass resource, and the required number of nodes and placement zones are defined by the NodeGroup resource with the `CloudEphemeral` type.
- **Connecting manually created nodes through a bootstrap script**. A virtual machine is created by the user in advance and connected to the cluster using the DP bootstrap script. This scenario uses the NodeGroup resource with the `CloudStatic` type.

Prerequisites for vSphere

Before you begin, make sure that the following conditions are met:

- The cluster was created with the `clusterType: Static` parameter.
- Network connectivity is configured between the network of static nodes and the network of virtual machines in vSphere.
- vSphere nodes added to the cluster have access to the Kubernetes API, DNS, and the required addresses according to the Network interaction and Network policy configuration sections.
- The requirements from the Connection and authorization in VMware vSphere section are met:
  - Access to vCenter is configured.
  - The vSphere account with the required privileges is prepared.
  - A virtual machine template is prepared.
  - Networks, Datastore, region tags, and zone tags are configured.
- When using Cilium with pod traffic tunneling, the `tunnelMode` mode is selected according to the network connectivity between sites.

Adding automatically created nodes

To connect an already running static cluster to vCenter, use the ModuleConfig resource of the `cloud-provider-vsphere` module.

In the `spec.settings` parameter, specify access parameters for vCenter, network settings, region and zone tags, and SSH keys that will be added to the created virtual machines.

An example configuration and description of the available parameters are provided in the module examples and in the section describing the module settings.

1. Create a file with ModuleConfig for the `cloud-provider-vsphere` module. For example, `vsphere-mc.yaml`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cloud-provider-vsphere
spec:
  version: 2
  enabled: true
  settings:
    host: "<VCENTER_FQDN>"
    username: "<USERNAME@DOMAIN.LOCAL>"
    password: "<PASSWORD>"
    insecure: true
    vmFolderPath: "<FOLDER_PATH_UNDER_DATACENTER>"
    regionTagCategory: "<TAG_CATEGORY_FOR_REGION>"
    zoneTagCategory: "<TAG_CATEGORY_FOR_ZONE>"
    region: "<REGION_TAG_NAME_ON_DATACENTER>"
    zones:
      - "<ZONE_TAG_NAME_ON_CLUSTER>"
    internalNetworkNames:
      - "<PORT_GROUP_NAME_FOR_INTERNAL_IP>"
    sshKeys:
      - "<SSH_PUBLIC_KEY_ONE_LINE>"
```

Parameter values:

- `host`: vCenter address.
- `username`, `password`: vSphere user credentials.
- `insecure`: Disables verification of the vCenter TLS certificate.
- `vmFolderPath`: Folder where virtual machines will be created.
- `regionTagCategory`, `zoneTagCategory`: Region and zone tag categories.
- `region`: Region tag.
- `zones`: List of zones where nodes can be created.
- `internalNetworkNames`: List of vSphere networks for connecting created nodes.
- `sshKeys`: Public SSH keys that will be added to the created virtual machines.

2. Apply the module configuration:

```
d8 k apply -f vsphere-mc.yaml
```

3. Wait for the `cloud-provider-vsphere` module to become ready:

```
d8 k get module cloud-provider-vsphere -o wide
```

4. Create a file with the VsphereInstanceClass and NodeGroup resources with the `nodeType: CloudEphemeral` value. For example, `vsphere-instance.yaml`:

```
apiVersion: deckhouse.io/v1
kind: VsphereInstanceClass
metadata:
  name: ephemeral
spec:
  numCPUs: 2
  memory: 4096
  rootDiskSize: 40
  template: "<PATH_TO_TEMPLATE_FROM_DATACENTER>"
  mainNetwork: "<PORT_GROUP_NAME>"
  datastore: "<DATASTORE_OR_FOLDER/DATASTORE>"
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: ephemeral
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: VsphereInstanceClass
      name: ephemeral
    maxPerZone: 1
    minPerZone: 1
    zones:
      - "<ZONE_TAG_NAME_ON_CLUSTER>"
  disruptions:
    approvalMode: Automatic
```

Where:

- VsphereInstanceClass describes the parameters of the virtual machine that will be created in vSphere.
- NodeGroup describes the node group that DP must maintain in the cluster.
- `nodeType: CloudEphemeral` means that nodes will be created automatically through the cloud provider.
- `cloudInstances.classReference` points to VsphereInstanceClass.
- `cloudInstances.zones` must contain zones from the `zones` list in ModuleConfig.

5. Apply the manifest:

   ```
   d8 k apply -f vsphere-instance.yaml
   ```

   After the manifest is applied, DP will start creating a virtual machine in vSphere. After the VM boots, kubelet will connect to the Kubernetes API, and the new node will appear in the cluster.

6. Check the node status:

   ```
   d8 k get nodes -o wide
   ```

   Example expected output:

   ```
   NAME                              STATUS   ROLES                  AGE   VERSION
   static-master-0                   Ready    control-plane,master   1h    v1.33.10
   ephemeral-1ca02a5b-7588b-k89dc    Ready    ephemeral              10m   v1.33.10
   ```

7. If VM creation fails, check the Machine and MachineSet objects and the machine-controller-manager logs:

   ```
   d8 k -n d8-cloud-instance-manager get machinesets,machines -o wide
   d8 k -n d8-cloud-instance-manager logs deploy/machine-controller-manager --tail=200
   ```

   Also check the cluster events:

   ```
   d8 k get events -A --sort-by=.lastTimestamp | tail -n 100
   ```

Adding manually created nodes through a bootstrap script

Before you begin, make sure that the following conditions are met:

- The `cloud-provider-vsphere` module is enabled:

  ```
  d8 k get module cloud-provider-vsphere -o wide
  ```

- The `cloud-provider-vsphere` module components are in the `Running` state:

```
d8 k -n d8-cloud-provider-vsphere get pods -o wide
```

- StorageClasses for vSphere have been created in the cluster:

```
d8 k get sc
```

- A virtual machine that will be connected to the cluster has been created in vSphere.
- The virtual machine name in vSphere matches the hostname inside the operating system.
- The following parameters are set in the VM advanced parameters in vSphere:

```
disk.EnableUUID = TRUE
guestinfo.metadata = <BASE64_ENCODED_METADATA>
guestinfo.metadata.encoding = base64
```

The `guestinfo.metadata` parameter must contain the metadata configuration encoded in Base64. Example `metadata.json` file:

```
{
   "instance-id": "cloud-static-worker-0",
   "local-hostname": "cloud-static-worker-0",
   "public-keys-data": "<SSH_PUBLIC_KEY>",
   "network": {
     "version": 2,
     "ethernets": {
       "id0": {
         "match": {
           "driver": "vmxnet3"
         },
         "set-name": "ens192",
         "dhcp4": true
       }
     }
   }
 }
```

Where:

- `instance-id`: Virtual machine identifier.
- `local-hostname`: Node hostname inside the operating system.
- `public-keys-data`: Public SSH key for accessing the virtual machine.
- `network`: Network settings that will be applied inside the virtual machine.

To get the value for the `guestinfo.metadata` parameter, run:

```
METADATA_B64="$(base64 -w0 metadata.json)"
echo "$METADATA_B64"
```

- The virtual machine is connected to the network specified in the `internalNetworkNames` parameter of the `cloud-provider-vsphere` module configuration.
- One of the package managers (`apt`/`apt-get`, `yum`, or `rpm`) for a supported OS is installed on the virtual machine.

1. Create a file with a NodeGroup resource and the CloudStatic node type. For example, `cloud-static-nodegroup.yaml`:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: cloud-static
spec:
  nodeType: CloudStatic
```

2. Make sure that the NodeGroup has been created and synchronized:

```
d8 k get nodegroup cloud-static
```

Example expected output:

```
NAME           TYPE          READY   NODES   UPTODATE   INSTANCES   DESIRED   MIN   MAX
STANDBY   STATUS   AGE   SYNCED
cloud-static   CloudStatic   0       0       0
1m    True
```

3. Get the bootstrap script for the created NodeGroup:

```
NODE_GROUP=cloud-static

d8 k -n d8-cloud-instance-manager get secret manual-bootstrap-for-${NODE_GROUP} \
  -o jsonpath='{.data.bootstrap\.sh}' > bootstrap.b64
```

4. Copy the bootstrap script to the virtual machine being connected:

```
scp bootstrap.b64 <USER>@<NODE_IP>:/tmp/bootstrap.b64
```

5. Connect to the virtual machine over SSH:

```
ssh <USER>@<NODE_IP>
```

6. On the virtual machine, set permissions and run the bootstrap script:

```
base64 -d /tmp/bootstrap.b64 > /tmp/bootstrap.sh
chmod +x /tmp/bootstrap.sh

sudo bash /tmp/bootstrap.sh
```

   After the bootstrap script is started, it will install the required components, configure the container runtime and kubelet, and connect the node to the cluster.

7. On the master node, check that the new node has appeared:

```
d8 k get nodes -o wide
```

   Example expected output:

```
NAME                      STATUS   ROLES          AGE   VERSION    INTERNAL-IP
static-master-0           Ready    master         1h    v1.33.10   192.168.240.135
cloud-static-worker-0     Ready    cloud-static   5m    v1.33.10   192.168.240.152
```

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Hybrid cluster with built-in virtualization

This section describes how to add built-in virtualization nodes to an existing static DP cluster.

Integration with built-in virtualization uses the `cloud-provider-dvp` module. It enables DP to interact with the built-in virtualization cluster API, create virtual machines, connect the created VMs to an existing Kubernetes cluster, and manage the lifecycle of nodes through Cluster API mechanisms.

This section describes two ways to add nodes:

- **Automatically creating built-in virtualization nodes**. DP creates virtual machines through the built-in virtualization API. VM parameters are specified using the DVPInstanceClass resource, while the required number of nodes and placement zones are specified using the NodeGroup resource with the `CloudEphemeral` type.
- **Connecting manually created nodes using a bootstrap script**. A virtual machine is created in advance by the user and connected to the cluster using a DP bootstrap script. This scenario uses a NodeGroup with the `CloudStatic` type.

Prerequisites

Before you begin, make sure that the following requirements are met:

- The cluster is created with the `clusterType: Static` parameter.
- Network connectivity is configured between the network of the static DP cluster nodes and the network of virtual machines in built-in virtualization. For details, see Network requirements. Nodes created in built-in virtualization have access to the Kubernetes API of the target DP cluster, DNS, and the required addresses according to the Network interaction and Configuring network policies sections. If Cilium is used with pod traffic tunneling, the `tunnelMode` mode is selected according to the network connectivity between sites. The Kubernetes API of the built-in virtualization cluster is accessible from the DP cluster.
- The requirements from the Preparing the environment section are met:
  - a ServiceAccount has been created to access the built-in virtualization API;
  - a kubeconfig has been generated to connect to the built-in virtualization API;
  - a namespace has been prepared where virtual machines and disks will be created.
- A Linux OS image with `cloud-init` support is available in built-in virtualization, for example `ubuntu-24-04-lts`.
- A suitable VirtualMachineClass is available in virtualization, for example `amd-epyc-gen-3`.
- A StorageClass for root disks of virtual machines is available in built-in virtualization, for example `replicated`.
- If a virtual machine template is used, make sure that it contains only one disk.

DVPInstanceClass parameters use resources from the built-in virtualization cluster: VirtualMachineClass, ClusterVirtualImage, VirtualImage, VirtualDisk, and StorageClass from built-in virtualization, not from the target DP cluster.

Make sure there are no StorageClass resources in the static DP cluster whose names match the names of StorageClass resources in the built-in virtualization cluster.

When the `cloud-provider-dvp` module is enabled, the corresponding StorageClass resources are automatically synchronized from built-in virtualization to the DP cluster. If a StorageClass with the same name already exists in the static cluster, a resource conflict may occur, causing the module installation or upgrade to fail.

Adding automatically created nodes

1. On the administrator’s machine where access to the built-in virtualization cluster is configured, prepare a kubeconfig for the `cloud-provider-dvp` module to access the virtualization API.

   Follow the steps in the “Preparing the environment” section and encode the generated kubeconfig

in Base64:

```
export DVP_PROVIDER_KUBECONFIG="./kubeconfig"
export DVP_KUBECONFIG_B64="$(base64 -w0 ${DVP_PROVIDER_KUBECONFIG})"
```

2. Specify the built-in virtualization namespace where virtual machines and disks will be created:

   ```
   export DVP_NAMESPACE="<DVP_NAMESPACE>"
   ```

3. Specify the built-in virtualization zone where nodes will be created.

   Currently, zoning in built-in virtualization is under development, so use the `default` value for the `zones` parameters in ModuleConfig and NodeGroup:

   ```
   export DVP_ZONE="default"
   ```

   If necessary, you can check the topology labels of nodes in the built-in virtualization cluster:

   ```
   d8 k get nodes -L topology.kubernetes.io/region,topology.kubernetes.io/zone
   ```

   ⚠ The zone value in ModuleConfig and NodeGroup must match. Currently, only the `default` value is available in DVP.

4. Create a file with the `cloud-provider-dvp` module configuration. For example, `cloud-provider-dvp-mc.yaml`:

   ```
   cat > cloud-provider-dvp-mc.yaml <<EOF
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: cloud-provider-dvp
   spec:
     enabled: true
     version: 2
     settings:
       nodes:
         parameters:
           layout: Standard
           sshPublicKey: "<SSH_PUBLIC_KEY>"
           zones:
             - ${DVP_ZONE}
       provider:
         parameters:
           namespace: ${DVP_NAMESPACE}
   EOF
   ```

   The manifest uses the environment variables set in the previous steps: `DVP_NAMESPACE` and `DVP_ZONE`. Replace `<SSH_PUBLIC_KEY>` with the public SSH key for access to the created nodes.

5. Apply the manifest:

   ```
   d8 k apply -f cloud-provider-dvp-mc.yaml
   ```

6. Wait until the `d8-cloud-provider-dvp` namespace appears:

   ```
   d8 k get ns d8-cloud-provider-dvp
   ```

   The namespace is created by the `cloud-provider-dvp` module, so the credentials Secret is applied as a separate step rather than together with the ModuleConfig. Until the Secret exists, the module components cannot reach the DVP API.

7. Create the credentials Secret:

   ```
   d8 k apply -f - <<EOF
   apiVersion: v1
   kind: Secret
   metadata:
     name: d8-credentials
     namespace: d8-cloud-provider-dvp
   type: cloud-provider.deckhouse.io/credentials
   stringData:
     authScheme: kubeconfig
     secret: ${DVP_KUBECONFIG_B64}
   EOF
   ```

   The Secret uses the `DVP_KUBECONFIG_B64` environment variable set in the first step.

8. Wait until the `cloud-provider-dvp` module is enabled:

   ```
   d8 k get module cloud-provider-dvp -o wide
   ```

   The module must switch to the `Ready` state, and the pods in the `d8-cloud-provider-dvp` namespace must be in the `Running` state.

9. Make sure that the `node-manager` module is in the `Ready` state:

   ```
   d8 k get module node-manager -o wide
   ```

   If the module is in the `Error` state, check that available built-in virtualization zones are specified in ModuleConfig and NodeGroup.

10. Make sure that the DVPInstanceClass resource is available in the cluster:

    ```
    d8 k get crd dvpinstanceclasses.deckhouse.io
    ```

11. On the administrator’s machine where access to the built-in virtualization cluster is configured, check the available virtual machine classes, images, and StorageClasses:

    ```
    d8 k --kubeconfig ${DVP_PROVIDER_KUBECONFIG} get virtualmachineclasses
    d8 k --kubeconfig ${DVP_PROVIDER_KUBECONFIG} get clustervirtualimages
    d8 k --kubeconfig ${DVP_PROVIDER_KUBECONFIG} get storageclasses
    ```

    Use the obtained values when creating DVPInstanceClass.

12. Create a file with DVPInstanceClass and NodeGroup resources. For example, `dvp-instanceclass-nodegroup.yaml`:

```
apiVersion: deckhouse.io/v1alpha1
kind: DVPInstanceClass
metadata:
  name: dvp-worker
spec:
  virtualMachine:
    cpu:
      cores: 3
      coreFraction: 20%
    memory:
      size: 6Gi
    virtualMachineClassName: <VIRTUAL_MACHINE_CLASS_NAME>
    bootloader: EFI
  rootDisk:
    size: 15Gi
    storageClass: <STORAGE_CLASS_NAME>
    image:
      kind: ClusterVirtualImage
      name: <CLUSTER_VIRTUAL_IMAGE_NAME>
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: dvp-worker
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: DVPInstanceClass
      name: dvp-worker
    minPerZone: 1
    maxPerZone: 1
    zones:
      - default
```

Where:

- `virtualMachineClassName` — name of the VirtualMachineClass in built-in virtualization, for example `amd-epyc-gen-3`;
- `rootDisk.storageClass` — name of the StorageClass in built-in virtualization, for example `replicated`;
- `rootDisk.image.kind` — image source type. For a cluster image, use `ClusterVirtualImage`;
- `rootDisk.image.name` — name of the OS image in built-in virtualization, for example `ubuntu-24-04-lts`;
- `cloudInstances.zones` — built-in virtualization zone where the node will be created. The value must match the `zones` value in ModuleConfig.

13. Apply the manifest:

```
d8 k apply -f dvp-instanceclass-nodegroup.yaml
```

After the manifest is applied, DP will start creating a virtual machine in DVP and connect it to the cluster as a node.

14. Check the NodeGroup status:

```
d8 k get nodegroup dvp-worker -o wide
d8 k describe nodegroup dvp-worker
```

15. Check that a new node appears in the DP cluster:

```
d8 k get nodes -o wide
```

Example expected output:

```
NAME                              STATUS   ROLES                  AGE   VERSION
INTERNAL-IP
dvp-hybrid-master-0               Ready    control-plane,master   1h
v1.33.10   10.12.0.69
dvp-worker-c75a75c1-twqp4-bjpvl   Ready    dvp-worker             10m
v1.33.10   10.12.3.15
```

Adding manually created nodes using a bootstrap script

Before you begin, make sure that the following requirements are met:

- The `cloud-provider-dvp` module is enabled:

  ```
  d8 k get module cloud-provider-dvp -o wide
  ```

- The `cloud-provider-dvp` module components are in the `Running` state:

  ```
  d8 k -n d8-cloud-provider-dvp get pods -o wide
  ```

- A virtual machine that will be connected to the cluster has been created in built-in virtualization.
- The virtual machine is connected to the built-in virtualization network used for hybrid integration with the cluster.
- The virtual machine IP address belongs to the range specified in `internalNetworkCIDRs`.
- The virtual machine name in built-in virtualization matches the hostname inside the operating system.
- SSH access is available on the virtual machine for copying and running the bootstrap script.
- The SSH user can run commands using `sudo` without entering a password.
- One of the package managers (`apt`/`apt-get`, `yum`, or `rpm`) for a supported OS is installed on the virtual machine.

1. Create a NodeGroup with the `CloudStatic` node type. In this example and the following steps, the `cloud-static` name is used:

   ```
   d8 k apply -f - <<EOF
   apiVersion: deckhouse.io/v1
   kind: NodeGroup
   metadata:
     name: cloud-static
   spec:
     nodeType: CloudStatic
   EOF
   ```

2. Make sure that NodeGroup has been created and synchronized:

   ```
   d8 k get nodegroup cloud-static
   ```

   Example expected output:

   ```
   NAME           TYPE          READY   NODES   UPTODATE   INSTANCES   DESIRED
   MIN   MAX   STANDBY   STATUS   AGE   SYNCED
   cloud-static   CloudStatic   0       0       0
   1m    True
   ```

3. Get the bootstrap script for the created NodeGroup:

   ```
   NODE_GROUP=cloud-static

   d8 k -n d8-cloud-instance-manager get secret manual-bootstrap-for-${NODE_GROUP} \
     -o jsonpath='{.data.bootstrap\.sh}' > ${NODE_GROUP}-bootstrap.b64
   ```

4. On the master node, verify that the file contains valid Base64 data of the bootstrap script:

```
base64 -d ${NODE_GROUP}-bootstrap.b64 > /dev/null
```

Check the beginning of the decoded content:

```
base64 -d ${NODE_GROUP}-bootstrap.b64 | head -n 5
```

The decoded content must start with a bash script:

```
#!/bin/bash
...
```

5. Copy the bootstrap script to the virtual machine being connected:

```
scp ${NODE_GROUP}-bootstrap.b64 <USER>@<NODE_IP>:/tmp/bootstrap.b64
```

6. Connect to the virtual machine over SSH:

```
ssh <USER>@<NODE_IP>
```

7. On the virtual machine, decode the bootstrap script, set permissions, and run it:

```
base64 -d /tmp/bootstrap.b64 > /tmp/bootstrap.sh
chmod +x /tmp/bootstrap.sh

sudo bash /tmp/bootstrap.sh
```

After the bootstrap script starts, it will install the required components, configure the container runtime and kubelet, and connect the node to the cluster.

8. On the master node, check that a new node appears:

```
d8 k get nodes -o wide
```

Example expected output:

```
NAME                   STATUS   ROLES                  AGE   VERSION
INTERNAL-IP
dvp-hybrid-master-0    Ready    control-plane,master   1h    v1.33.12
10.12.0.69
cloud-static-worker-0  Ready    cloud-static           5m    v1.33.12
10.12.3.88
```

9. If connection fails, check the NodeGroup status, events, and bootstrap logs on the virtual machine being connected:

```
d8 k get nodegroup cloud-static
d8 k describe nodegroup cloud-static
d8 k get events -A --sort-by=.lastTimestamp | tail -n 100
```

On the virtual machine being connected:

```
sudo tail -n 120 /var/log/d8/bashible/bootstrap.log
```

If the logs contain the `Failed to discover node_ip that matches internalNetworkCIDRs` error, check that the virtual machine IP address belongs to `internalNetworkCIDRs`.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

High reliability and availability

The reliability and resilience of a Kubernetes cluster are key characteristics that define the stability of the infrastructure. Deckhouse Platform (DP) ensures high availability (HA) and fault tolerance through built-in mechanisms and modules.

When HA mode is enabled, critical cluster components are launched with the necessary redundancy to guarantee their continuous operation. Even if a single instance fails, services can continue functioning without downtime. For more information on enabling HA mode, refer to Managing HA mode.

If the cluster has more than one master node, HA mode is automatically enabled, both during the initial deployment and when additional nodes are added later. Recommended roles and number of nodes can be found in Recommendations for configuring cluster nodes and preventing overload.

DP provides chaos engineering tools to test cluster resilience. These tools let you deliberately or randomly disrupt individual components and observe the infrastructure's response. For information on configuring these tools, refer to Chaos engineering.

You can further increase cluster fault tolerance by enabling inter-cluster communication based on the Service Mesh mode of the `istio` module. In this mode, federation is configured between multiple clusters. In case of failures in one cluster, the load is automatically redistributed to others. For configuration details, refer to Federation.

Virtual machines also survive node failures and overload. Rebalancing moves them off loaded nodes by live migration, and the ColdStandby mechanism brings machines back into operation after a node fails. For details, refer to Virtual machine fault tolerance and balancing.

Additional resources

- Module `istio` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Recommendations for configuring cluster nodes and preventing overload

Proper node configuration increases cluster fault tolerance and simplifies maintenance. Below are the recommended roles and number of nodes for various components.

Master nodes

To ensure cluster fault tolerance, **always** use at least three master nodes. This number ensures uninterrupted cluster operation and lets you update master nodes safely. More than three nodes are unnecessary, and two nodes are insufficient to maintain alignment (quorum) in case of issues in one of the nodes.

Using only one master node means its failure will bring down the entire cluster since it manages key components that keep the cluster running.

Frontend nodes

Frontend nodes balance incoming traffic. Ingress controllers run on them. Use more than one frontend node. These nodes must be able to handle traffic in case at least one frontend node fails.

For example, if the cluster has two frontend nodes, each must be capable of handling the full load if the other fails. If there are three, each node must be able to handle at least a 150% load increase.

Monitoring nodes

Monitoring nodes run Grafana, Prometheus, and other monitoring components. In heavily loaded clusters with multiple alerts and large metric volumes, it’s recommended that you allocate dedicated nodes for monitoring. Otherwise, monitoring components will run on system nodes.

When dedicating nodes for monitoring, it’s important they use fast disks (at least 400 IOPS).

System nodes

System nodes are used to run Deckhouse modules. Allocate two system nodes. This ensures Deckhouse modules will run on them without interfering with user applications in the cluster.

Preventing Kubernetes API overload (FlowSchema)

By default, a DP cluster includes a component that implements FlowSchema and PriorityLevelConfiguration to prevent Kubernetes API overload.

`FlowSchema` assigns `PriorityLevel` for `list` requests from all service accounts in Deckhouse namespaces (with the label `heritage: deckhouse`) to the following apiGroups:

- `v1` (Pod, Secret, ConfigMap, Node, etc.): Useful for clusters with numerous basic resources (for example, Secrets or Pods).
- `apps/v1` (DaemonSet, Deployment, StatefulSet, ReplicaSet, etc.): Useful when numerous applications are deployed in the cluster (for example, Deployments).
- `deckhouse.io` (Deckhouse custom resources): Useful when there are numerous Deckhouse custom resources in the cluster.
- `cilium.io` (Cilium custom resources): Useful for clusters with numerous Cilium policies.

All API requests matching a `FlowSchema` are placed into a single queue with a shared priority. This limits the load on the Kubernetes API and prevents it from being overloaded by mass `list` requests.

This component does not have settings, but the following commands are available:

- Check the state of priority levels:

  ```
  d8 k get --raw /debug/api_priority_and_fairness/dump_priority_levels
  ```

- Check the state of priority level queues:

  ```
  d8 k get --raw /debug/api_priority_and_fairness/dump_queues
  ```

The component also provides the following metrics to Grafana:

- `apiserver_flowcontrol_rejected_requests_total`: Total number of rejected requests.
- `apiserver_flowcontrol_dispatched_requests_total`: Total number of processed requests.
- `apiserver_flowcontrol_current_inqueue_requests`: Number of requests in queues.
- `apiserver_flowcontrol_current_executing_requests`: Number of requests being executed.

Delaying node reboot or shutdown while critical pods are running

DP supports a mechanism for delaying the shutdown or reboot of a node if it is running stateful applications or virtual machines (VMs). This is implemented by the `d8-shutdown-inhibitor` service of the `node-manager` module.

The delay is triggered if pods with the label `pod.deckhouse.io/inhibit-node-shutdown` are running on the node. DP delays the shutdown or restart of the node so that the user can migrate critical pods or terminate them in a controlled manner. This is useful, for example, for stateful workloads and other cases where data loss must be avoided. For information about the mechanism’s principles and features, refer to the `node-manager` module documentation.

Enabling a node shutdown delay

⚠ To decide whether to block a node shutdown, DP additionally queries the NodeGroup. If the current node belongs to the `master` group and it is the only master node in the cluster, the shutdown block will not be applied to it.

To enable the mechanism that delays a node's restart or shutdown, add the label `pod.deckhouse.io/inhibit-node-shutdown` to the Pod (for a Deployment, specify the label in the pod template).

Example of a Pod manifest with the `pod.deckhouse.io/inhibit-node-shutdown` label:

```
apiVersion: v1
kind: Pod
metadata:
  name: my-stateful-app
  labels:
    app: my-stateful-app
    pod.deckhouse.io/inhibit-node-shutdown: "true"
spec:
  containers:
    - name: app
      image: my-registry/my-app:1.0.0
```

⚠ The block only applies to pods labeled with `pod.deckhouse.io/inhibit-node-shutdown` that are in the `Running` phase on the node. Kubelet shuts down the pods without this label according to the standard graceful shutdown process.

Searching pods that prevent shutdown and performing the node troubleshooting

To search the pods that are blocking a node shutdown, use the following command:

```
d8 k get po -A -l pod.deckhouse.io/inhibit-node-shutdown -o wide
```

To view the `GracefulShutdownPostpone` condition on a node, use the following command:

```
d8 k get node <NODE_NAME> -o jsonpath='{range .status.conditions[?
(@.type=="GracefulShutdownPostpone")]}{.type}{"\t"}{.status}{"\t"}{.reason}{"\t"}
{.message}{"\n"}{end}'
```

Possible values of the `reason` field:

- `WaitingForShutdownSignal`: The shutdown blocking mechanism is running on the node, but the blocking has not yet begun.
- `PodsWithLabelAreRunningOnNode`: The shutdown has been blocked because there are pods with the label `pod.deckhouse.io/inhibit-node-shutdown` still running on the node.
- `NoRunningPodsWithLabel`: The blocking has been released and the shutdown can continue.

Additional resources

- Module `node-manager` documentation

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managing HA mode

> **i** Note that if the cluster has **more than one master node**, HA mode is **enabled automatically**. This applies both when deploying a cluster with multiple master nodes from the start and when increasing the number of master nodes from one to three.

Enabling HA mode globally

You can enable HA mode globally for DP in one of the following ways.

Using ModuleConfig/global custom resource

1. Set the `settings.highAvailability` parameter to `true` in `ModuleConfig/global`:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: global
   spec:
     version: 2
     settings:
       highAvailability: true
   ```

2. To ensure HA mode is enabled, you can, for example, check the number of `deckhouse` Pods in the `d8-system` namespace. To do that, run the following command:

   ```
   d8 k -n d8-system get po | grep deckhouse
   ```

   The number of `deckhouse` Pods in the output must be more than one:

   ```
   deckhouse-57695f4d68-8rk6l                          2/2     Running   0             3m49s
   deckhouse-5764gfud68-76dsb                          2/2     Running   0             3m49s
   deckhouse-fgrhy4536s-fhu6s                          2/2     Running   0             3m49s
   ```

Using Deckhouse web UI

If the `console` module is enabled in the cluster, open the Deckhouse web UI, navigate to **Deckhouse — Global settings — Global module settings**, and switch the **HA mode** toggle to **Yes**.

Configuring HA mode with two master nodes and an arbiter node

Deckhouse Platform allows you to configure HA mode with two master nodes and an arbiter node. This approach allows you to meet HA requirements in conditions of limited resources.

Only etcd is placed on the arbiter node, without the other control plane components. This node is used to ensure the etcd quorum.

Requirements for the arbiter node:

- At least 2 CPU cores
- At least 4 GB of RAM
- At least 8 GB of disk space for etcd

The network latency requirements for the arbiter node are similar to those for the master nodes.

Configuring in a cloud cluster

The example below applies to a cloud cluster with three master nodes. To configure HA mode with two master nodes and an arbiter node in a cloud cluster, you need to remove one master node from the cluster and add one arbiter node.

To do this, follow these steps:

> **⚠** The following steps must be performed starting from the first master node (`master-0`) in the cluster. This is because the cluster scales in order — for example, it is not possible to remove `master-0` and `master-1` while leaving `master-2`.

> ⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before adding or removing a master node. We strongly recommend creating a backup of the module's data before making any changes.

1. Create a backup of etcd and the `/etc/kubernetes` directory.
2. Copy the resulting archive outside the cluster (for example, to a local machine).
3. Ensure there are no alerts in the cluster that may interfere with the master node update process.
4. Make sure the DP queue is empty:

   ```
   d8 system queue list
   ```

5. On the **local machine**, run the DP installer container for the corresponding edition and version (change the container registry address if needed):

   ```
   DH_VERSION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/version}')
   DH_EDITION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/edition}' | tr '[:upper:]'
   '[:lower:]' )
   docker run --pull=always -it -v "$HOME/.ssh/:/tmp/.ssh/" \
     registry.deckhouse.io/deckhouse/${DH_EDITION}/install:${DH_VERSION} bash
   ```

6. **In the installer container**, run the following command:

   ```
   dhctl config edit provider-cluster-configuration --ssh-agent-private-
   keys=/tmp/.ssh/<SSH_KEY_FILENAME> \
     --ssh-user=<USERNAME> --ssh-host <MASTER-NODE-0-HOST>
   ```

   Change the cloud provider settings:

   - Set `masterNodeGroup.replicas` to `2`.
   - Create a NodeGroup for the arbiter node. The arbiter node **must have** the label `node.deckhouse.io/etcd-arbiter: ""` and a taint that prevents user workloads from being placed on it. Example of a NodeGroup description for the arbiter node:

     ```
     nodeGroups:
       - name: arbiter
         replicas: 1
         nodeTemplate:
           labels:
             node.deckhouse.io/etcd-arbiter: ""
           taints:
             - key: node.deckhouse.io/etcd-arbiter
               effect: NoSchedule
         zones:
           - europe-west3-b
         instanceClass:
           machineType: n1-standard-4
       # ... the rest of the manifest
     ```

   - Save your changes.

> **i** For **Yandex Cloud**, if external IPs are used for master nodes, the number of items in the `masterNodeGroup.instanceClass.externalIPAddresses` array must match the number of master nodes. Even when using `Auto` (automatic public IP allocation), the number of entries must still match.
>
> For example, for a single master node (`masterNodeGroup.replicas: 1`) and automatic IP assignment, the `masterNodeGroup.instanceClass.externalIPAddresses` section would look as follows:
>
> ```
> externalIPAddresses:
> - "Auto"
> ```

7. **In the installer container**, run the following command to trigger the scaling operation:

   ```
   dhctl converge --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-user=<USERNAME>
   --ssh-host <MASTER-NODE-0-HOST> --ssh-host <MASTER-NODE-1-HOST>
   ```

   > **i** **Important**. For **OpenStack** and **VK Cloud (OpenStack)**, after confirming the node deletion, it is extremely important to check the disk deletion `<prefix>kubernetes-data-N` in OpenStack itself.
   >
   > For example, when deleting the `cloud-demo-master-2` node in the OpenStack web interface or in the OpenStack CLI, it is necessary to check the absence of the `cloud-demo-kubernetes-data-2` disk.
   >
   > If the `kubernetes-data` disk remains, there may be problems with etcd operation as the number of master nodes increases.

8. Check the Deckhouse queue with the following command and make sure there are no errors:

   ```
   d8 system queue list
   ```

Configuring in a static cluster

To configure HA mode with two master nodes and an arbiter node in a static cluster, follow these steps:

1. Create a NodeGroup for the arbiter node. The arbiter node **must have** the label `node.deckhouse.io/etcd-arbiter: ""` and a taint that prevents user workloads from being placed on it. Example of a NodeGroup description for the arbiter node:

   ```
   apiVersion: deckhouse.io/v1
     kind: NodeGroup
     metadata:
       name: arbiter
     spec:
       nodeType: Static
       nodeTemplate:
         labels:
           node.deckhouse.io/etcd-arbiter: ""
         taints:
           - key: node.deckhouse.io/etcd-arbiter
             effect: NoSchedule
     # ... the rest of the manifest
   ```

2. Add a node to the cluster that will be used as an arbiter node in a way that is convenient for you.
3. Ensure that the added arbiter node is in the list of etcd cluster members.
4. Remove one master node from the cluster.

Enabling HA mode for individual components

Some DP modules may have their own HA mode settings. To enable HA mode in a specific module, set the `settings.highAvailability` parameter in its configuration. The HA mode operation in individual modules is independent of the global HA mode.

List of modules supporting individual HA mode:

- `deckhouse`
- `openvpn`
- `istio`
- `dashboard`
- `multitenancy-manager`
- `user-authn`
- `ingress-nginx`
- `prometheus-monitoring`
- `monitoring-kubernetes`
- `snapshot-controller`

To enable HA mode manually for a specific module, add the `settings.highAvailability` parameter to its configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    highAvailability: true
```

To ensure HA mode is enabled, check the number of Pods for the target module. For example, to verify the mode operation for the `deckhouse` module, check the number of corresponding Pods in the `d8-system` namespace by running the following command:

```
d8 k -n d8-system get po | grep deckhouse
```

The number of `deckhouse` Pods in the output must be more than one:

```
deckhouse-57695f4d68-8rk6l                    2/2     Running   0             3m49s
deckhouse-5764gfud68-76dsb                    2/2     Running   0             3m49s
deckhouse-fgrhy4536s-fhu6s                    2/2     Running   0             3m49s
```

Chaos engineering

> ⚠ Chaos engineering mode can only be enabled for node groups with `nodeType: CloudEphemeral`.

Enable chaos engineering mode for a node group in one of the following ways:

1. Define the `spec.chaos` parameter in the configuration of the target node group with two nested parameters:

```
chaos:
  mode: DrainAndDelete
  period: 24h
```

Where:

- `mode`: Operation mode. Two options are available:
  - `DrainAndDelete`: When triggered, drains the node and deletes it.
  - `Disabled`: Skips this specific node group.
- `period`: Chaos Monkey trigger interval. Defined as a string with hours and minutes: `30m`, `1h`, `2h30m`, `24h`.

Example configuration for a node group:

```
# NodeGroup for cloud nodes in AWS.
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: test
spec:
  nodeType: CloudEphemeral
  chaos:
    mode: DrainAndDelete
    period: 24h
```

2. If the `console` module is enabled in the cluster, open the Deckhouse web UI, go to the settings of the desired node group under **Nodes** — **Node Groups**, and enable Chaos Monkey in the **Chaos monkey settings** section by specifying the time intervals in the corresponding fields.

Virtual machine fault tolerance and balancing

Node load changes over time, and nodes sometimes fail. Deckhouse Platform (DP) balances the placement of virtual machines (VMs) across nodes and restarts machines from a failed node, while metrics help you find out why a machine runs slowly.

VM rebalancing

Over time, the distribution of virtual machines across nodes stops being even. The `descheduler` module restores the balance by moving VMs with live migration, without interrupting them. Enable this module, and the distribution is maintained without your involvement.

Rebalancing solves two tasks:

- It evens out the load. DP tracks how much CPU is reserved on each node and, when a node reserves more than 80%, moves some VMs to the nodes that reserve less than 50%.
- It restores correct placement. DP checks whether the current node meets the VM requirements and the rules of mutual VM placement. For example, if the rules forbid keeping certain VMs on the same node, the extra ones are moved.

DP sets the rebalancing parameters itself: with the `descheduler` module enabled, it creates a Descheduler resource named `virtualization` and selects in it only the machines that can be moved by live migration. How the eviction strategies work is covered in Pod eviction.

- Using the CLI
- Using the web interface

To view the rebalancing settings, run the following command:

```
d8 k get descheduler virtualization -o yaml
```

1. Go to the **System** tab, then to **Configuration → Deschedulers**.
2. Click **Create**.
3. In the **Create resource** window that opens, enter the resource name in the **Name** field.
4. On the **Configuration** tab, in the **Strategies** block, enable the strategies you need. The **Low node utilization (balancing)** strategy moves VMs from overloaded nodes, while **Inter-Pod Anti-Affinity violations** and **Node Affinity violations** restore correct placement.
5. Click **Apply**.

The created resources and the strategies enabled in them appear in the list of the section.

Rebalancing covers only the VMs that can leave their node by live migration. A VM that can’t be live migrated, for example one with a passed-through device, is never moved by rebalancing, because the only other way off the node is a restart. Such a VM is restarted only during node maintenance and only with the permission of an administrator.

Diagnosing a slow VM

A slowdown of a virtual machine has two different causes. The guest OS is either busy with its own computations, or waiting for the node to give it processor time. From the outside both cases look the same, as a loaded processor of the machine.

DP metrics tell them apart, so you don’t have to log in to the guest system. The “Virtualization VM Happiness” Grafana dashboard shows how long each machine waits for a processor and what it lacks, as well as which nodes are loaded more than the rest.

What to do next depends on which of the causes is confirmed.

- **The machine consumes its entire guaranteed processor share.** Moving it to another node doesn’t help, because the same share is guaranteed there. Raise the core fraction `.spec.cpu.coreFraction` or reduce the number of virtual cores, so that the guest OS doesn’t spread the load across the cores that get no processor time. With the `Auto` value, DP picks the share from actual consumption, so you can’t change it manually and have to change the number of cores or set an explicit percentage.
- **The machine waits for processor time without consuming its guaranteed share.** The node doesn’t deliver the declared guarantee, and moving the machine to a less loaded node eliminates the delays.

The guarantee isn’t absolute under CPU oversubscription. Processor time is distributed between machines in proportion to their shares, so a machine with a few loaded cores among many competing ones can get less than it’s guaranteed.

When freeing up a node, move the machine with the highest consumption rather than the one that has slowed down. Moving the main consumer frees the node resources, while moving the other machines has little effect.

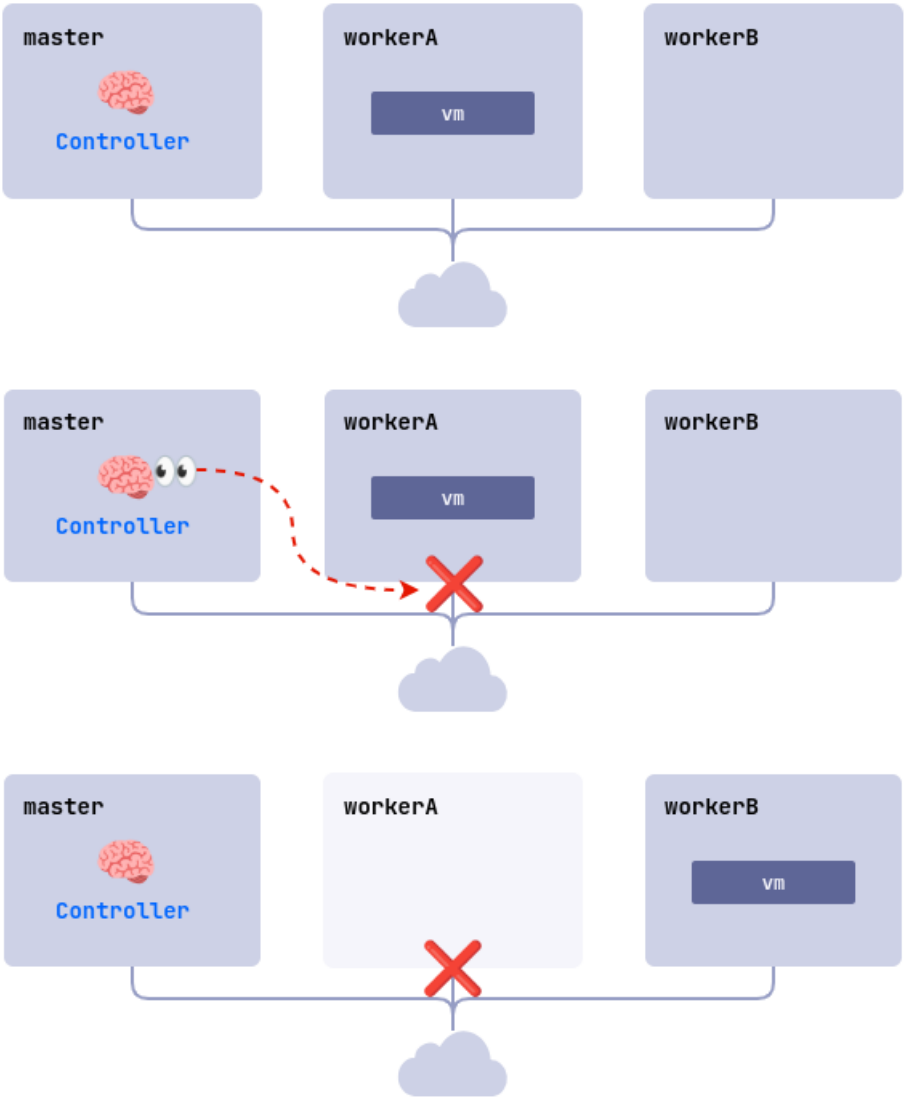
Before a move, check whether migration is possible, so that freeing up a node doesn’t turn into a restart of a machine. A machine held by its storage is in many cases moved along with its disks, while a machine with a passed-through device can’t be moved by live migration at all.

Make sure as well that the cluster has a suitable node. The VirtualMachineClass limits the choice to the nodes whose processors match the class. If only the current node is left on that list, migration is impossible under any resource shortage, and what’s left is freeing up the node itself by moving the other machines off it, or assigning the machine a class with a wider choice of nodes.

DP measures storage and network latency by comparison with the rest of the cluster rather than against a fixed threshold, because the same disk latency is normal for a replicated volume and indicates a problem for a local one. If the storage is equally slow across the cluster, moving a machine doesn’t eliminate the delays.

ColdStandby

The ColdStandby mechanism returns a virtual machine to service after the failure of the node it was running on.



For the mechanism to work, meet two requirements:

- The `.spec.runPolicy` run policy of the virtual machine must be set to `AlwaysOnUnlessStoppedManually` or `AlwaysOn`.
- The Fencing mechanism must be enabled on the nodes that run virtual machines.

Without Fencing, the mechanism doesn’t work. An unavailable VM doesn’t move in that case, but stays on the failed node and resumes together with it.

Here’s the recovery sequence, using a cluster of three nodes, `master`, `workerA`, and `workerB`, where Fencing is enabled on both worker nodes and the `linux-vm` VM runs on `workerA`:

1. The `workerA` node fails, for example because of a power or network loss.
2. The controller checks node availability and finds that `workerA` doesn’t respond.
3. The controller removes `workerA` from the cluster.
4. The `linux-vm` VM starts on another suitable node, `workerB` in this example.

Platform scaling and node management

Deckhouse Platform (DP) provides built-in mechanisms for comprehensive management of cluster architecture — both at the control plane level and at the node level.

Management capabilities include:

- Control plane management — automation of configuration and updates for Kubernetes API, etcd, and other system components; issuance and renewal of certificates; scaling of the control plane and transitioning between single-master and multi-master modes; high availability and recovery.
- Node management — creation and scaling of node groups using NodeGroup objects; automatic deployment and updating of nodes; support for various types of infrastructure (cloud and bare-metal); management of static and cloud nodes; use of additional tools for fine-tuning.

These capabilities allow the creation of reliable, scalable, and self-healing clusters, adapting them to any requirements for performance, high availability, and infrastructure constraints.

The following sections provide detailed descriptions of features, configuration examples, and best practices for effective control plane and node management in Deckhouse Platform.

If a cluster runs virtual machines, taking a node out for maintenance affects them as well. How to move machines to other nodes, what limits the migration, and what to do with machines that can’t be migrated is described in Maintenance of nodes running virtual machines.

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

General management and configuration of the control plane

Main features

Deckhouse Platform (DP) manages control plane components using the `control-plane-manager` module, which runs on all master nodes (nodes with the label `node-role.kubernetes.io/control-plane: ""`).

The control plane management functionality includes:

- Managing certificates required for the control plane to function, including their renewal and issuance when the configuration changes. Secure configuration is maintained automatically, with the ability to quickly add additional SANs for secure access to the Kubernetes API.
- Component configuration. DP generates all necessary configurations and manifests (kube-apiserver, etcd, etc.), reducing the risk of human error.
- Upgrade/downgrade of components. DP supports consistent version upgrades or downgrades of the control plane, helping maintain version uniformity across the cluster.
- Managing the etcd cluster configuration and its members. DP scales master nodes and performs migrations between single-master and multi-master modes.
- Periodic defragmentation of etcd. In clusters with three or more etcd members, this feature is enabled by default.
- Configuring kubeconfig. DP generates an up-to-date configuration file (with `cluster-admin` permissions), creates, renews, and updates the kubeconfig for control-plane components and the admin kubeconfig (`admin.conf`), and creates a symlink for the `root` user (`/root/.kube/config` → `admin.conf`). When the `user-authz` module is enabled, the symlink can be disabled using the `rootKubeconfigSymlink` parameter in the `control-plane-manager` module (for more details, see the FAQ of the `control-plane-manager` module). DP also tightens access permissions for the `admin.conf` and `super-admin.conf` files to enhance security.

> **i** Some parameters affecting control plane behavior are taken from the ClusterConfiguration resource.

Enabling, disabling, and configuring the module

Enabling / disabling

You can enable or disable the `control-plane-manager` module in the following ways:

1. Create (or modify) the ModuleConfig/control-plane-manager resource by setting `spec.enabled` to `true` or `false`:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: control-plane-manager
   spec:
     enabled: true
   ```

2. Using the command:

   ```
   d8 system module enable control-plane-manager
   ```

   or to disable:

   ```
   d8 system module disable control-plane-manager
   ```

3. Via the Deckhouse web interface:

   - Go to the “Deckhouse → Modules” section.
   - Find the `control-plane-manager` module and click on it.
   - Toggle the “Module enabled” switch.

Configuration

To configure the module, use the ModuleConfig/control-plane-manager resource and specify the required parameters in `spec.settings`.

Example with the schema version, enabled module, and a few settings:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  enabled: true
  settings:
    apiserver:
      bindToWildcard: true
      certSANs:
      - bakery.infra
      - devs.infra
      publishAPI: {}
```

Checking DP status and queues

How to verify that `control-plane-manager` is running correctly and is not in a pending state, and how to check active DP tasks (queues):

1. Make sure the module is enabled:

   ```
   d8 k get modules control-plane-manager
   ```

2. Check the status of `control-plane-manager` pods (they run in the `kube-system` namespace and have the label `app=d8-control-plane-manager`):

   ```
   d8 k -n kube-system get pods -l app=d8-control-plane-manager -o wide
   ```

   Ensure that all pods are in the `Running` or `Completed` state.

3. Verify that master nodes are in the `Ready` state:

```
d8 k get nodes -l node-role.kubernetes.io/control-plane
```

To view detailed information:

```
d8 k describe node <node-name>
```

4. Get the list of queues and active tasks:

```
d8 system queue list
```

Example output:

```
Summary:
- 'main' queue: empty.
- 107 other queues (0 active, 107 empty): 0 tasks.
- no tasks to handle.
```

⚠ Before performing heavy operations (e.g., transitioning from single-master to multi-master or upgrading the Kubernetes version), it is recommended to wait until all tasks in the queues are completed.

Certificate management

In DP, the `control-plane-manager` module is responsible for issuing and renewing all SSL certificates for control plane components. It manages:

1. **Server certificates** for kube-apiserver and etcd, stored in the `d8-pki` secret (namespace: `kube-system`):
   - Kubernetes root CA (`ca.crt`, `ca.key`).
   - etcd root CA (`etcd/ca.crt`, `etcd/ca.key`).
   - RSA certificate and key for signing Service Accounts (`sa.pub`, `sa.key`).
   - Root CA for extension API servers (`front-proxy-ca.key`, `front-proxy-ca.crt`).
2. **Client certificates** required for mutual communication between control plane components (e.g., `apiserver.crt`, `apiserver-etcd-client.crt`, etc.). These files are stored only on the nodes. If any changes occur (e.g., new SANs are added), certificates are automatically reissued, and the kubeconfig is synchronized.

PKI management

DP also manages the Public Key Infrastructure (PKI) used for encryption and authentication throughout the Kubernetes cluster:

- PKI for control plane components (kube-apiserver, kube-controller-manager, kube-scheduler, etc.).
- PKI for the etcd cluster (etcd certificates and inter-node communication).

DP assumes control of this PKI after the initial cluster installation and once its pods are running. As a result, all key issuance, renewal, and rotation operations (both for control plane and etcd) are performed automatically and centrally, without requiring manual intervention.

Additional SANs and auto-update

Deckhouse simplifies the addition of new Subject Alternative Names (SANs) for the Kubernetes API endpoint: you only need to specify them in the configuration. After any SAN change, the module automatically regenerates the certificates and updates the kubeconfig.

To add additional SANs (extra DNS names or IP addresses) for the Kubernetes API, specify the new SANs in the `spec.settings.apiserver.certSANs` field of your ModuleConfig/control-plane-manager resource.

DP will automatically generate new certificates and update all required configuration files (including kubeconfig).

Kubelet certificate rotation

In Deckhouse Platform, kubelet certificate rotation is automatic. The `--tls-cert-file` and `--tls-private-key-file` parameters for kubelet are not set directly. Instead, a dynamic TLS certificate

mechanism is used: kubelet applies the client certificate located at `/var/lib/kubelet/pki/kubelet-client-current.pem`, which it uses to request a new client or server certificate (file `/var/lib/kubelet/pki/kubelet-server-current.pem`) from kube-apiserver. Also, the CIS benchmark `AVD-KCV-0088` and `AVD-KCV-0089` checks, which track whether the `--tls-cert-file` and `--tls-private-key-file` arguments were passed to kubelet, are disabled in the `operator-trivy` module.

Features of kubelet certificate rotation in Deckhouse Platform:

- By default, kubelet generates its own keys in the `/var/lib/kubelet/pki/` directory and, if necessary, independently requests certificate renewal from kube-apiserver.
- lifetime of certificates is 1 year (8760 hours). When there are between 5 and 10% of the time remaining before expiration (the exact value is randomly selected from this range), kubelet automatically initiates a request for a new certificate. For more details, see the official documentation Kubernetes. If necessary, lifetime of certificates can be changed using `--cluster-signing-duration` parameter in `/etc/kubernetes/manifests/kube-controller-manager.yaml` manifest. However, in order for kubelet to obtain and install a new certificate before the current one expires, it is recommended to set the validity period of certificates to at least 1 hour.
- If the kubelet fails to renew the certificate before it expires, it will lose the ability to make requests to the kube-apiserver and, accordingly, renew certificates. As a result, the node will be marked as `NotReady` and automatically recreated.

Manual renewal of control plane certificates

If the master nodes were offline for an extended period (e.g., the servers were shut down), some control plane certificates may become outdated. In such cases, automatic renewal will not occur upon reboot — manual intervention is required.

To manually renew the control plane certificates, use the `kubeadm` utility on each master node:

1. Locate the `kubeadm` binary on the master node and create a symbolic link:

   ```
   ln -s  $(find /var/lib/containerd  -name kubeadm -type f -executable -print -quit) /usr/bin/kubeadm
   ```

2. Execute the following command:

   ```
   kubeadm certs renew all
   ```

   This command will regenerate the necessary certificates (for kube-apiserver, kube-controller-manager, kube-scheduler, etcd, and others).

Speeding up pod restarts after losing connection to a node

By default, if a node does not report its status within 40 seconds, it is marked as `Unreachable`. Then, after another 5 minutes, the pods on that node begin to be restarted on other nodes. As a result, the total application downtime can reach approximately 6 minutes.

In specific cases where an application cannot run in multiple instances, there is a way to reduce the downtime period:

1. Reduce the time before a node is marked as `Unreachable` by configuring the `nodeMonitorGracePeriodSeconds` parameter.
2. Set a shorter timeout for evicting pods from the unreachable node using the `failedNodePodEvictionTimeoutSeconds` parameter.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  settings:
    nodeMonitorGracePeriodSeconds: 10
    failedNodePodEvictionTimeoutSeconds: 50
```

⚠ The shorter the timeouts, the more frequently system components check node status and plan pod rescheduling. This increases the load on the control plane, so choose values that match your requirements for high availability and performance.

Forcibly disabling IPv6 on cluster nodes

Internal communication between Deckhouse cluster components is performed via IPv4 protocol. However, at the operating system level of the cluster nodes, IPv6 is usually active by default. This leads to automatic assignment of IPv6 addresses to all network interfaces, including Pod interfaces. This results in unwanted network traffic - for example, redundant DNS queries like `AAAAA` - which can affect performance and make debugging network communications more difficult.

To correctly disable IPv6 at the node level in a Deckhouse-managed cluster, it is sufficient to set the necessary parameters via the NodeGroupConfiguration resource:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: disable-ipv6.sh
spec:
  nodeGroups:
  - '*'
  bundles:
  - '*'
  weight: 50
  content: |
    GRUB_FILE_PATH="/etc/default/grub"

    if ! grep -q "ipv6.disable" "$GRUB_FILE_PATH"; then
      sed -E -e 's/^(GRUB_CMDLINE_LINUX_DEFAULT="[^"]*)"/\1 ipv6.disable=1"/' -i
"$GRUB_FILE_PATH"
      update-grub

      bb-flag-set reboot
    fi
```

⚠ After applying the resource, the GRUB settings will be updated and the cluster nodes will begin a sequential reboot to apply the changes.

etcd periodic defragmentation configuration

In clusters with three or more etcd members (3 and more master nodes or 2 and more master nodes if an etcd-arbiter is present), this feature is enabled by default. Defragmentation runs once a day at exactly 1:00 a.m. server time.

⚠ Enabling periodic defragmentation in a cluster with a single master node causes the control plane to be temporarily unavailable each time it runs.

To configure periodic etcd defragmentation, use the `etcd.defrag` parameter in the `control-plane-manager` module configuration. Specify the desired defragmentation frequency in the `etcd.defrag.cronSchedule` parameter using the cron (UTC) format.

Example configuration of the `control-plane-manager` module with settings for etcd defragmentation once a day at 4:00 a.m. server time:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  enabled: true
  settings:
    apiserver:
      bindToWildcard: true
      certSANs:
        - bakery.infra
        - devs.infra
      publishAPI: {}
    etcd:
      defrag:
        enabled: true
        cronSchedule: 0 4 * * *
```

Control plane recovery and debugging

Recovery from failures

During its operation DP automatically creates backups of configuration and data that may be useful in case of problems. These backups are saved in the `/etc/kubernetes/deckhouse/backup` directory. If any issues or unexpected situations occur during operation, you can use these backups to restore the system to a previously healthy state.

Restoring etcd cluster functionality

If the etcd cluster is not functioning and cannot be restored from a backup, you can attempt to recover it from scratch by following the steps below.

1. On all nodes that are part of your etcd cluster, **except one**, delete the `etcd.yaml` manifest located in `/etc/kubernetes/manifests/`. This will leave only one active node, from which the multi-master cluster state will be restored.
2. On the remaining node, open the `etcd.yaml` manifest and add the `--force-new-cluster` flag under `spec.containers.command`.
3. After the cluster is successfully restored, remove the `--force-new-cluster` flag.

> This operation is destructive: it completely wipes the existing data and initializes a new cluster based on the state preserved on the remaining node. All pending records will be lost.

Restoring a master node when kubelet fails to load control plane components

Such a situation may occur if images of the control plane components on the master were deleted in a cluster that has a single master node (e.g., the directory `/var/lib/containerd` was deleted). In this case, kubelet cannot pull images of the control plane components when restarted since the master node lacks authorization parameters required for accessing `registry.deckhouse.io`.

Below is an instruction on how you can restore the master node.

containerd

1. Execute the following command to restore the master node in any cluster running under DP:

   ```
   d8 k -n d8-system get secrets deckhouse-registry -o json |
   jq -r '.data.".dockerconfigjson"' | base64 -d |
   jq -r '.auths."registry.deckhouse.io".auth'
   ```

2. Copy the command's output and use it for setting the `AUTH` variable on the corrupted master.
3. Next, pull images of control plane components to the corrupted master:

   ```
   for image in $(grep "image:" /etc/kubernetes/manifests/* | awk '{print $3}'); do
     crictl pull --auth $AUTH $image
   done
   ```

4. Restart kubelet after pulling the images.

etcd restore

Viewing etcd cluster members

Option 1

Use the `etcdctl member list` command.

Example:

```
for pod in $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name); do
  d8 k -n kube-system exec "$pod" -- etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
  --cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
  --endpoints https://127.0.0.1:2379/ member list -w table
  if [ $? -eq 0 ]; then
    break
  fi
done
```

Warning. The last parameter in the output table shows etcd member is in `learner` state, is not in `leader` state.

Option 2

To obtain information about etcd cluster nodes in tabular form, use the `etcdctl endpoint status` command. For the leader, the `IS LEADER` column will show `true`.

Example:

```
for pod in $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name); do
  d8 k -n kube-system exec "$pod" -- etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
  --cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
  --endpoints https://127.0.0.1:2379/ endpoint status --cluster -w table
  if [ $? -eq 0 ]; then
    break
  fi
done
```

Restoring the etcd cluster in case of complete unavailability

1. Stop all etcd nodes except one by deleting the `etcd.yaml` manifest on the others.
2. On the remaining node, add the `--force-new-cluster` option to the etcd startup command.
3. After the cluster is restored, remove this option.

✖ Be careful: these actions completely erase the previous data and form a new etcd cluster.

Recovering etcd after panic: unexpected removal of unknown remote peer error

1. Find the `etcdutl` utility on the master node and copy the executable to `/usr/local/bin/`:

   ```
   cp $(find /var/lib/containerd/ \
   -name etcdutl -print -quit) /usr/local/bin/etcdutl
   ```

2. Create a new etcd database snapshot from the current local snapshot (`/var/lib/etcd/member/snap/db`):

   ```
   etcdutl snapshot restore /var/lib/etcd/member/snap/db --name <HOSTNAME> \
   --initial-cluster=<HOSTNAME>=https://<ADDRESS>:2380 --initial-advertise-peer-
   urls=https://<ADDRESS>:2380 \
   --skip-hash-check=true --data-dir /var/lib/etcdtest
   ```

   where:

   - `<HOSTNAME>`: Name of the master node.
   - `<ADDRESS>`: Address of the master node.

3. Execute the following commands to use the new snapshot:

   ```
   cp -r /var/lib/etcd /tmp/etcd-backup
   rm -rf /var/lib/etcd
   mv /var/lib/etcdtest /var/lib/etcd
   ```

4. Locate the `etcd` and `api-server` containers:

   ```
   crictl ps -a | egrep "etcd|apiserver"
   ```

5. Remove the `etcd` and `api-server` containers:

   ```
   crictl rm <CONTAINER-ID>
   ```

6. Restart the master node.

Actions to take when etcd database exceeds quota-backend-bytes limit

When the database volume of etcd reaches the limit set by the `quota-backend-bytes` parameter, it switches to “read-only” mode. This means that the etcd database stops accepting new entries but remains available for reading data. You can tell that you are facing a similar situation by executing the command:

```
d8 k -n kube-system exec -ti $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o
name | sed -n 1p) -- \
etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
--cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
--endpoints https://127.0.0.1:2379/ endpoint status -w table --cluster
```

If you see a message like `alarm:NOSPACE` in the `ERRORS` field, you need to take the following steps:

1. Make change to `/etc/kubernetes/manifests/etcd.yaml` — find the line with `--quota-backend-bytes` and increase the value by multiplying the specified number by two. If there is no such line — add, for example: `- --quota-backend-bytes=8589934592` — this sets the limit to 8 GB.

2. Disarm the active alarm that occurred due to reaching the limit. To do this, execute the command:

```
d8 k -n kube-system exec -ti $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name | sed -n 1p) -- \
etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
--cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
--endpoints https://127.0.0.1:2379/ alarm disarm
```

3. Change the `maxDbSize` parameter in the `control-plane-manager` settings to match the value specified in the manifest.

etcd defragmentation

i In clusters with three or more etcd members, periodic etcd defragmentation is enabled by default. It runs once a day at exactly 1:00 a.m. server time. For more details, see the `control-plane-manager` module documentation.

⚠ Before defragmenting, back up etcd.

To view the size of the etcd database on a specific node before and after defragmentation, use the command (where `NODE_NAME` is the name of the master node):

```
d8 k -n kube-system exec -it etcd-NODE_NAME -- /usr/bin/etcdctl \
  --cert=/etc/kubernetes/pki/etcd/server.crt \
  --key=/etc/kubernetes/pki/etcd/server.key \
  --cacert=/etc/kubernetes/pki/etcd/ca.crt \
  endpoint status --cluster -w table
```

Output example (the size of the etcd database on the node is specified in the `DB SIZE` column):

```
+----------------------------+-----------------+---------+----------------+------

How to defragment an etcd node in a single-master cluster

⚠ Defragmenting etcd is a resource-intensive operation that temporarily blocks etcd from running on that node. Keep this in mind when choosing a time to perform the operation in a cluster with a single master node.

To defragment etcd in a cluster with a single master node, use the following command (where `NODE_NAME` is the name of the master node):

```
d8 k -n kube-system exec -ti etcd-NODE_NAME -- /usr/bin/etcdctl \
  --cacert /etc/kubernetes/pki/etcd/ca.crt \
  --cert /etc/kubernetes/pki/etcd/ca.crt \
  --key /etc/kubernetes/pki/etcd/ca.key \
  --endpoints https://127.0.0.1:2379/ defrag --command-timeout=30s
```

Example output when the operation is successful:

```
Finished defragmenting etcd member[https://localhost:2379]. took 848.948927ms
```

i If a timeout error occurs, increase the value of the `—command-timeout` parameter from the command above until defragmentation is successful.

How to defragment etcd in a cluster with multiple master nodes

To defragment etcd in a cluster with multiple master nodes:

1. Get a list of etcd pods. To do this, use the following command:

   ```
   d8 k -n kube-system get pod -l component=etcd -o wide
   ```

   Example output:

   ```
   NAME            READY    STATUS    RESTARTS   AGE     IP               NODE
   NOMINATED NODE   READINESS GATES
   etcd-master-0   1/1     Running   0          3d21h   192.168.199.80   master-0
   <none>           <none>
   etcd-master-1   1/1     Running   0          3d21h   192.168.199.81   master-1
   <none>           <none>
   etcd-master-2   1/1     Running   0          3d21h   192.168.199.82   master-2
   <none>           <none>
   ```

2. Identify the leader master node. To do this, contact any etcd pod and get a list of nodes participating in the etcd cluster using the command (where `NODE_NAME` is the name of the master node):

   ```
   d8 k -n kube-system exec -it etcd-NODE_NAME -- /usr/bin/etcdctl \
     --cert=/etc/kubernetes/pki/etcd/server.crt \
     --key=/etc/kubernetes/pki/etcd/server.key \
     --cacert=/etc/kubernetes/pki/etcd/ca.crt \
     endpoint status --cluster -w table
   ```

   Output example (the leader in the `IS LEADER` column will have the value `true`):

```
+----------------------------+------------------+---------+-----------------+-
--------+--------+----------------------+--------+------------+------------+--
---------+------------+--------------------+--------+--------------------------
+-------------------+
|          ENDPOINT          |        ID        | VERSION | STORAGE VERSION |
DB SIZE | IN USE | PERCENTAGE NOT IN USE | QUOTA  | IS LEADER  | IS LEARNER |
RAFT TERM | RAFT INDEX | RAFT APPLIED INDEX | ERRORS | DOWNGRADE TARGET VERSION
| DOWNGRADE ENABLED |
+----------------------------+------------------+---------+-----------------+-
--------+--------+----------------------+--------+------------+------------+--
---------+------------+--------------------+--------+--------------------------
+-------------------+
| https://192.168.199.80:2379 | 489a8af1e7acd7a0 |   3.6.1 |           3.6.0 |
76 MB |  62 MB |                  20% | 2.1 GB |       true |      false |
56 |  258054684 |          258054684 |        |                            |
false |
+----------------------------+------------------+---------+-----------------+-
--------+--------+----------------------+--------+------------+------------+--
---------+------------+--------------------+--------+--------------------------
+-------------------+
| https://192.168.199.81:2379 | 589a8ad1e7ccd7b0 |   3.6.1 |           3.6.0 |
76 MB |  62 MB |                  20% | 2.1 GB |      false |      false |
56 |  258054685 |          258054685 |        |                            |
false |
+----------------------------+------------------+---------+-----------------+-
--------+--------+----------------------+--------+------------+------------+--
---------+------------+--------------------+--------+--------------------------
+-------------------+
| https://192.168.199.82:2379 | 229a8cd1e7bcd7a0 |   3.6.1 |           3.6.0 |
76 MB |  62 MB |                  20% | 2.1 GB |      false |      false |
56 |  258054685 |          258054685 |        |                            |
false |
+----------------------------+------------------+---------+-----------------+-
--------+--------+----------------------+--------+------------+------------+--
---------+------------+--------------------+--------+--------------------------
+-------------------+
```

3. Defragment the etcd nodes that are members of the etcd cluster one by one. Use the following command to defragment (where `NODE_NAME` is the name of the master node):

> **i** Important: Defragment the leader last.
>
> Restoring etcd on a node after defragmentation may take some time. It is recommended to wait at least a minute before proceeding to defragment the next etcd node.

```
d8 k -n kube-system exec -ti etcd-NODE_NAME -- /usr/bin/etcdctl \
  --cacert /etc/kubernetes/pki/etcd/ca.crt \
  --cert /etc/kubernetes/pki/etcd/ca.crt \
  --key /etc/kubernetes/pki/etcd/ca.key \
  --endpoints https://127.0.0.1:2379/ defrag --command-timeout=30s
```

Example output when the operation is successful:

```
Finished defragmenting etcd member[https://localhost:2379]. took 848.948927ms
```

> **i** If a timeout error occurs, increase the value of the `–command-timeout` parameter from the command above until defragmentation is successful.

High availability

If any component of the control plane becomes unavailable, the cluster temporarily maintains its current state but cannot process new events. For example:

- If `kube-controller-manager` fails, Deployment scaling will stop working.
- If `kube-apiserver` is unavailable, no requests can be made to the Kubernetes API, although existing applications will continue to function.

However, prolonged unavailability of control plane components disrupts the processing of new objects, handling of node failures, and other operations. Over time, this can lead to cluster degradation and impact user applications.

To mitigate these risks, the control plane should be scaled to a high-availability configuration — a minimum of three nodes. This is especially critical for etcd, which requires a quorum to elect a leader. The quorum works on a majority basis (N/2 + 1) of the total number of nodes.

Example:

Cluster size	Quorum (majority)	Max fault tolerance
1	1	0
3	2	1
5	3	2
7	4	3
9	5	4

> **i** An even number of nodes does not improve fault tolerance but increases replication overhead.

In most cases, three etcd nodes are sufficient. Use five if high availability is critical. More than seven is rarely necessary and not recommended due to high resource consumption.

After new control plane nodes are added:

- The label `node-role.kubernetes.io/control-plane=""` is applied.
- A DaemonSet launches control plane pods on the new nodes.
- DP creates or updates files in `/etc/kubernetes`: manifests, configuration files, certificates, etc.
- All DP modules that support high availability will enable it automatically, unless the global setting `highAvailability` is manually overridden.

Control plane node removal is performed in reverse:

- Labels `node-role.kubernetes.io/control-plane`, `node-role.kubernetes.io/master`, and `node.deckhouse.io/group` are removed.
- DP removes its pods from these nodes.
- etcd members on the nodes are automatically deleted.
- If the number of nodes drops from two to one, etcd may enter `readonly` mode. In this case, you must start etcd with the `--force-new-cluster` flag, which should be removed after a successful startup.

Additional resources

- Global parameters
- Module `control-plane-manager` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Scaling and changing master nodes

Scaling and single/multi-master transition

Control plane operation modes

Deckhouse Platform (DP) supports two operation modes for the control plane:

1. **Single-master**:
   - `kube-apiserver` uses only the local `etcd` instance.
   - A proxy server runs on the node to handle requests on `localhost`.
   - The `kube-apiserver` listens only on the master node's IP address.
2. **Multi-master**:
   - `kube-apiserver` interacts with all `etcd` instances in the cluster.
   - A proxy is configured on all nodes:
     - If the local `kube-apiserver` is unavailable, requests are automatically forwarded to other nodes.
   - This ensures high availability and supports scaling.

Automatic scaling of master nodes

DP allows automatic addition and removal of master nodes using the label `node-role.kubernetes.io/control-plane=""`.

Automatic control of master nodes includes:

- **Adding the label** `node-role.kubernetes.io/control-plane=""` to a node:
  - All control plane components are deployed.
  - The node is added to the etcd cluster.
  - Certificates and configuration files are regenerated automatically.
- **Removing the label**:
  - Control plane components are removed.
  - The node is properly removed from the etcd cluster.
  - Related configuration files are updated.

> **i** Transitioning from 2 to 1 master node requires manual etcd adjustment. All other changes in master node count are handled automatically.

Common scaling scenarios

> **⚠** For cluster stability, it is necessary to maintain an odd number of nodes with etcd to ensure quorum.

DP supports both automatic and manual scaling of master nodes in cloud and bare-metal clusters:

1. **Single-master → Multi-master**:
   - Add one or more master nodes.
   - Apply the label `node-role.kubernetes.io/control-plane=""` to them.
   - DP will automatically:
     - Deploy all control plane components.
     - Configure the nodes to work with the `etcd` cluster.
     - Synchronize certificates and configuration files.
2. **Multi-master → Single-master**:
   - Remove the labels `node-role.kubernetes.io/control-plane=""` and `node-role.kubernetes.io/master=""` from the extra master nodes.
   - For **bare-metal clusters**:
     - To correctly remove the nodes from `etcd`:
       - Run `d8 k delete node <node-name>`;
       - Power off the corresponding VMs or servers.

   > **i** **Important**. In cloud clusters, all necessary actions are automatically handled by the `dhctl converge` command.

3. **Changing the number of master nodes in a cloud cluster**:
   - Similar to node addition/removal, typically done using the `dhctl converge` command or cloud tools.
4. **Multi-master migration (3 master nodes) → 2 master nodes and 1 arbiter node in a**

4. **Multi-master migration (3 master nodes) → 2 master nodes and 1 arbiter node in a cloud cluster**:

   - In the cloud provider settings, set `masterNodeGroup.replicas` to `2` and create a NodeGroup for the arbiter node. Similar to node addition/removal, typically done using the `dhctl converge` command or cloud tools.

     For details on configuring HA mode with 2 master nodes and 1 arbiter node in a cloud cluster, refer to Managing HA mode.

5. **Multi-master migration (3 master nodes) → 2 master nodes and 1 arbiter node in a static cluster**:

   - Create a NodeGroup for the arbiter node and add the node to the cluster.
   - Remove the labels `node-role.kubernetes.io/control-plane=""`, `node-role.kubernetes.io/master=""` and `node.deckhouse.io/group-""` from the extra master node.
   - To correctly remove the node from etcd in **bare-metal clusters**:
     - Run `d8 k delete node <node-name>`.
     - Power off the corresponding VM or server.

     For details on configuring HA mode with 2 master nodes and 1 arbiter node in a static cluster, refer to Managing HA mode.

Removing the master role from a node without deleting the node itself

> ⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before changing master nodes. Create a backup of the module's data before making any changes.

If you need to remove a node from the set of master nodes but keep it in the cluster for other purposes, follow these steps:

1. Remove the labels so the node is no longer treated as a master:

```
d8 k label node <node-name> node-role.kubernetes.io/control-plane-
d8 k label node <node-name> node-role.kubernetes.io/master-
d8 k label node <node-name> node.deckhouse.io/group-
```

2. Make sure that the master node to be deleted is no longer listed as a member of the etcd cluster:

```
for pod in $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name); do
  d8 k -n kube-system exec "$pod" -- etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
  --cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
  --endpoints https://127.0.0.1:2379/ member list -w table
  if [ $? -eq 0 ]; then
    break
  fi
done
```

3. Delete the static manifests of the control plane components so they no longer start on the node, and remove unnecessary PKI files. Exec to the node and run the following commands:

```
rm -f /etc/kubernetes/manifests/{etcd,kube-apiserver,kube-scheduler,kube-controller-manager}.yaml
rm -f /etc/kubernetes/{scheduler,controller-manager}.conf
rm -f /etc/kubernetes/authorization-webhook-config.yaml
rm -f /etc/kubernetes/admin.conf /root/.kube/config
rm -rf /etc/kubernetes/deckhouse
rm -rf /etc/kubernetes/pki/{ca.key,apiserver*,etcd/,front-proxy*,sa.*}
rm -rf /var/lib/etcd/member/
```

After completing these steps, the node will no longer be considered a master node, but it will remain part of the cluster and can be used for other tasks.

Changing the OS image of master nodes in a multi-master cluster

The OS change method depends on the cluster type: in a cloud cluster, nodes are replaced with `dhctl converge`; in a static cluster, nodes are replaced manually, one at a time.

For moving the nodes of the other types to a new image, see “How do I replace the OS image in a cloud cluster?”.

In a cloud cluster

To change the OS image of master nodes in a cloud multi-master cluster, follow these steps:

⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before changing master nodes. Create a backup of the module’s data before making any changes.

1. Create a backup of etcd and the `/etc/kubernetes` directory.
2. Copy the resulting archive outside the cluster (e.g., to a local machine).
3. Make sure there are no alerts in the cluster that could interfere with updating master nodes.
4. Ensure the DP queue is empty:

   ```
   d8 system queue list
   ```

5. **On your local machine**, log in to the registry (change the container registry address if necessary):

   ```
   docker login registry.deckhouse.io
   ```

   During the login process, you will need to enter your `Username` and `Password`.

   i When logging in to the `registry.deckhouse.io` registry, the `Username` field must be set to `license-token`, and the `Password` field must contain the Deckhouse Platform license key.

6. **On your local machine**, run the Deckhouse installer container for the corresponding edition and version (change the container registry address if necessary):

   ```
   DH_VERSION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/version}')
   DH_EDITION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/edition}' | tr '[:upper:]'
   '[:lower:]' )
   docker run --pull=always -it -v "$HOME/.ssh/:/tmp/.ssh/" \
     registry.deckhouse.io/deckhouse/${DH_EDITION}/install:${DH_VERSION} bash
   ```

7. **In the installer container**, run the following command to check the state before starting the operation:

   ```
   dhctl terraform check --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-
   user=<USERNAME> \
     --ssh-host <MASTER-NODE-0-HOST> --ssh-host <MASTER-NODE-1-HOST> --ssh-host <MASTER-NODE-2-
   HOST>
   ```

   The output should indicate that Terraform has found no discrepancies and no changes are required.

8. **In the installer container**, run the following command and specify the desired OS image in the `masterNodeGroup.instanceClass` parameter
   (provide all master node addresses using the `--ssh-host` parameter):

   ```
   dhctl config edit provider-cluster-configuration --ssh-agent-private-
   keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-user=<USERNAME> \
     --ssh-host <MASTER-NODE-0-HOST> --ssh-host <MASTER-NODE-1-HOST> --ssh-host <MASTER-NODE-2-
   HOST>
   ```

9. **In the installer container**, run the following command to update the nodes:

   Carefully review the actions that `converge` plans to perform when it prompts for confirmation.

During execution, nodes will be replaced with new ones, one by one, starting from the highest numbered node (2) down to the lowest (0):

```
dhctl converge --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-user=<USERNAME>
\
  --ssh-host <MASTER-NODE-0-HOST> --ssh-host <MASTER-NODE-1-HOST> --ssh-host <MASTER-NODE-2-
HOST>
```

The following steps should be performed **sequentially on each** master node, starting with the highest numbered node (with suffix 2) and ending with the lowest (with suffix 0).

10. **On the newly created node**, open the systemd journal for the `bashible.service`.
    Wait until the setup process is complete — the log should contain the message `nothing to do`:

    ```
    journalctl -fu bashible.service
    ```

11. Verify that the etcd node appears in the cluster node list:

    ```
    for pod in $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name); do
      d8 k -n kube-system exec "$pod" -- etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
      --cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
      --endpoints https://127.0.0.1:2379/ member list -w table
      if [ $? -eq 0 ]; then
        break
      fi
    done
    ```

12. Make sure that `control-plane-manager` is running on the node:

    ```
    d8 k -n kube-system wait pod --timeout=10m --for=condition=ContainersReady \
      -l app=d8-control-plane-manager --field-selector spec.nodeName=<MASTER-NODE-N-NAME>
    ```

13. Check the Deckhouse queue and make sure that there are no errors with the command:

    ```
    d8 system queue list
    ```

14. Proceed to updating the next master node.

In a static cluster

The following instruction describes OS replacement on master nodes that were added to the cluster **manually** using the `bootstrap.sh` script. Perform the steps for each master node, one node at a time. Do not proceed to the next node until the current node has rejoined the cluster and is healthy.

⚠ If master nodes are managed by Cluster API Provider Static (CAPS) through StaticInstance resources, do not use this instruction. First delete the StaticInstance, install the required OS, and add the node to the `master` NodeGroup again.

⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before adding or removing a master node. Create a backup of the module's data before making any changes.

To change the OS of a manually added master node, follow these steps:

1. Create a backup of etcd and the `/etc/kubernetes` directory. If the `stronghold` module is enabled, make sure its data has also been backed up.
2. Check the cluster health and make sure there are no alerts or pending Deckhouse queue tasks:

   ```
   d8 status
   ```

3. Remove the master node labels from the node:

```
d8 k label node <MASTER_NODE_NAME> node-role.kubernetes.io/control-plane- \
  node-role.kubernetes.io/master- node.deckhouse.io/group-
```

where `<MASTER_NODE_NAME>`: Name of the master node being changed.

4. Make sure the node has been removed from the etcd cluster member list:

```
for pod in $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name); do
  d8 k -n kube-system exec "$pod" -- etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
    --cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
    --endpoints https://127.0.0.1:2379/ member list -w table
  if [ $? -eq 0 ]; then
    break
  fi
done
```

5. Evict workloads from the node with `d8 k drain`:

```
d8 k drain <MASTER_NODE_NAME> --ignore-daemonsets --delete-emptydir-data
```

6. Force-delete any Pods remaining on the node:

```
d8 k delete pods --all-namespaces --field-selector spec.nodeName=<MASTER_NODE_NAME> --
force
```

7. Delete the Node object:

```
d8 k delete node <MASTER_NODE_NAME>
```

8. Clean up the DP data on the removed master node. This command irreversibly removes Kubernetes and DP data from the node. Before running it, make sure you have selected the correct node and created the required backups:

```
bash /var/lib/bashible/cleanup_static_node.sh --yes-i-am-sane-and-i-understand-what-i-am-
doing
```

9. Install the required OS on the node.
10. On one of the remaining master nodes in the cluster, retrieve and decode the script for adding a master node:

```
d8 k -n d8-cloud-instance-manager get secret manual-bootstrap-for-master \
  -o jsonpath='{.data.bootstrap\.sh}' | base64 -d > bootstrap.sh
```

11. Securely copy the `bootstrap.sh` file obtained in the previous step to the node being added and run it as `root` on that node:

```
bash bootstrap.sh
```

12. **On the node being added**, open the systemd journal for the `bashible.service`. Wait until the setup process is complete — the log should contain the message `nothing to do`:

```
journalctl -fu bashible.service
```

13. Wait until the node reaches the `Ready` status:

```
d8 k wait node <MASTER_NODE_NAME> --for=condition=Ready --timeout=10m
```

14. Make sure the node is listed as an etcd cluster member:

```
for pod in $(d8 k -n kube-system get pod -l component=etcd,tier=control-plane -o name); do
  d8 k -n kube-system exec "$pod" -- etcdctl --cacert /etc/kubernetes/pki/etcd/ca.crt \
    --cert /etc/kubernetes/pki/etcd/ca.crt --key /etc/kubernetes/pki/etcd/ca.key \
    --endpoints https://127.0.0.1:2379/ member list -w table
  if [ $? -eq 0 ]; then
    break
  fi
done
```

15. Make sure that `control-plane-manager` is running on the node:

```
d8 k -n kube-system wait pod --timeout=10m --for=condition=ContainersReady \
  -l app=d8-control-plane-manager --field-selector spec.nodeName=<MASTER_NODE_NAME>
```

16. Make sure there are no alerts or pending queue tasks:

```
d8 status
```

17. Repeat the procedure for the next master node.

Changing the OS image in a single-master cluster

The method depends on the cluster type: first add extra master nodes, replace the OS in multi-master mode, then restore the original number of master nodes.

⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before changing master nodes. Create a backup of the module's data before making any changes.

In a cloud cluster

1. Convert the single-master cluster into a multi-master one according to the instructions.
2. Change the OS on the master nodes according to the instructions.
3. Convert the multi-master cluster back to a single-master one following the instructions.

In a static cluster

1. Add extra master nodes according to the instructions.
2. Change the OS on the master nodes according to the instructions.
3. Remove extra master nodes from the control plane role according to the instructions. Then delete them from the cluster with `d8 k delete node <MASTER_NODE_NAME>` and power off the corresponding servers.

Adding master nodes to a static or hybrid cluster

i It is important to have an odd number of masters to ensure a quorum.

⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before changing master nodes. Create a backup of the module's data before making any changes.

When installing Deckhouse Platform with default settings, the NodeGroup `master` lacks the section `spec.staticInstances.labelSelector` with label filter settings for `staticInstances` resources. Because of this, after changing the number of `staticInstances` nodes in the NodeGroup `master` (parameter `spec.staticInstances.count`), when adding a regular node using Cluster API Provider Static (CAPS), it can be "intercepted" and added to the NodeGroup `master`, even if the corresponding `StaticInstance` (in `metadata`) specifies a label with a `role` different from `master`. To avoid this "interception", after installing DP, edit the NodeGroup `master` — add the section `spec.staticInstances.labelSelector` with label filter settings for `staticInstances` resources. Example of NodeGroup `master` with `spec.staticInstances.labelSelector`:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: master
spec:
  nodeType: Static
  staticInstances:
    count: 2
    labelSelector:
      matchLabels:
        role: master
```

Next, when adding master nodes to the cluster using CAPS, specify the label specified in `spec.staticInstances.labelSelector` NodeGroup `master` in the corresponding `StaticInstance`. Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: StaticInstance
metadata:
  name: static-master-1
  labels:
    # The label specified in spec.staticInstances.labelSelector NodeGroup master.
    role: master
spec:
  # Specify the IP address of the static node server.
  address: "<SERVER-IP>"
  credentialsRef:
    kind: SSHCredentials
    name: credentials
```

i

When adding new master nodes using CAPS and changing the number of master nodes in the NodeGroup `master` (parameter `spec.staticInstances.count`), please note the following:

During the initial cluster installation, the configuration specifies the first master node on which the installation takes place. If, after installation, you need to create a multi-master cluster and add master nodes using CAPS, you must specify the number of nodes in the `spec.staticInstances.count` parameter of the NodeGroup `master` as one less than the desired number.

For example, if you need to create a multi-master with three master nodes in `spec.staticInstances.count` NodeGroup `master`, specify the value `2` and create two `staticInstances` for the nodes to be added. After adding them to the cluster, the number of master nodes will be three: the master node on which the installation took place and two master nodes added using CAPS.

Otherwise, adding a master node to a static or hybrid cluster is similar to adding a regular node. To do this, use the corresponding examples. All the necessary actions to configure a cluster control plane components on the new master nodes are performed automatically. Wait until the master nodes appear in `Ready` status.

Adding master nodes in a cloud cluster

This section describes how to convert a single-master cluster into a multi-master cluster.

⚠ Before adding nodes, make sure the required quotas are available. It’s important to have an odd number of master nodes to maintain etcd quorum.

⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before adding or removing a master node. Create a backup of the module’s data before making any changes.

1. Create a backup of etcd and the `/etc/kubernetes` directory.
2. Copy the resulting archive outside the cluster (e.g., to a local machine).
3. Ensure there are no active alerts in the cluster that may interfere with adding new master nodes.
4. Make sure the Deckhouse queue is empty:

   ```
   d8 system queue list
   ```

5. **On your local machine**, log in to the registry (change the container registry address if necessary):

   ```
   docker login registry.deckhouse.io
   ```

   During the login process, you will need to enter your `Username` and `Password`.

   > **i** When logging in to the `registry.deckhouse.io` registry, the `Username` field must be set to `license-token`, and the `Password` field must contain the Deckhouse Platform license key.

6. On the **local machine**, run the Deckhouse installer container for the appropriate edition and version (change the container registry address if necessary):

   ```
   DH_VERSION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/version}')
   DH_EDITION=$(d8 k -n d8-system get deployment deckhouse -o
   jsonpath='{.metadata.annotations.core\.deckhouse\.io\/edition}' | tr '[:upper:]'
   '[:lower:]' )
   docker run --pull=always -it -v "$HOME/.ssh/:/tmp/.ssh/" \
     registry.deckhouse.io/deckhouse/${DH_EDITION}/install:${DH_VERSION} bash
   ```

7. **In the installer container**, run the following command to verify the state before proceeding:

   ```
   dhctl terraform check --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-
   user=<USERNAME> --ssh-host <MASTER-NODE-0-HOST>
   ```

   The output should confirm that Terraform found no differences and no changes are needed.

8. **In the installer container**, run the following command and set the target number of master nodes in the `masterNodeGroup.replicas` parameter:

   ```
   dhctl config edit provider-cluster-configuration --ssh-agent-private-
   keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-user=<USERNAME> \
     --ssh-host <MASTER-NODE-0-HOST>
   ```

   > **i** For **Yandex Cloud**, if public IPs are assigned to master nodes, the number of elements in the `masterNodeGroup.instanceClass.externalIPAddresses` array must match the number of master nodes. Even when using the `Auto` value (automatic public IP assignment), the number of items in the array must still match.
   >
   > For example, with three master nodes (`masterNodeGroup.replicas: 3`) and automatic IP assignment, the `masterNodeGroup.instanceClass.externalIPAddresses` section would look like:
   >
   > ```
   > externalIPAddresses:
   > - "Auto"
   > - "Auto"
   > - "Auto"
   > ```

9. **In the installer container**, run the following command to trigger scaling:

```
dhctl converge --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-user=<USERNAME>
--ssh-host <MASTER-NODE-0-HOST>
```

10. Wait until the required number of master nodes reaches the `Ready` status and all `control-plane-manager` pods become ready:

```
d8 k -n kube-system wait pod --timeout=10m --for=condition=ContainersReady -l app=d8-
control-plane-manager
```

Reducing the number of master nodes in a cloud cluster

This section describes the process of converting a multi-master cluster into a single-master cluster.

⚠ The following steps must be performed starting from the first master node (`master-0`) in the cluster. This is because the cluster scales in order — for example, it is not possible to remove `master-0` and `master-1` while leaving `master-2`.

⚠ If your cluster uses the `stronghold` module, make sure the module is fully operational before adding or removing a master node. Create a backup of the module's data before making any changes.

1. Create a backup of etcd and the `/etc/kubernetes` directory.
2. Copy the resulting archive outside the cluster (e.g., to a local machine).
3. Ensure there are no alerts in the cluster that may interfere with the master node update process.
4. Make sure the DP queue is empty:

```
d8 system queue list
```

5. **On your local machine**, log in to the registry (change the container registry address if necessary):

```
docker login registry.deckhouse.io
```

During the login process, you will need to enter your `Username` and `Password`.

i When logging in to the `registry.deckhouse.io` registry, the `Username` field must be set to `license-token`, and the `Password` field must contain the Deckhouse Platform license key.

6. On the **local machine**, run the DP installer container for the corresponding edition and version (change the container registry address if needed):

```
DH_VERSION=$(d8 k -n d8-system get deployment deckhouse -o
jsonpath='{.metadata.annotations.core\.deckhouse\.io\/version}')
DH_EDITION=$(d8 k -n d8-system get deployment deckhouse -o
jsonpath='{.metadata.annotations.core\.deckhouse\.io\/edition}' | tr '[:upper:]'
'[:lower:]' )
docker run --pull=always -it -v "$HOME/.ssh/:/tmp/.ssh/" \
  registry.deckhouse.io/deckhouse/${DH_EDITION}/install:${DH_VERSION} bash
```

7. **In the installer container**, run the following command and set `masterNodeGroup.replicas` to `1`:

```
dhctl config edit provider-cluster-configuration --ssh-agent-private-
keys=/tmp/.ssh/<SSH_KEY_FILENAME> \
  --ssh-user=<USERNAME> --ssh-host <MASTER-NODE-0-HOST>
```

> **i** For **Yandex Cloud**, if external IPs are used for master nodes, the number of items in the `masterNodeGroup.instanceClass.externalIPAddresses` array must match the number of master nodes. Even when using `Auto` (automatic public IP allocation), the number of entries must still match.
>
> For example, for a single master node (`masterNodeGroup.replicas: 1`) and automatic IP assignment, the `masterNodeGroup.instanceClass.externalIPAddresses` section would look like:
>
> ```
> externalIPAddresses:
> - "Auto"
> ```

8. **In the installer container**, run the following command to trigger the scaling operation:

   ```
   dhctl converge --ssh-agent-private-keys=/tmp/.ssh/<SSH_KEY_FILENAME> --ssh-user=<USERNAME>
   --ssh-host <MASTER-NODE-0-HOST>
   ```

   > **i** For **OpenStack** and **VK Cloud (OpenStack)**, after confirming the node deletion, it is extremely important to check the disk deletion `<prefix>kubernetes-data-N` in Openstack itself.
   >
   > For example, when deleting the `cloud-demo-master-2` node in the Openstack web interface or in the OpenStack CLI, it is necessary to check the absence of the `cloud-demo-kubernetes-data-2` disk.
   >
   > If the kubernetes-data disk remains, there may be problems with ETCD operation as the number of master nodes increases.

9. Check the Deckhouse queue and make sure that there are no errors with the command:

   ```
   d8 system queue list
   ```

Accessing the DP controller in a multi-master cluster

In clusters with multiple master nodes, DP runs in high-availability mode (with multiple replicas). To access the active DP controller, you can use the following command (example shown for the `deckhouse-controller queue list` command):

```
d8 system queue list
```

- Module `node-manager` custom resources
- Module `stronghold` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Node management basics in Deckhouse

Deckhouse Platform (DP) supports the full lifecycle of node management:

- Automatic node scaling based on workload.
- Node updates and maintenance to keep them up to date.
- Centralized configuration management for node groups using the NodeGroup CRD.
- Support for various types of nodes: permanent, ephemeral, cloud-based, or bare-metal.

> **i** DP can operate on both bare-metal and cloud-based clusters, providing flexibility and scalability.

Node groups allow logical segmentation of the cluster infrastructure. In DP, the following NodeGroup roles are commonly used:

- `master`: Control plane nodes.
- `front`: Nodes for routing HTTP(S) traffic.
- `monitoring`: Nodes for hosting monitoring components.
- `worker`: Nodes for user applications.
- `system`: Dedicated nodes for system components.

Each group can have centralized configuration settings, including the Kubernetes version, resources, taints, labels, kubelet parameters, and more.

> **i** Node management is only available for clusters fully managed by DP. This feature is not supported for Managed Kubernetes clusters.

Automatic deployment and updates

Deckhouse Platform (DP) provides an automated mechanism for managing the lifecycle of nodes based on NodeGroup resources. DP supports both initial node provisioning and updates when configuration changes, for both cloud and bare-metal clusters (if the `node-manager` module is enabled).

How it works:

1. A NodeGroup is the primary resource for managing groups of nodes. It defines the node type, number of nodes, resource templates, and key parameters (e.g., kubelet settings, taints, etc.).
2. When a NodeGroup is created or modified, the `node-manager` module automatically reconciles the node state with the specified configuration.
3. Updates occur without user intervention — outdated nodes are removed, and new ones are created automatically.

Let’s take a look at automatic updates using the example of a kubelet version upgrade.

1. The user updates the `kubelet` section in the NodeGroup specification.
2. DP detects that current nodes do not match the new configuration.
3. New nodes with the updated settings are created sequentially.
4. Old nodes are gradually removed from the cluster.

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker-cloud
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: AnotherCloudInstanceClass
      name: my-class
```

Basic node and OS configuration

When nodes are created and joined to the cluster, DP automatically performs a series of actions required for proper cluster operation:

- Installing and configuring a supported operating system.
- Disabling automatic package updates.
- Setting up logging and system parameters.
- Installing necessary packages and utilities.
- Configuring the `kubernetes-api-proxy` component to balance traffic between `kubelet` and API servers.
- Installing and configuring the container runtime (`containerd`) and `kubelet`.
- Registering the node with the Kubernetes cluster.

These actions are performed automatically when using `bootstrap.sh` or when connecting nodes via StaticInstance and SSHCredentials resources.

Disruptive updates

Some updates — for example, upgrading `containerd` or kubelet across multiple versions — require node downtime and may cause short-term disruption of system components (*disruptive updates*).
The application mode for such updates is configured via the `disruptions.approvalMode` parameter:

- `Manual`: Manual approval mode for disruptive updates.
  When a disruptive update is available, the `NodeRequiresDisruptionApprovalForUpdate` alert is triggered.

  To approve the update, add the annotation `update.node.deckhouse.io/disruption-approved=` to each node in the group. Example:

  ```
  d8 k annotate node <NODE-NAME> update.node.deckhouse.io/disruption-approved=
  ```

  > **Important**: In this mode, the node is not drained automatically.
  > If needed, perform the drain manually before applying the annotation.
  >
  > To avoid issues during draining, always use the `Manual` mode for master node groups.

- `Automatic`: Automatic approval mode for disruptive updates.

  In this mode, the node is drained automatically before applying the update by default.
  This behavior can be changed using the `disruptions.automatic.drainBeforeApproval` parameter in the node group settings.

- `RollingUpdate`: A mode in which a new node with updated settings is created and the old one is removed.
  Applicable only to cloud nodes.

  In this mode, an additional node is created in the cluster during the update.
  This can be useful if the cluster lacks sufficient resources to temporarily relocate workloads from the updating node.

Example of a system NodeGroup

System nodes are dedicated to running system components.
They are typically isolated using labels and taints to prevent user pods from being scheduled on them.
System nodes can be either static or cloud-based.

Example:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: system
spec:
  nodeTemplate:
    labels:
      node-role.deckhouse.io/system: ""
    taints:
      - effect: NoExecute
        key: dedicated.deckhouse.io
        value: system
  nodeType: Static
```

Example NodeGroupConfiguration descriptions

Installing the cert-manager plugin for kubectl on master nodes

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: add-cert-manager-plugin.sh
spec:
  weight: 100
  bundles:
  - "*"
  nodeGroups:
  - "master"
  content: |
    if [ -x /usr/local/bin/kubectl-cert_manager ]; then

Werf configuration for ignoring the Ready status of a node group

Werf checks the `Ready` status of resources and, if available, waits for the value to become `True`.

Creating (or updating) a NodeGroup resource in the cluster may take a significant amount of time (until all nodes become ready). When using werf (e.g., in CI/CD), this can lead to a build timeout.

To make werf ignore the NodeGroup status, add the following annotations to the NodeGroup resource:

```
metadata:
  annotations:
    werf.io/fail-mode: IgnoreAndContinueDeployProcess
    werf.io/track-termination-mode: NonBlocking
```

Settings for Static and CloudStatic NodeGroups

Node groups with types Static and CloudStatic are intended for managing manually created nodes — either physical (bare-metal) or virtual (in the cloud, but outside DP automation). These nodes are connected manually or via StaticInstance and do not support automatic updates or scaling.

Configuration specifics:

- All update operations (e.g., kubelet updates, node restarts, replacements) must be performed manually or through external automation tools outside of DP.
- It is recommended to explicitly set the desired kubelet version to ensure consistency across nodes, especially if they are added with different versions manually:

  ```
  nodeTemplate:
    kubelet:
      version: "1.28"
  ```

- Node registration to the cluster can be performed either manually or automatically, depending on the configuration:
  - **Manual**: The user downloads the bootstrap script, configures the server, and runs the script manually.
  - **Automatic (CAPS)**: When using StaticInstance and SSHCredentials, DP automatically connects and configures the nodes.
  - **Hybrid approach**: A manually added node can be handed over to CAPS by using the annotation `static.node.deckhouse.io/skip-bootstrap-phase: ""`.

If the Cluster API Provider Static (CAPS) is enabled, the NodeGroup resource can use the `staticInstances` section. This allows DP to automatically connect, configure, and, if necessary, clean up static nodes based on StaticInstance and SSHCredentials resources.

> **i** In a NodeGroup of type Static or CloudStatic, you can explicitly specify the number of nodes using the `spec.staticInstances.count` parameter. This allows you to define the expected number of nodes — DP uses this value for state monitoring and automation.

Running DP on an arbitrary node

To run DP on an arbitrary node, configure the `deckhouse` module with the appropriate `nodeSelector` parameter and **do not** specify `tolerations`. The required `tolerations` will be set automatically in this case.

> **⚠** Only use nodes of type **CloudStatic** or **Static** to run DP. Avoid using a `NodeGroup` that contains only a single node for running DP.

Example module configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  settings:
    nodeSelector:
      node-role.deckhouse.io/deckhouse: ""
```

Additional resources

- Module `deckhouse` parameters
- Module `node-manager` custom resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Adding and managing cloud nodes

In Deckhouse Platform (DP), cloud nodes can be of the following types:

- **CloudEphemeral** — temporary nodes that are automatically created and deleted.
- **CloudPermanent** — permanent nodes managed manually via `replicas`.
- **CloudStatic** — static cloud nodes. The machines are created manually or by external tools and DP connects them to the cluster and manages them just like the regular nodes.

Below are instructions for adding and configuring each type.

Adding CloudEphemeral nodes in a cloud cluster

CloudEphemeral nodes are automatically created and managed within the cluster using the Machine Controller Manager (MCM) or Cluster API (depending on configuration) — both components are part of the `node-manager` module in DP.

To add nodes:

1. Ensure that the cloud provider module is enabled. For example: `cloud-provider-yandex`, `cloud-provider-openstack`, `cloud-provider-aws`.
2. Create an InstanceClass object with the machine configuration. This object describes the parameters of the virtual machines to be created in the cloud.

   Example (for OpenStack):

```
apiVersion: deckhouse.io/v1
kind: OpenStackInstanceClass
metadata:
  name: worker-instance
spec:
  flavorName: m1.medium
  imageName: ubuntu-24-04-cloud-amd64
  rootDiskSize: 20
  mainNetwork: default
```

The following parameters are specified:

- `flavorName`: Instance type (CPU/RAM).
- `imageName`: OS image.
- `rootDiskSize`: Size of the root disk.
- `mainNetwork`: Cloud network for the instance.

3. Create a NodeGroup with the `CloudEphemeral` type. Example manifest:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: workers
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: OpenStackInstanceClass
      name: worker-instance
    minPerZone: 1
    maxPerZone: 3
    zones:
      - nova
  nodeTemplate:
    labels:
      node-role.deckhouse.io/worker: ""
    taints: []
```

4. Wait for the nodes to be launched and added automatically.

Configuration for CloudEphemeral NodeGroups

NodeGroups of CloudEphemeral type are designed for automatic scaling by creating and removing virtual machines in the cloud using the Machine Controller Manager (MCM). This type of groups is commonly used in cloud-based DP clusters.

Node configuration is defined in the `cloudInstances` section and includes parameters for scaling, zoning, fault tolerance, and prioritization.

Example basic configuration:

```
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    minPerZone: 1
    maxPerZone: 5
    maxUnavailablePerZone: 1
    zones:
    - ru-central1-a
    - ru-central1-b
```

Modifying the cloud provider configuration in a cluster

The configuration of the cloud provider used in a cloud or hybrid cluster is stored in the

`<PROVIDER_NAME>ClusterConfiguration` structure, where `<PROVIDER_NAME>` is the name/code of the provider. For example, for the OpenStack provider, the structure is called OpenStackClusterConfiguration.

Regardless of the cloud provider used, its settings can be modified using the following command:

```
d8 system edit provider-cluster-configuration
```

For moving the nodes to a new operating system image, see “How do I replace the OS image in a cloud cluster?”.

NodeGroup autoscaling

In Deckhouse Platform (DP), node group autoscaling is performed based on resource demands (CPU and memory) by the `Cluster Autoscaler` component, which is part of the `node-manager` module.

Autoscaling is triggered only when there are Pending pods that cannot be scheduled on existing nodes due to insufficient resources (e.g., CPU or memory). In this case, `Cluster Autoscaler` attempts to add nodes based on the NodeGroup configuration.

Key scaling parameters are defined in the `cloudInstances` section of the NodeGroup resource:

- `minPerZone`: The minimum number of virtual machines per zone. This number is always maintained, even with no workload.
- `maxPerZone`: The maximum number of nodes that can be created per zone. This defines the upper scaling limit.
- `maxUnavailablePerZone`: Limits the number of unavailable nodes during updates, deletions, or creation.
- `standby`: Optional parameter that allows pre-provisioning standby nodes.
- `priority`: Integer priority of the group. When scaling, `Cluster Autoscaler` prefers groups with a higher `priority` value. This allows you to define scaling order among multiple NodeGroups. You can control the rate at which nodes are switched to lower-priority groups on demand (for more details, see the FAQ).

Example configuration of a NodeGroup with autoscaling:

```
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    minPerZone: 1       # Minimum number of nodes per zone.
    maxPerZone: 5       # Maximum number of nodes per zone.
    maxUnavailablePerZone: 1  # Number of nodes that can be updated/removed
simultaneously.
    zones:
      - nova
      - supernova
      - hypernova
```

Example autoscaling scenario

Assume the following NodeGroup configuration:

```
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    classReference:
      kind: OpenStackInstanceClass
      name: m4.large
    minPerZone: 1
    maxPerZone: 5
    zones:
      - nova
      - supernova
      - hypernova
```

There is also a Deployment with the following configuration:

```
kind: Deployment
spec:
  replicas: 3
  template:
    spec:
      containers:
      - name: app
        resources:
          requests:
            cpu: 1500m
            memory: 5Gi
```

In this case, launching all replicas will require 3 nodes — one in each zone.

Now let's increase the number of replicas to 5. As a result, two Pods will enter the `Pending` state.

`Cluster Autoscaler`:

- Detects the situation.
- Calculates the amount of lacking resources.
- Decides to create two more nodes.
- Hands off the task to the Machine Controller Manager.
- Two new VMs will be created in the cloud and automatically join the cluster.
- The Pods will be scheduled onto the new nodes.

Allocating nodes for specific workloads

⚠ You cannot use the `deckhouse.io` domain in `labels` and `taints` keys of the NodeGroup. It is reserved for DP components. Use the `dedicated` or `dedicated.client.com` keys instead.

There are two ways to solve this problem:

1. You can set labels to NodeGroup `spec.nodeTemplate.labels`, to use them in the `Pod`'s `spec.nodeSelector` or `spec.affinity.nodeAffinity` parameters. In this case, you select nodes that the scheduler will use for running the target application.
2. You cat set taints to NodeGroup's `spec.nodeTemplate.taints` and then remove them via the `Pod`'s `spec.tolerations` parameter. In this case, you disallow running applications on these nodes unless those applications are explicitly allowed.

i DP tolerates the `dedicated` key by default, so we recommend using the `dedicated` key with any value for taints on your dedicated nodes.

To use custom keys for taints (e.g., `dedicated.client.com`), you must add the key's value to the `modules.placement.customTolerationKeys` parameter. This way, Deckhouse can deploy system components (e.g., `cni-flannel`) to these dedicated nodes.

Accelerating node provisioning in the cloud during horizontal application scaling

To speed up the launch of new application replicas during automatic horizontal scaling, it is recommended to maintain a certain number of pre-provisioned (standby) nodes in the cluster. This allows new application Pods to be scheduled quickly without waiting for node creation and initialization. Keep in mind that having standby nodes increases infrastructure costs.

The target NodeGroup configuration should be as follows:

1. Specify the absolute number of pre-provisioned nodes (or a percentage of the maximum number of nodes in the group) using the `cloudInstances.standby` parameter.
2. If there are additional service components on nodes that are not handled by Deckhouse (e.g., the `filebeat` DaemonSet), you can specify the percentage of node resources they can consume via the `standbyHolder.overprovisioningRate` parameter.
3. This feature requires that at least one group node is already running in the cluster. In other words, there must be either a single replica of the application, or the `cloudInstances.minPerZone` parameter must be set to `1`.

Example:

```
cloudInstances:
  maxPerZone: 10
  minPerZone: 1
  standby: 10%
  standbyHolder:
    overprovisioningRate: 30%
```

Example NodeGroup definition

Cloud nodes

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: test
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    zones:
      - eu-west-1a
      - eu-west-1b
    minPerZone: 1
    maxPerZone: 2
    classReference:
      kind: AWSInstanceClass
      name: test
  nodeTemplate:
    labels:
      tier: test
```

Configuring CloudEphemeral nodes using NodeGroupConfiguration

Additional settings for cloud nodes can be defined using NodeGroupConfiguration objects. These allow you to:

- Modify OS parameters (e.g., `sysctl`).
- Add root certificates.
- Configure trust for private image registries, etc.

NodeGroupConfiguration is applied to new nodes at creation time, including CloudEphemeral nodes.

> **i**
> NodeGroupConfiguration applies only to nodes with a specified operating system image (`bundle`).
> You can set the `bundle` value to a specific name (e.g., `ubuntu-lts`, `centos-7`, `rocky-linux`) or use `*` to apply the configuration to all OS images.

Example NodeGroupConfiguration definitions

Setting a sysctl parameter

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: sysctl-tune.sh
spec:
  weight: 100
  bundles:
  - "*"
  nodeGroups:
  - "*"
  content: |
    sysctl -w vm.max_map_count=262144
```

Adding a root certificate to the host

⚠

- This example is for Ubuntu OS.
  The method for adding certificates to the trust store may differ depending on the OS.
  When adapting the script to another OS, adjust the `bundles` and `content` fields accordingly.
- To use the certificate in `containerd`, you must restart the `containerd` service after adding the certificate.

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: add-custom-ca.sh
spec:
  weight: 31
  nodeGroups:
  - '*'
  bundles:
  - 'ubuntu-lts'
  content: |-
    CERT_FILE_NAME=example_ca
    CERTS_FOLDER="/usr/local/share/ca-certificates"
    CERT_CONTENT=$(cat <<EOF
    -----BEGIN CERTIFICATE-----
    MIIDSjCCAjKgAwIBAgIRAJ4RR/WDuAym7M11JA8W7D0wDQYJKoZIhvcNAQELBQAw
    ...
    -----END CERTIFICATE-----
    EOF
    )

    # bb-event           - Creating subscription for event function. More
information: http://www.bashbooster.net/#event
    ## ca-file-updated   - Event name
    ## update-certs      - The function name that the event will call

    bb-event-on "ca-file-updated" "update-certs"

    update-certs() {          # Function with commands for adding a certificate to
the store
      update-ca-certificates
    }

    # bb-tmp-file - Creating temp file function. More information:
http://www.bashbooster.net/#tmp
    CERT_TMP_FILE="$( bb-tmp-file )"
    echo -e "${CERT_CONTENT}" > "${CERT_TMP_FILE}"

    # bb-sync-file                                - File synchronization function.
More information: http://www.bashbooster.net/#sync
    ## "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt"    - Destination file
    ##  ${CERT_TMP_FILE}                          - Source file
    ##  ca-file-updated                           - Name of event that will be called
if the file changes.

    bb-sync-file \
      "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt" \
      ${CERT_TMP_FILE} \
      ca-file-updated
```

Adding a certificate to the OS and containerd

> ⚠ This example is for Ubuntu OS.
> The method for adding certificates to the trust store may differ depending on the OS.
> When adapting the script to another OS, update the `bundles` and `content` parameters accordingly.

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: add-custom-ca-containerd.sh
```

```
spec:
  weight: 31
  nodeGroups:
  - '*'
  bundles:
  - 'ubuntu-lts'
  content: |-
    REGISTRY_URL=private.registry.example
    CERT_FILE_NAME=${REGISTRY_URL}
    CERTS_FOLDER="/usr/local/share/ca-certificates"
    CERT_CONTENT=$(cat <<EOF
    -----BEGIN CERTIFICATE-----
    MIIDSjCCAjKgAwIBAgIRAJ4RR/WDuAym7M11JA8W7D0wDQYJKoZIhvcNAQELBQAw
    ...
    -----END CERTIFICATE-----
    EOF
    )
    CONFIG_CONTENT=$(cat <<EOF
    [plugins]
      [plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".tls]
        ca_file = "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt"
    EOF
    )

    mkdir -p /etc/containerd/conf.d

    # bb-tmp-file - Create temp file function. More information:
http://www.bashbooster.net/#tmp

    CERT_TMP_FILE="$( bb-tmp-file )"
    echo -e "${CERT_CONTENT}" > "${CERT_TMP_FILE}"

    CONFIG_TMP_FILE="$( bb-tmp-file )"
    echo -e "${CONFIG_CONTENT}" > "${CONFIG_TMP_FILE}"

    # bb-event           - Creating subscription for event function. More
information: http://www.bashbooster.net/#event
    ## ca-file-updated   - Event name
    ## update-certs      - The function name that the event will call

    bb-event-on "ca-file-updated" "update-certs"

    update-certs() {          # Function with commands for adding a certificate to
the store
      update-ca-certificates  # Restarting the containerd service is not required as
this is done automatically in the script 032_configure_containerd.sh
    }

    # bb-sync-file                                - File synchronization function.
More information: http://www.bashbooster.net/#sync
    ## "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt"    - Destination file
    ##  ${CERT_TMP_FILE}                          - Source file
    ##  ca-file-updated                           - Name of event that will be called
if the file changes.

    bb-sync-file \
      "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt" \
      ${CERT_TMP_FILE} \
      ca-file-updated

    bb-sync-file \
      "/etc/containerd/conf.d/${REGISTRY_URL}.toml" \
      ${CONFIG_TMP_FILE}
```

Kernel update on nodes

Debian-based distros

Create a NodeGroupConfiguration resource by specifying the target kernel version in the `desired_version` variable of the shell script (the resource's `spec.content` parameter):

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: install-kernel.sh
spec:
  bundles:
    - '*'
  nodeGroups:
    - '*'
  weight: 32
  content: |
    # Copyright 2022 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    desired_version="5.15.0-53-generic"

    bb-event-on 'bb-package-installed' 'post-install'
    post-install() {
      bb-log-info "Setting reboot flag due to kernel was updated"
      bb-flag-set reboot
    }

    version_in_use="$(uname -r)"

    if [[ "$version_in_use" == "$desired_version" ]]; then
      exit 0
    fi

    bb-deckhouse-get-disruptive-update-approval
    bb-apt-install "linux-image-${desired_version}"
```

CentOS-based distros

Create a NodeGroupConfiguration resource by specifying the target kernel version in the `desired_version` variable of the shell script (the resource's `spec.content` parameter):

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: install-kernel.sh
spec:
  bundles:
    - '*'
  nodeGroups:
    - '*'
  weight: 32
  content: |
    # Copyright 2022 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    desired_version="3.10.0-1160.42.2.el7.x86_64"

    bb-event-on 'bb-package-installed' 'post-install'
    post-install() {
      bb-log-info "Setting reboot flag due to kernel was updated"
      bb-flag-set reboot
    }

    version_in_use="$(uname -r)"

    if [[ "$version_in_use" == "$desired_version" ]]; then
      exit 0
    fi

    bb-deckhouse-get-disruptive-update-approval
    bb-dnf-install "kernel-${desired_version}"
```

Adding CloudPermanent nodes to a cloud cluster

To add `CloudPermanent` nodes to a DP cloud cluster:

1. Make sure that the corresponding cloud provider module is enabled, for example, `cloud-provider-yandex`, `cloud-provider-openstack`, or `cloud-provider-aws`.

   You can check the status of a specific module using the following command:

   ```
   d8 k -n d8-system get module <MODULE_NAME>
   ```

   For example:

   ```
   d8 k -n d8-system get module cloud-provider-yandex
   ```

2. Add a `CloudPermanent` node group to the `nodeGroups` section of the `(Provider)ClusterConfiguration` object. `CloudPermanent` nodes are managed by Terraform built into DP.

   To edit the configuration of a running cluster, use the following command:

```
d8 system edit provider-cluster-configuration
```

Example:

```
nodeGroups:
- name: cloud-permanent
  replicas: 2
  instanceClass:
    flavorName: m1.large
    imageName: ubuntu-24-04-cloud-amd64
    rootDiskSize: 20
    mainNetwork: default
  volumeTypeMap:
    nova: ceph-ssd
```

3. Specify the instance template parameters. The fields inside `instanceClass` depend on the cloud provider. The following fields are used in the OpenStack example:
   - `flavorName` — instance type and its resources, such as CPU and RAM
   - `imageName` — operating system image
   - `rootDiskSize` — root disk size in GB
   - `mainNetwork` — network name
   - optionally: etcd disk, zones, volume types, and other parameters

   Field names and structure may differ for other cloud providers. Refer to the `(Provider)ClusterConfiguration` specification or the documentation for the corresponding cloud provider, for example, YandexClusterConfiguration.
4. Start the DP installer container on your local computer or an administrative host. Use an image with the same edition and version as the cluster:

```
docker run --pull=always --rm -it \
  -v "$HOME/.ssh/:/tmp/.ssh/" \
  registry.deckhouse.io/deckhouse/<EDITION>/install:<VERSION> \
  bash
```

5. In the installer container, check the Terraform state:

```
dhctl terraform check \
  --ssh-host <MASTER_NODE_IP> \
  --ssh-user <USER_NAME> \
  --ssh-agent-private-keys /tmp/.ssh/<KEY>
```

6. Apply the configuration. For the `--ssh-user` parameter, specify a user that can connect to the master node over SSH and execute commands using `sudo`:

```
dhctl converge \
  --ssh-host <MASTER_NODE_IP> \
  --ssh-user <USER_NAME> \
  --ssh-agent-private-keys /tmp/.ssh/<KEY>
```

   This command will:
   - run Terraform
   - create the required virtual machines
   - bootstrap and configure the new nodes
   - register the nodes in the cluster
7. The new nodes will automatically appear in the cluster. You can check that the nodes have been added using the following command:

```
d8 k get nodes
```

   The new nodes are also available in the Deckhouse web interface.

Deckhouse Platform can run on top of Managed Kubernetes services, such as GKE and EKS. In this case, the `node-manager` module manages node configuration and automates node-related operations, but some features may be limited by the API of the corresponding cloud provider.

Adding a CloudStatic node to a cluster

Adding a static node can be done manually or using the Cluster API Provider Static (CAPS).

Manually

Follow the steps below to add a new static node (e.g., VM or bare metal server) to the cluster:

1. For CloudStatic nodes in the following cloud providers, refer to the steps outlined in the documentation:
   - For AWS
   - For GCP
   - For YC
2. Use the existing NodeGroup resource or create a new one. The `nodeType` parameter for static nodes in the NodeGroup must be set to `Static` or `CloudStatic`.
3. Get the Base64-encoded script code to add and configure the node.

   Here is how you can get Base64-encoded script code to add a node to the `worker` NodeGroup:

   ```
   NODE_GROUP=worker
   d8 k -n d8-cloud-instance-manager get secret manual-bootstrap-for-${NODE_GROUP} -o json | jq '.data."bootstrap.sh"' -r
   ```
4. Pre-configure the new node according to the specifics of your environment. For example:
   - Add all the necessary mount points to the `/etc/fstab` file (NFS, Ceph, etc.).
   - Install the necessary packages.
   - Configure network connectivity between the new node and the other nodes of the cluster.
5. Connect to the new node over SSH and run the following command, inserting the Base64 string you got in step 3:

   ```
   echo <Base64-CODE> | base64 -d | bash
   ```

Using the Cluster API Provider Static

A brief example of adding a static node to a cluster using Cluster API Provider Static (CAPS):

1. Prepare the necessary resources.

   - Allocate a server (or a virtual machine), configure networking connectivity, etc. If required, install specific OS packages and add the mount points on the node.
   - Create a user (`caps` in the example below) capable of executing `sudo` by running the following command **on the server**:

     ```
     useradd -m -s /bin/bash caps
     usermod -aG sudo caps
     ```
   - Allow the user to run `sudo` commands without entering a password. For this, add the following line to the `sudo` configuration **on the server** (you can either edit the `/etc/sudoers` file or run the `sudo visudo` command, or use some other method):

     ```
     caps ALL=(ALL) NOPASSWD: ALL
     ```
   - Generate a pair of SSH keys with an empty passphrase **on the server**:

     ```
     ssh-keygen -t ed25519 -f caps-id -C "" -N ""
     ```

     The public and private keys of the `caps` user will be stored in the `caps-id.pub` and `caps-id` files in the current directory on the server.
   - Add the generated public key to the `/home/caps/.ssh/authorized_keys` file of the `caps` user by executing the following commands in the keys directory **on the server**:

```
mkdir -p /home/caps/.ssh
cat caps-id.pub >> /home/caps/.ssh/authorized_keys
chmod 700 /home/caps/.ssh
chmod 600 /home/caps/.ssh/authorized_keys
chown -R caps:caps /home/caps/
```

2. Create an SSHCredentials resource in the cluster:

   Run the following command in the user key directory **on the server** to encode the private key to Base64:

   ```
   base64 -w0 caps-id
   ```

   On any computer with `d8 k` configured to manage the cluster, create an environment variable with the value of the Base64-encoded private key you generated in the previous step:

   ```
   CAPS_PRIVATE_KEY_BASE64=<BASE64-ENCODED PRIVATE KEY>
   ```

   To create an SSHCredentials resource in the cluster (note that from this point on, you have to use `d8 k` configured to manage the cluster), run the following command:

   ```
   d8 k create -f - <<EOF
   apiVersion: deckhouse.io/v1alpha1
   kind: SSHCredentials
   metadata:
     name: credentials
   spec:
     user: caps
     privateSSHKey: "${CAPS_PRIVATE_KEY_BASE64}"
   EOF
   ```

3. Create a StaticInstance resource in the cluster and specify the IP address of the static node server:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: StaticInstance
   metadata:
     name: static-worker-1
     labels:
       role: worker
   spec:
     # Specify the IP address of the static node server.
     address: "<SERVER-IP>"
     credentialsRef:
       kind: SSHCredentials
       name: credentials
   EOF
   ```

4. Create a NodeGroup resource in the cluster. The value of `count` defines a number of `staticInstances` which fall under the `labelSelector` that will be added to the cluster. In this example it's `1`:

   > **i** The `labelSelector` field in the NodeGroup resource is immutable. To update the `labelSelector`, you need to create a new NodeGroup and move the static nodes into it by changing their labels.

```
d8 k create -f - <<EOF
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: Static
  staticInstances:
    count: 1
    labelSelector:
      matchLabels:
        role: worker
EOF
```

Using Cluster API Provider Static for multiple node groups

This example shows how you can use filters in the StaticInstance `label selector` to group static nodes and use them in different NodeGroups. Here, two node groups (`front` and `worker`) are used for different tasks. Each group includes nodes with different characteristics — the `front` group has two servers and the `worker` group has one.

1. Prepare the required resources (3 servers or virtual machines) and create the SSHCredentials resource the same way as on step 1 and step 2 of the example.
2. Create two NodeGroup resources in the cluster (from this point on, use `d8 k` configured to manage the cluster):

   > **i** The `labelSelector` field in the `NodeGroup` resource is immutable. To update the `labelSelector`, you need to create a new NodeGroup and move the static nodes into it by changing their labels.

   ```
   apiVersion: deckhouse.io/v1
   kind: NodeGroup
   metadata:
     name: front
   spec:
     nodeType: Static
     staticInstances:
       count: 2
       labelSelector:
         matchLabels:
           role: front
   ---
   apiVersion: deckhouse.io/v1
   kind: NodeGroup
   metadata:
     name: worker
   spec:
     nodeType: Static
     staticInstances:
       count: 1
       labelSelector:
         matchLabels:
           role: worker
   EOF
   ```

3. Create StaticInstance resources in the cluster and specify the valid IP addresses of the servers:

```
apiVersion: deckhouse.io/v1alpha1
kind: StaticInstance
metadata:
  name: static-front-1
  labels:
    role: front
spec:
  address: "<SERVER-FRONT-IP1>"
  credentialsRef:
    kind: SSHCredentials
    name: credentials
---
apiVersion: deckhouse.io/v1alpha1
kind: StaticInstance
metadata:
  name: static-front-2
  labels:
    role: front
spec:
  address: "<SERVER-FRONT-IP2>"
  credentialsRef:
    kind: SSHCredentials
    name: credentials
---
apiVersion: deckhouse.io/v1alpha1
kind: StaticInstance
metadata:
  name: static-worker-1
  labels:
    role: worker
spec:
  address: "<SERVER-WORKER-IP>"
  credentialsRef:
    kind: SSHCredentials
    name: credentials
EOF
```

Adding master nodes in a cloud cluster

To add master nodes in a cloud cluster:

1. Make sure the `control-plane-manager` module is enabled.
2. Open the ClusterConfiguration file (e.g., OpenStackClusterConfiguration).
3. Add or update the `masterNodeGroup` section:

   ```
   masterNodeGroup:
     replicas: 3
     instanceClass:
       flavorName: m1.medium
       imageName: ubuntu-24-04-cloud-amd64
       rootDiskSize: 20
       mainNetwork: default
   ```

4. Apply the changes using `dhctl converge`:

   ```
   dhctl converge \
     --ssh-host <master node IP> \
     --ssh-user <username> \
     --ssh-agent-private-keys /tmp/.ssh/<key>
   ```

Using NodeGroup with priority

The `priority` parameter of the NodeGroup custom resource allows you to define the order in which nodes are provisioned in the cluster.
For example, you can configure the cluster to first provision *spot-node* instances and fall back to regular nodes if spot capacity runs out.
Or you can instruct the system to prioritize larger nodes when available, and use smaller ones when resources are limited.

Example of creating two NodeGroups using spot-node instances:

```
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker-spot
spec:
  cloudInstances:
    classReference:
      kind: AWSInstanceClass
      name: worker-spot
    maxPerZone: 5
    minPerZone: 0
    priority: 50
  nodeType: CloudEphemeral
---
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  cloudInstances:
    classReference:
      kind: AWSInstanceClass
      name: worker
    maxPerZone: 5
    minPerZone: 0
    priority: 30
  nodeType: CloudEphemeral
```

In the example above, the `Cluster Autoscaler` will first attempt to provision a spot-node. If it fails to add the node to the cluster within 15 minutes, the `worker-spot` NodeGroup will be paused for 20 minutes, and the `Cluster Autoscaler` will start provisioning nodes from the `worker` NodeGroup.

If a new node is needed again after 30 minutes, `Cluster Autoscaler` will again attempt `worker-spot` first, then fall back to `worker`.

Once the `worker-spot` NodeGroup reaches its maximum (5 nodes in the example), all further nodes will be provisioned from the `worker` NodeGroup.

The node templates (labels/taints) for `worker` and `worker-spot` NodeGroups should be identical or at least compatible with the workload that triggers scaling.

NodeGroup states and their interpretation

Ready — the NodeGroup contains the minimum required number of scheduled nodes with the status `Ready` for all zones.

Example 1. A group of nodes in the `Ready` state:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: ng1
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    maxPerZone: 5
    minPerZone: 1
status:
  conditions:
  - status: "True"
    type: Ready
---
apiVersion: v1
kind: Node
metadata:
  name: node1
  labels:
    node.deckhouse.io/group: ng1
status:
  conditions:
  - status: "True"
    type: Ready
```

Example 2. A group of nodes in the `Not Ready` state:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: ng1
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    maxPerZone: 5
    minPerZone: 2
status:
  conditions:
  - status: "False"
    type: Ready
---
apiVersion: v1
kind: Node
metadata:
  name: node1
  labels:
    node.deckhouse.io/group: ng1
status:
  conditions:
  - status: "True"
    type: Ready
```

Updating: A node group contains at least one node in which there is an annotation with the prefix `update.node.deckhouse.io` (for example, `update.node.deckhouse.io/waiting-for-approval`).

WaitingForDisruptiveApproval: A node group contains at least one node that has an annotation `update.node.deckhouse.io/disruption-required` and there is no annotation `update.node.deckhouse.io/disruption-approved`.

Scaling: Calculated only for node groups with the type `CloudEphemeral`. The state `True` can be in two cases:

1. When the number of nodes is less than the *target number of nodes* in the group, i.e. when it is

necessary to increase the number of nodes in the group.
2. When a node is marked for deletion or the number of nodes is greater than the *target number of nodes*, i.e. when it is necessary to reduce the number of nodes in the group.

The *target number of nodes* is the sum of all replicas in the node group.

Example. The desired number of nodes is 2:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: ng1
spec:
  nodeType: CloudEphemeral
  cloudInstances:
    maxPerZone: 5
    minPerZone: 2
status:
...
  desired: 2
...
```

Error: Contains the last error that occurred when creating a node in a node group.

Adding and managing bare-metal nodes

For more details on sizing resources for a bare-metal cluster, see the “Hardware requirements for bare-metal cluster” guide.

Adding nodes to a bare-metal cluster

Manual method

1. Enable the `node-manager` module.
2. Create a NodeGroup object with the type `Static`:

   ```
   apiVersion: deckhouse.io/v1
   kind: NodeGroup
   metadata:
     name: worker
   spec:
     nodeType: Static
   ```

   In this resource, specify the `Static` node type. For all NodeGroup objects in the cluster, Deckhouse automatically generates a `bootstrap.sh` script used to add nodes to the group. When adding nodes manually, you need to copy this script to the server and run it.

   You can obtain the script from the Deckhouse web interface under the “ Node Groups → Scripts”

tab or via the following `d8 k` command:

```
d8 k -n d8-cloud-instance-manager get secrets manual-bootstrap-for-worker -ojsonpath="
{.data.bootstrap\.sh}"
```

The script needs to be decoded from Base64 and then executed as `root`.

3. Once the script finishes, the server will be added to the cluster as a node in the specified group.

Automatic method

⚠ If you have previously increased the number of master nodes in the cluster in the NodeGroup `master` (parameter `spec.staticInstances.count`), before adding nodes using automatic method, make sure that they will not be “captured”.

DP supports automatic addition of physical (bare-metal) servers to the cluster without the need to manually run an installation script on each node. To enable this:

1. Prepare the server (OS, networking):
   - Install a supported operating system.
   - Configure networking and ensure the server is accessible via SSH.
   - Create a system user (e.g., `ubuntu`) for SSH access.
   - Ensure the user can execute commands using `sudo`.
2. Create an SSHCredentials object to define access to the server. DP uses this object to connect to the server over SSH. It specifies:
   - A private SSH key encoded in Base64 format.
   - The OS user.
   - The SSH port.
   - (Optional) A `sudo` password, if required.

   Example:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: SSHCredentials
   metadata:
     name: static-nodes
   spec:
     privateSSHKey:
   LS0tLS1CRUdJTiBPUEVOU1NIIFBSSVZBVEUgS0VZLS0tLS0KTUlJRXZBSUJBREFOQmdrcWhraUc
   5dzBCQVFFRkFBT0NBZzhBTUlJQkNnS0NBUUVB
     sshPort: 22
     sudoPassword: password
     user: ubuntu
   ```

   i **Important**. The `privateSSHKey` field must contain a private SSH key encoded in Base64 format. The private key must match the corresponding public key added to the `~/.ssh/authorized_keys` file on the server.

   For details on SSHCredentials sensitive data protection, see the `node-manager` module FAQ.
3. Create a StaticInstance` object for each server:

```
apiVersion: deckhouse.io/v1alpha1
kind: StaticInstance
metadata:
  name: static-0
  labels:
    static-node: auto
spec:
  address: 192.168.1.10
  credentialsRef:
    apiVersion: deckhouse.io/v1alpha1
    kind: SSHCredentials
    name: static-nodes
```

A separate StaticInstance resource must be created for each server, but the same SSHCredentials can be reused to access multiple servers.

Possible StaticInstance states:

- `Pending`: The server has not yet been configured; the corresponding node is not present in the cluster.
- `Bootstrapping`: The server is being configured and the node is being added to the cluster.
- `Running`: The server is successfully configured and the node has joined the cluster.
- `Cleaning`: The server is being cleaned up and the node is being removed from the cluster.

These states reflect the current stage of node management. CAPS automatically transitions a StaticInstance between these states depending on whether a node needs to be added or removed from a group.

4. Create a NodeGroup resource describing how DP should use these servers:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: Static
  staticInstances:
    count: 3
    labelSelector:
      matchLabels:
        static-node: auto
  nodeTemplate:
    labels:
      node-role.deckhouse.io/worker: ""
```

This section defines parameters for using StaticInstance resources:

- `count` specifies how many nodes will be added to the group.
- `labelSelector` defines the rules for selecting nodes.

When using the Cluster API Provider Static (CAPS), it is important to correctly set the `nodeType` to `Static` and provide the `staticInstances` section in the NodeGroup resource:

- If the `labelSelector` is not specified, CAPS will use any available StaticInstance resources in the cluster.
- The same StaticInstance can be used in multiple NodeGroups if it matches the filters.
- CAPS automatically maintains the number of nodes in the group according to the `count` parameter.
- When a node is removed, CAPS performs cleanup and disconnection, and the corresponding StaticInstance transitions to the `Pending` status, allowing it to be reused.

After the node group is created, a script for adding servers to the group will become available. DP will wait for the required number of StaticInstance objects that match the specified labels. As soon as such an object appears, DP will use the provided IP address and SSH connection parameters to run the `bootstrap.sh` script and add the server to the group.

Creating nodes through BMC

If servers have baseboard management controllers (BMCs) with Redfish or IPMI support, Deckhouse Platform can install an operating system on them and join them to the cluster by itself. The `infra-provider-baremetal` module provides this capability. With it, `node-manager` creates nodes on such servers in node groups with the `CloudEphemeral` type and scales them automatically.

The setup procedure is described on the Usage page of the `infra-provider-baremetal` module.

Modifying a static cluster configuration

The static cluster settings are stored in the StaticClusterConfiguration structure.

To modify the static cluster parameters, run the following command:

```
d8 system edit static-cluster-configuration
```

Moving a static node between NodeGroups

⚠ During the migration of static nodes between NodeGroups, the node is cleaned up and bootstrapped again, and the `Node` object is recreated.

1. Create a new NodeGroup resource, for example named `front`, which will manage the static node labeled `role: front`:

   ```
   d8 k create -f - <<EOF
   apiVersion: deckhouse.io/v1
   kind: NodeGroup
   metadata:
     name: front
   spec:
     nodeType: Static
     staticInstances:
       count: 1
       labelSelector:
         matchLabels:
           role: front
   ```

2. Change the `role` label of the existing StaticInstance from `worker` to `front`.
   This will allow the new NodeGroup named `front` to manage this node:

   ```
   d8 k label staticinstance static-worker-1 role=front --overwrite
   ```

3. Update the `worker` NodeGroup resource by decreasing the `count` parameter from `1` to `0`:

   ```
   d8 k patch nodegroup worker -p '{"spec": {"staticInstances": {"count": 0}}}' --
   type=merge
   ```

Manual cleanup of a static node

To remove a node from the cluster and clean the server, run the `/var/lib/bashible/cleanup_static_node.sh` script, which is already present on every static node.

Example of disconnecting a node from the cluster and cleaning the server:

```
bash /var/lib/bashible/cleanup_static_node.sh --yes-i-am-sane-and-i-understand-what-i-am-
doing
```

ℹ This instruction applies both to nodes manually configured using the bootstrap script and to nodes configured via CAPS.

NodeGroup example

Example NodeGroup definition for static nodes

For virtual machines on hypervisors or physical servers, use static nodes by setting `nodeType: Static` in the NodeGroup.

Example:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: Static
```

Nodes are added to such a group manually using preconfigured scripts or automatically via CAPS.

Changing the CRI for a NodeGroup

CRI (Container Runtime Interface) is a standard interface between the kubelet and the container runtime.

> ⚠ CRI can only be switched between `Containerd` and `NotManaged` via the `cri.type` parameter.

To change the CRI for a NodeGroup, set the `cri.type` parameter to either `Containerd` or `NotManaged`.

Example YAML manifest:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  nodeType: Static
  cri:
    type: Containerd
```

You can also perform this operation using a patch:

- To set `Containerd`:

  ```
  d8 k patch nodegroup <NodeGroup name> --type merge -p '{"spec":{"cri":
  {"type":"Containerd"}}}'
  ```

- To set `NotManaged`:

  ```
  d8 k patch nodegroup <NodeGroup name> --type merge -p '{"spec":{"cri":
  {"type":"NotManaged"}}}'
  ```

> ⚠ When changing the `cri.type` for a NodeGroup created using `dhctl`, you must also update this value in `dhctl config edit provider-cluster-configuration` and in the NodeGroup object settings.

After changing the CRI for a NodeGroup, the `node-manager` module will sequentially reboot the nodes, applying the new CRI.
Node updates involve disruption. Depending on the `disruption` settings for the NodeGroup, the `node-manager` module will either automatically update the nodes or require manual approval.

Changing the NodeGroup of a static node

If a node is managed by CAPS, you can’t change its associated NodeGroup.
The only option is to delete the StaticInstance and create a new one.

To move an existing manually added static node from one NodeGroup to another, you need to update the group label on the node:

```
d8 k label node --overwrite <node_name> node.deckhouse.io/group=<new_node_group_name>
d8 k label node <node_name> node-role.kubernetes.io/<old_node_group_name>-
```

It will take some time for the changes to take effect.

Changing the IP address in a StaticInstance

You cannot change the IP address of a StaticInstance resource.
If an incorrect address is specified in a StaticInstance, you need to delete the StaticInstance and create a new one.

Deleting a StaticInstance

A StaticInstance in the `Pending` state can be safely deleted without any issues.

To delete a StaticInstance that is in any state other than `Pending` (`Running`, `Cleaning`, `Bootstrapping`), follow these steps:

1. Add the label `"node.deckhouse.io/allow-bootstrap": "false"` to the StaticInstance.

   Example command for adding a label:

   ```
   d8 k label staticinstance d8cluster-worker node.deckhouse.io/allow-bootstrap=false
   ```

2. Wait until the StaticInstance transitions to the `Pending` state.

   To check the status of StaticInstance, use the command:

   ```
   d8 k get staticinstances
   ```

3. Delete the StaticInstance.

   Example command for deleting StaticInstance:

   ```
   d8 k delete staticinstance d8cluster-worker
   ```

4. Decrease the `NodeGroup.spec.staticInstances.count` parameter by 1.

Custom node configuration

To automate actions on group nodes, use the NodeGroupConfiguration resource. It allows you to run bash scripts on the nodes using the Bash Booster command set, as well as apply the Go Template templating engine. This is useful for automating operations such as:

- Installing and configuring additional OS packages.

  Examples:

  - Installing the kubectl plugin

- Updating the OS kernel to a specific version.

Examples:

  - Debian kernel update
  - CentOS kernel update

- Modifying OS parameters.

  Examples:

  - Tuning a sysctl parameter
  - Adding a root certificate

- Collecting information on the node and performing similar tasks.

The NodeGroupConfiguration resource allows you to define execution priority for scripts, limit execution to specific node groups or OS types.

The script code is specified in the `content` field of the resource. When a script is created on a node, the content passes through the Go Template templating engine, which adds a layer of logic to script generation. A dynamic context with a set of variables is available in the template.

Available template variables include:

- `.cloudProvider` (for node groups with `CloudEphemeral` or `CloudPermanent` nodeType) — an array of cloud provider data.

  Example data...

  ```
  cloudProvider:
    instanceClassKind: OpenStackInstanceClass
    machineClassKind: OpenStackMachineClass
    openstack:
      connection:
        authURL: https://cloud.provider.com/v3/
        domainName: Default
        password: p@ssw0rd
        region: region2
        tenantName: mytenantname
        username: mytenantusername
      externalNetworkNames:
      - public
      instances:
        imageName: ubuntu-24-04-cloud-amd64
        mainNetwork: kube
        securityGroups:
        - kube
        sshKeyPairName: kube
      internalNetworkNames:
      - kube
      podNetworkMode: DirectRoutingWithPortSecurityEnabled
    region: region2
    type: openstack
    zones:
    - nova
  ```

- `.cri` — the container runtime interface in use (since Deckhouse version 1.49, only `Containerd` is used).
- `.kubernetesVersion` — the version of Kubernetes in use.
- `.nodeUsers` — an array of user data added to the node using the NodeUser resource.

  Example data...

```
nodeUsers:
- name: user1
  spec:
    isSudoer: true
    nodeGroups:
    - '*'
    passwordHash: PASSWORD_HASH
    sshPublicKey: SSH_PUBLIC_KEY
    uid: 1050
```

- `.nodeGroup` — an array of NodeGroup data.

  Example data...

  ```
  nodeGroup:
    cri:
      type: Containerd
    disruptions:
      approvalMode: Automatic
    kubelet:
      containerLogMaxFiles: 4
      containerLogMaxSize: 50Mi
      resourceReservation:
        mode: "Off"
    kubernetesVersion: "1.31"
    manualRolloutID: ""
    name: master
    nodeTemplate:
      labels:
        node-role.kubernetes.io/control-plane: ""
        node-role.kubernetes.io/master: ""
      taints:
      - effect: NoSchedule
        key: node-role.kubernetes.io/master
    nodeType: CloudPermanent
    updateEpoch: "1699879470"
  ```

Example of using variables in the template engine:

```
{{- range .nodeUsers }}
echo 'Tuning environment for user {{ .name }}'
# Some code for tuning user environment
{{- end }}
```

Example of using Bash Booster commands:

```
bb-event-on 'bb-package-installed' 'post-install'
post-install() {
  bb-log-info "Setting reboot flag due to kernel was updated"
  bb-flag-set reboot
}
```

Monitoring script execution

Applying NodeGroupConfiguration triggers an update of the **`bashible` configuration of the node group** in the specified groups. Deckhouse Platform automatically detects the change in this configuration and then sets the `UPTODATE` field (in the output of the `d8 k get nodegroup` command) to `0`. The `UPTODATE` field shows how many nodes have already been brought to the **target `bashible` configuration of the node group**; a value of `0` means that no node has been brought to the target `bashible` configuration yet (i.e., the update has not been applied to any node).

Deckhouse Platform controls the start of updates on nodes via the `update.node.deckhouse.io/approved` annotation on the `Node` object. By default, the update runs

simultaneously on one node from each group. Update parallelism is defined by the `maxConcurrent` parameter in the node group configuration. When Deckhouse Platform selects a node to update (taking the queue and `maxConcurrent` into account), it sets the `update.node.deckhouse.io/approved` annotation, after which the `bashible` service on that node begins applying the **target `bashible` configuration of the node group**.

You can view the node annotations set by Deckhouse Platform to start the update using the following command:

```
d8 k get nodes -o json | jq '.items[] |
select(.metadata.annotations."update.node.deckhouse.io/approved"=="") |
.metadata.name' -r
```

You can monitor script execution on the node in the `bashible` service logs using:

```
journalctl -fu bashible.service
```

The scripts are located in the `/var/lib/bashible/bundle_steps/` directory on the node.

Script re-execution mechanism

The service decides whether to re-run the scripts by comparing a unified checksum of all files, located at `/var/lib/bashible/configuration checksum`, with the checksum stored in the `configuration-checksums` secret in the `d8-cloud-instance-manager` namespace in the Kubernetes cluster.

You can check the checksum with the following command:

```
d8 k -n d8-cloud-instance-manager get secret configuration-checksums -o yaml
```

The checksum comparison is performed by the service every minute.

The checksum in the cluster is updated every 4 hours, thereby re-triggering the execution of scripts on all nodes.

To manually trigger `bashible` execution on a node, you can delete the checksum file using the following command:

```
rm /var/lib/bashible/configuration_checksum
```

Script writing specifics

When writing scripts, it’s important to consider the following features of their usage in Deckhouse:

1. Scripts in Deckhouse Platform are executed every 4 hours or based on external triggers. Therefore, it’s important to write scripts in a way that they first check whether changes are necessary, to avoid repeated or unnecessary actions on each execution.
2. There are predefined scripts that perform various actions, including service installation and configuration. It’s important to consider this when assigning priority to custom scripts. For example, if a custom script restarts a service, it must run after the script that installs that service. Otherwise, the custom script won’t be able to run during the initial provisioning of the node (since the service won’t be installed yet).

Useful specifics of certain scripts:

- `032_configure_containerd.sh`: Merges the containerd configuration files and **restarts** the service. The location of the configuration files depends on the CRI used on the cluster nodes:
  - `/etc/containerd/conf.d/*.toml`: For containerd v1.
  - `/etc/containerd/conf2.d/*.toml`: For containerd v2.

  Note that directories containing configuration files are not created automatically. Files must be added to these directories in scripts with a priority of less than `32`.

How to use containerd with Nvidia GPU support

On GPU nodes, containerd is configured by the `gpu` module: it adds the `nvidia` runtime and the required system settings to the nodes of the node groups with the `spec.gpu` section. Do not configure the `nvidia` runtime with your own NodeGroupConfiguration resources: such a configuration conflicts with the one of the `gpu` module.

How to install the NVIDIA driver and NVIDIA Container Toolkit on the nodes and how to verify a GPU node is described in the `gpu` module FAQ.

How to deploy a custom containerd configuration file

✖ Adding custom settings will trigger a restart of the `containerd` service.

Bashible on nodes merges main Deckhouse containerd config with configs from:

- `/etc/containerd/conf.d/*.toml` — if containerd v1 is used as the CRI on the cluster nodes.
- `/etc/containerd/conf2.d/*.toml` — if containerd v2 is used as the CRI on the cluster nodes.

⚠ You can override the parameter values defined in the `/etc/containerd/deckhouse.toml` file. However, you are responsible for ensuring the correct operation of such changes. It is recommended **not to modify the configuration** on control plane (master) nodes (NodeGroup `master`).

- For containerd v1
- For containerd v2

```
apiVersion: deckhouse.io/v1alpha1

        SystemdCgroup = true
        ShmSize = 17179869184
    EOF
  nodeGroups:
    - "worker"
  weight: 31
```

Adding a configuration for an additional registry

Containerd supports two methods for registry configuration: the **deprecated** method and the **actual** method.

To check for the presence of the **deprecated** configuration method, run the following commands on the cluster nodes:

```
cat /etc/containerd/config.toml | grep
'plugins."io.containerd.grpc.v1.cri".registry.mirrors'
cat /etc/containerd/config.toml | grep
'plugins."io.containerd.grpc.v1.cri".registry.configs'
```

Example output:

```
[plugins."io.containerd.grpc.v1.cri".registry.mirrors]
  [plugins."io.containerd.grpc.v1.cri".registry.mirrors."<REGISTRY_URL>"]
[plugins."io.containerd.grpc.v1.cri".registry.configs]
  [plugins."io.containerd.grpc.v1.cri".registry.configs."<REGISTRY_URL>".auth]
```

To check for the presence of the **actual** configuration method, run the following command on the cluster nodes:

```
cat /etc/containerd/config.toml | grep '/etc/containerd/registry.d'

# Example output:
# config_path = "/etc/containerd/registry.d"
```

⚠ For more configuration examples for additional registry (for example, deploying a custom containerd configuration file), see the “FAQ” section of the `node-manager` module documentation.

Old Method

⚠ This containerd configuration format is deprecated.

i Used in containerd v1 when Deckhouse is not managed by the Registry module.

The configuration is described in the main containerd configuration file `/etc/containerd/config.toml`.

Adding custom configuration is carried out through the `toml merge` mechanism. Configuration files from the `/etc/containerd/conf.d` directory are merged with the main file `/etc/containerd/config.toml`. The merge takes place during the execution of the `032_configure_containerd.sh` script, so the corresponding files must be added in advance.

Example configuration file for the `/etc/containerd/conf.d/` directory:

```
[plugins]
  [plugins."io.containerd.grpc.v1.cri"]
    [plugins."io.containerd.grpc.v1.cri".registry]
      [plugins."io.containerd.grpc.v1.cri".registry.mirrors]
        [plugins."io.containerd.grpc.v1.cri".registry.mirrors."${REGISTRY_URL}"]
          endpoint = ["https://${REGISTRY_URL}"]
      [plugins."io.containerd.grpc.v1.cri".registry.configs]
        [plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".auth]
          auth = "${BASE_64_AUTH}"
          username = "${USERNAME}"
          password = "${PASSWORD}"
        [plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".tls]
          ca_file = "${CERT_DIR}/${CERT_NAME}.crt"
          insecure_skip_verify = true
```

✖ Adding custom settings through the `toml merge` mechanism causes the containerd service to restart.

Adding authorization to an additional registry (deprecated method)

Example of adding authorization to an additional registry when using the **deprecated** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-auth.sh
spec:
  # To add a file before the '032_configure_containerd.sh' step.
  weight: 31
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/additional_registry.toml - << EOF
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry]
          [plugins."io.containerd.grpc.v1.cri".registry.mirrors]
            [plugins."io.containerd.grpc.v1.cri".registry.mirrors."${REGISTRY_URL}"]
              endpoint = ["https://${REGISTRY_URL}"]
          [plugins."io.containerd.grpc.v1.cri".registry.configs]

[plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".auth]
              username = "username"
              password = "password"
              # OR
              auth = "dXNlcm5hbWU6cGFzc3dvcmQ="
    EOF
```

Configuring a certificate for an additional registry (deprecated method)

Example of configuring a certificate for an additional registry when using the **deprecated** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-tls.sh
spec:
  # To add a file before the '032_configure_containerd.sh' step.
  weight: 31
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example
    CERT_FILE_NAME=${REGISTRY_URL}
    CERTS_FOLDER="/var/lib/containerd/certs/"

    mkdir -p ${CERTS_FOLDER}
    bb-sync-file "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt" - << EOF
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----
    EOF

    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/additional_registry.toml - << EOF
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry]
          [plugins."io.containerd.grpc.v1.cri".registry.configs]

[plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".tls]
            ca_file = "${CERTS_FOLDER}/${CERT_FILE_NAME}.crt"
    EOF
```

i In addition to containerd, the certificate can be added to the OS.

Adding TLS skip verify (deprecated method)

Example of adding TLS skip verify when using the **deprecated** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-skip-tls.sh
spec:
  # To add a file before the '032_configure_containerd.sh' step.
  weight: 31
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/additional_registry.toml - << EOF
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry]
          [plugins."io.containerd.grpc.v1.cri".registry.configs]

[plugins."io.containerd.grpc.v1.cri".registry.configs."${REGISTRY_URL}".tls]
            insecure_skip_verify = true
    EOF
```

After applying the configuration file, verify access to the registry from the nodes using the command:

```
# Via the CRI interface
crictl pull private.registry.example/image/repo:tag
```

Configuring a mirror for access to public registries (deprecated method)

Example of configuring a mirror for public image registries when using the **deprecated** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: mirror-to-harbor.sh
spec:
  weight: 31
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    sed -i '/endpoint = \["https:\/\/registry-1.docker.io"\]/d'
/var/lib/bashible/bundle_steps/032_configure_containerd.sh
    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/mirror-to-harbor.toml - << "EOF"
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry]
          [plugins."io.containerd.grpc.v1.cri".registry.mirrors]
            [plugins."io.containerd.grpc.v1.cri".registry.mirrors."docker.io"]
              endpoint = ["https://registry.private.network/v2/dockerhub-proxy/"]
            [plugins."io.containerd.grpc.v1.cri".registry.mirrors."gcr.io"]
              endpoint = ["https://registry.private.network/v2/YOUR_GCR_PROXY_REPO/"]
    EOF
```

New Method

> **i**
>
> Used in containerd v2.
>
> Used in containerd v1 when managed through the `registry` module (for example, in `Direct` mode).

The configuration is defined in the `/etc/containerd/registry.d` directory.
Configuration is specified by creating subdirectories named after the registry address:

```
/etc/containerd/registry.d
├── private.registry.example:5001
│   ├── ca.crt
│   └── hosts.toml
└── registry.deckhouse.io
    ├── ca.crt
    └── hosts.toml
```

Example contents of the `hosts.toml` file:

```
[host]
  # Mirror 1.
  [host."https://${REGISTRY_URL_1}"]
    capabilities = ["pull", "resolve"]
    ca = ["${CERT_DIR}/${CERT_NAME}.crt"]

    [host."https://${REGISTRY_URL_1}".auth]
      username = "${USERNAME}"
      password = "${PASSWORD}"

  # Mirror 2.
  [host."http://${REGISTRY_URL_2}"]
    capabilities = ["pull", "resolve"]
    skip_verify = true
```

i Configuration changes do not cause the containerd service to restart.

Adding authorization to an additional registry (actual method)

Example of adding authorization to an additional registry when using the **actual** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-auth.sh
spec:
  # The step can be arbitrary, as restarting the containerd service is not required.
  weight: 0
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p "/etc/containerd/registry.d/${REGISTRY_URL}"
    bb-sync-file "/etc/containerd/registry.d/${REGISTRY_URL}/hosts.toml" - << EOF
    [host]
      [host."https://${REGISTRY_URL}"]
        capabilities = ["pull", "resolve"]
        [host."https://${REGISTRY_URL}".auth]
          username = "username"
          password = "password"
    EOF
```

Configuring a certificate for an additional registry (actual method)

Example of configuring a certificate for an additional registry when using the **actual** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-tls.sh
spec:
  # The step can be arbitrary, as restarting the containerd service is not required.
  weight: 0
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p "/etc/containerd/registry.d/${REGISTRY_URL}"

    bb-sync-file "/etc/containerd/registry.d/${REGISTRY_URL}/ca.crt" - << EOF
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----
    EOF

    bb-sync-file "/etc/containerd/registry.d/${REGISTRY_URL}/hosts.toml" - << EOF
    [host]
      [host."https://${REGISTRY_URL}"]
        capabilities = ["pull", "resolve"]
        ca = ["/etc/containerd/registry.d/${REGISTRY_URL}/ca.crt"]
    EOF
```

i In addition to containerd, the certificate can be added to the OS.

Adding TLS skip verify (actual method)

Example of adding TLS skip verify when using the **actual** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerd-additional-config-skip-tls.sh
spec:
  # The step can be arbitrary, as restarting the containerd service is not required.
  weight: 0
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY_URL=private.registry.example

    mkdir -p "/etc/containerd/registry.d/${REGISTRY_URL}"
    bb-sync-file "/etc/containerd/registry.d/${REGISTRY_URL}/hosts.toml" - << EOF
    [host]
      [host."https://${REGISTRY_URL}"]
        capabilities = ["pull", "resolve"]
        skip_verify = true
    EOF
```

After applying the configuration file, check access to the registry from the nodes using the following commands:

```
# Via the CRI interface.
crictl pull private.registry.example/image/repo:tag

# Via ctr with the configuration directory specified.
ctr -n k8s.io images pull --hosts-dir=/etc/containerd/registry.d/
private.registry.example/image/repo:tag

# Via ctr for an HTTP registry.
ctr -n k8s.io images pull --hosts-dir=/etc/containerd/registry.d/ --plain-http
private.registry.example/image/repo:tag
```

Configuring a mirror for access to public registries (actual method)

Example of configuring a mirror for public image registries when using the **actual** configuration method:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: mirror-to-harbor.sh
spec:
  weight: 31
  bundles:
    - '*'
  nodeGroups:
    - "*"
  content: |
    # Copyright 2023 Flant JSC
    #
    # Licensed under the Apache License, Version 2.0 (the "License");
    # you may not use this file except in compliance with the License.
    # You may obtain a copy of the License at
    #
    #     http://www.apache.org/licenses/LICENSE-2.0
    #
    # Unless required by applicable law or agreed to in writing, software
    # distributed under the License is distributed on an "AS IS" BASIS,
    # WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
    # See the License for the specific language governing permissions and
    # limitations under the License.

    REGISTRY1_URL=docker.io
    mkdir -p "/etc/containerd/registry.d/${REGISTRY1_URL}"
    bb-sync-file "/etc/containerd/registry.d/${REGISTRY1_URL}/hosts.toml" - << EOF
    [host."https://registry.private.network/v2/dockerhub-proxy/"]
      capabilities = ["pull", "resolve"]
      override_path = true
    EOF
    REGISTRY2_URL=gcr.io
    mkdir -p "/etc/containerd/registry.d/${REGISTRY2_URL}"
    bb-sync-file "/etc/containerd/registry.d/${REGISTRY2_URL}/hosts.toml" - << EOF
    [host."https://registry.private.network/v2/dockerhub-proxy/"]
      capabilities = ["pull", "resolve"]
      override_path = true
    EOF
```

How to automatically put custom labels on the node

1. On the node, create the directory `/var/lib/node_labels`.
2. In this directory, create a single of multiple files containing the necessary labels. There can be any number of files, as well as the number of subdirectories containing them.
3. Add the necessary labels to the files in the `key=value` format. For example:

   ```
   example-label=test
   ```

4. Save the files.

When adding a node to the cluster, the labels specified in the files will be automatically affixed to the node.

> ⚠ Note that it is not possible to add labels used in Deckhouse Platform in this way. This method will only work with custom labels that do not overlap with those reserved for Deckhouse.

Migrating container runtime to containerd v2

You can configure containerd v2 as the primary container runtime either at the cluster level or for specific node groups. This runtime option enables the use of cgroups v2, provides improved security, and allows more flexible resource management.

> To view the current container runtime type used by default in the cluster NodeGroups, use the following command:
>
> ```
> d8 system edit cluster-configuration
> ```
>
> The container runtime type is specified in the `defaultCRI` parameter.

Requirements

Migration to containerd v2 is possible under the following conditions:

- Nodes meet the requirements described in the cluster-wide parameters.
- The node kernel version is not in the range 6.12.0–6.12.28 or 6.14.0–6.14.6 (these versions are affected by CVE-2025-37999 in EROFS).
- There are no custom configurations on the server in `/etc/containerd/conf.d` (example of a custom configuration).

> ⚠ On Ubuntu nodes in AWS, the `erofs` kernel module required by containerd v2 is shipped in a separate `linux-modules-extra` package. Deckhouse Platform installs it automatically, but for some kernels, mostly outdated ones, the package is no longer published in the APT repository. In that case, the installation is skipped, a warning is written to the node logs, the node gets the `node.deckhouse.io/containerd-v2-unsupported` label, and the `D8NodeContainerdV2NotSupported` alert fires.
>
> The problem has been confirmed for the `5.15.0-1028-aws`, `6.8.0-1024-aws`, and `6.8.0-1029-aws` kernels. To migrate such nodes, switch the node group to a newer AMI or kernel that provides `erofs`.
>
> Before migrating, check whether there are such nodes in the cluster: check the alerts and the list of labelled nodes (see the commands below).

If any of the requirements described in the general cluster parameters are not met, Deckhouse Platform adds the label `node.deckhouse.io/containerd-v2-unsupported` to the node. If the node has custom configurations in the `/etc/containerd/conf.d/` (if CRI containerd v1 is used on the cluster nodes) or `/etc/containerd/conf2.d/` (if CRI containerd v2 is used on the cluster nodes) directories, the label `node.deckhouse.io/containerd-config=custom` is added to it.

If one of these labels is present, changing the `spec.cri.type` parameter for the node group will be unavailable. Nodes that do not meet the migration conditions can be viewed using the following commands:

```
d8 k get node -l node.deckhouse.io/containerd-v2-unsupported
d8 k get node -l node.deckhouse.io/containerd-config=custom
```

Additionally, a administrator can verify if a specific node meets the requirements using the following commands:

```
uname -r | cut -d- -f1
stat -f -c %T /sys/fs/cgroup
systemctl --version | awk 'NR==1{print $2}'
modprobe -qn erofs && echo "TRUE" || echo "FALSE"
ls -l /etc/containerd/conf.d
```

How to enable containerd v2

> **i** During migration the directory `/var/lib/containerd` will be cleared, causing all pod images to be re-pulled, and the node will reboot.
>
> Also note that this is a disruptive update. If `spec.disruptions.approvalMode: Manual` is set for a node group, approve the update on the respective nodes with the annotation: `d8 k annotate node <NODE-NAME> update.node.deckhouse.io/disruption-approved=`.

You can enable containerd v2 in two ways:

1. **For the entire cluster**. Set the value `ContainerdV2` for the `defaultCRI` parameter in the `ClusterConfiguration` resource. This value will apply to all NodeGroup objects where `spec.cri.type` is not explicitly defined.

   Example:

   ```
   apiVersion: deckhouse.io/v1
   kind: ClusterConfiguration
   ...
   defaultCRI: ContainerdV2
   ```

2. **For a specific node group**. Set `ContainerdV2` in the `spec.cri.type` parameter of the NodeGroup object.

   Example:

   ```
   apiVersion: deckhouse.io/v1
   kind: NodeGroup
   metadata:
     name: worker
   spec:
     cri:
       type: ContainerdV2
   ```

   When migrating to containerd v2 Deckhouse Platform will begin sequentially updating the nodes.

Maintenance of nodes running virtual machines

Work on a node affects the virtual machines (VMs) running on it. The sections below cover how to move machines to other nodes, how to take a node out for maintenance, and what to do with machines that cannot be moved.

VM migration and node maintenance

Live migration moves a running virtual machine from one node to another without shutting it down. It’s needed in three situations:

- Load balancing, to distribute VMs evenly across nodes.
- Node maintenance or update, to free the node from VMs.
- Virtual machine firmware update, which would otherwise require a restart.

> **i** Live migration is limited in speed and in the number of concurrent moves:
>
> - A node prepares and sends the memory of only one VM at a time, and accepts only one incoming migration at a time.
> - This also sets the cluster limit: no more concurrent migrations than there are nodes allowed to run virtual machines.
> - The transfer rate of a single migration is limited to 640 MiB/s, which is about 5 Gbit/s.

Moving a selected VM to another node

The following steps show how to move a selected VM to another node.

- Using the CLI
- Using the web interface

1. Check which node the VM currently runs on:

   ```
   d8 k get vm
   ```

   Example output:

   ```
   NAME       PHASE     UPTIME   NODE           IPADDRESS     AGE
   linux-vm   Running   79m      virtlab-pt-1   10.66.10.14   79m
   ```

   The VM runs on the `virtlab-pt-1` node.

2. Create a VirtualMachineOperation resource with the `Evict` type. Deckhouse Platform (DP) selects a new node for the VM, respecting its placement requirements:

   ```
   d8 k create -f - <<EOF
   apiVersion: virtualization.deckhouse.io/v1alpha2
   kind: VirtualMachineOperation
   metadata:
     generateName: evict-linux-vm-
   spec:
     # Virtual machine name.
     virtualMachineName: linux-vm
     # Operation for the migration.
     type: Evict
   EOF
   ```

3. Right after creating the resource, follow the migration progress:

   ```
   d8 k get vm -w
   ```

   Example output:

   ```
   NAME       PHASE       UPTIME   NODE           IPADDRESS     AGE
   linux-vm   Running     79m      virtlab-pt-1   10.66.10.14   79m
   linux-vm   Migrating   79m      virtlab-pt-1   10.66.10.14   79m
   linux-vm   Migrating   79m      virtlab-pt-1   10.66.10.14   79m
   linux-vm   Running     79m      virtlab-pt-2   10.66.10.14   79m
   ```

   The VM keeps its IP address during the move; only the node in the `NODE` column changes.

4. To interrupt the migration, delete the created resource while it's in the `Pending` or `InProgress` phase.

1. Go to the **Projects** tab and select the project you need.
2. Go to **Virtualization → Virtual machines**.
3. Select the virtual machine from the list and click the ellipsis button.
4. In the menu that opens, select **Migrate**.
5. In the **Virtual machine migration** window, select **Migrate to an arbitrary node** or **Migrate to a selected node** and specify the node in the **Nodes available for migration** field.
6. If required, enable **Migrate disks** to move the VM disks along with the VM, and **Force (slow down guest CPU)** to make sure the migration completes for an actively running VM.
7. Click **Migrate**, or cancel the operation with **Cancel**.

Dedicated migration network

By default, live migration traffic goes over the main node network and competes for bandwidth with workloads. You can route it through a dedicated VLAN provided by the `sdn` module.

This requires the `sdn` module to be enabled and a SystemNetwork resource to be created and in the `Ready` state.

To route the traffic to the dedicated network, set the `.spec.settings.liveMigration.network` block in the `virtualization` ModuleConfig. Specify `type: SystemNetwork` in it and the name of the prepared network in the `systemNetwork.name` field. After that, all migrations in the cluster go over the VLAN of that network.

```
spec:
  settings:
    liveMigration:
      network:
        type: SystemNetwork
        systemNetwork:
          name: migration-net
```

To return migration traffic to the main node network, delete the `network` block. When it isn't set, the node network is used by default.

To create a system network in the web interface:

1. Go to the **System** tab, then to **Network → SDN → System networks**.
2. Click **Create**.
3. In the **Create resource** window that opens, enter the network name in the **Name** field.
4. On the **Configuration** tab, select the type (`VLAN`, `Access`, or `SRIOVVirtualFunction`) in the **Type** field, the underlay network in the **Underlay network** field, and the VLAN identifier in the **VLAN** block. Set the **IPAM** block parameters, if required.
5. Click **Apply**.
6. Review the created networks in the list, which shows the **Status**, **Type**, **Underlay network**, **VLAN ID**, and **IP pool** columns.

Beforehand, create a network class (VLAN ID ranges and parent network interfaces of nodes) and an underlay network (participating network interfaces of nodes and the **Dedicated** or **Shared** mode) in the **Network → SDN → Network classes** and **Underlay networks** sections.

Checking VMs before node maintenance

It's better to find the VMs that won't be able to migrate off a node before maintenance starts, before the node is made unschedulable:

```
d8 k get vm -o wide | grep <NODE_NAME>
```

VMs with the `False` value in the `MIGRATABLE` column have to be stopped when the node is drained. Live migration isn't possible for them, and the evacuation fails.

The column value alone isn't enough. A VM with the `True` value and the `VirtualMachineWaitingForMigrationTarget` reason won't move anywhere either, until a suitable node returns to scheduling, so before maintenance, look at the reasons for all VMs on the node:

```
d8 k get vm -o json | jq -r '.items[] | [.metadata.name, (.status.conditions[] |
select(.type=="Migratable") | .reason)] | @tsv'
```

Maintenance mode

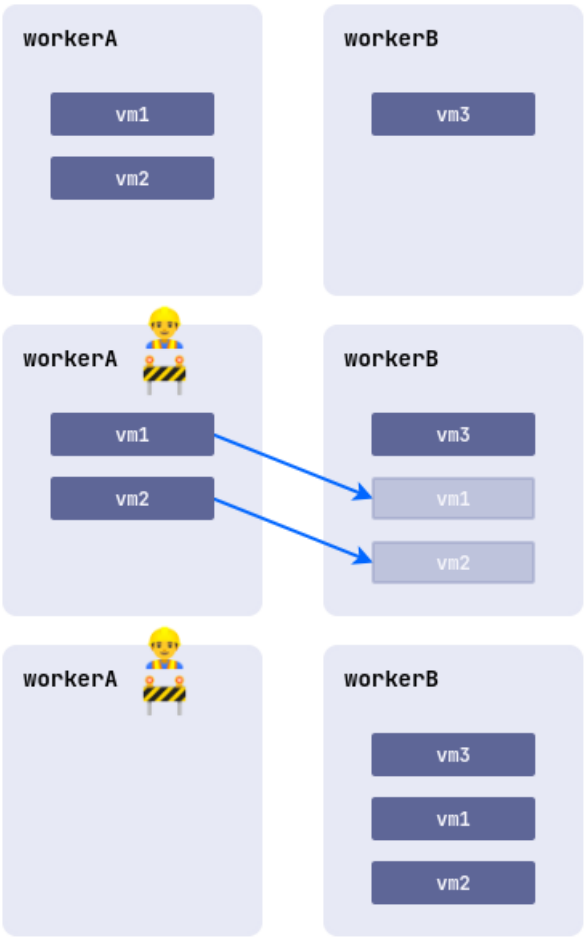
Work on a node that runs virtual machines can disrupt them. To prevent this, switch the node to maintenance mode, and DP moves the VMs to other nodes.

- Using the CLI
- Using the web interface

To free the node from all resources, including system ones, run:

```
d8 k drain <NODE_NAME> --ignore-daemonsets --delete-emptydir-data
```

To evict only virtual machines from the node, add a label selector:



```
d8 k drain <NODE_NAME> --pod-selector vm.kubevirt.internal.virtualization.deckhouse.io/name --
delete-emptydir-data
```

Where `<NODE_NAME>` is the name of the node scheduled for maintenance.

After the command runs, the node switches to maintenance mode, and virtual machines can’t be started on it.

To return the node to service, stop the `drain` command with `Ctrl+C`, and then run:

```
d8 k uncordon <NODE_NAME>
```

1. Go to the **System** tab, then to **Nodes**.
2. Select the node from the list, click the ellipsis button, and select **Cordon + Drain** in the menu that opens.
3. To take the node out of maintenance mode, select **Uncordon** in the same menu.

Restarting virtual machines during node maintenance

A virtual machine can’t always be moved to another node by live migration. It can be pinned to the node by placement rules or use a device passed through from the node. The `Migratable` condition in

the VM status shows the reason. Such a VM keeps running and holds the node, so maintenance can’t complete until the VM is restarted.

When DP finds such a VM while switching the node to maintenance mode, it adds the `virtualization.deckhouse.io/virtualmachines-restart-required` annotation to the node. To allow the restart, add the matching annotation to the node:

```
d8 k annotate node <NODE_NAME> virtualization.deckhouse.io/virtualmachines-restart-approved=""
```

Where `<NODE_NAME>` is the name of the node being switched to maintenance mode.

Only the VMs that can’t be moved by live migration are restarted. The guest OS shuts down gracefully, after which the VM starts according to the `.spec.runPolicy` run policy. For each restart, a VirtualMachineOperation resource named `node-maintenance-restart-*` is created. A restart interrupts the applications inside the VM, so coordinate it with the project owners.

The approval doesn’t apply to VMs that can be moved by live migration, including those with no suitable node at the moment. Such VMs are moved by live migration as soon as a suitable node appears.

You can grant the approval in advance, while planning the work. Until the node is switched to maintenance mode, the annotation has no effect. DP removes both annotations once the node is free, so one approval covers one maintenance of one node.

DP reacts to VM eviction from a node. If eviction stopped on timeout (the `.spec.nodeDrainTimeoutSecond` parameter of the NodeGroup resource, 10 minutes by default), eviction isn’t retried. An approval granted after that doesn’t trigger a restart, and you have to free the node manually.

A restart frees the node but doesn’t guarantee that the VM starts on another one right away. The limitation that prevents live migration usually prevents the start on another node as well. In that case, the VM stays in the `Pending` phase, and the `Running` condition reports the reason received from the scheduler. Maintenance can continue meanwhile. The VM starts as soon as a suitable node appears, including after the node returns to service with `d8 k uncordon`.

The VM owner sees the same information in the `EvictionRequired` condition of the VM status. While the node is only being prepared for maintenance, the condition is a warning. Once eviction starts, the condition shows what happens to the VM: a move by live migration, a restart by DP, or a wait if the restart isn’t approved.

Shutting down and rebooting a node with virtual machines

Running virtual machines postpone the shutdown and reboot of their node. DP labels their workloads with `pod.deckhouse.io/inhibit-node-shutdown` and uses this label to delay the node shutdown. The mechanism is available in commercial DP editions, is described in the `node-manager` module documentation, and doesn’t need to be enabled.

If a shutdown or reboot is requested on a node that still runs virtual machines:

- The node shutdown is postponed for up to three days.
- A message about the workloads holding the shutdown is periodically printed to the node console.

On nodes where the delay mechanism works, the `GracefulShutdownPostpone` condition is always present. While the mechanism waits for a shutdown signal or holds the node, the condition has the `True` status, and once there’s nothing left to hold, it switches to `False`. What actually happens to the node is shown by the reason in the `reason` field of this condition:

- `WaitingForShutdownSignal`: The mechanism is active and waiting for a node shutdown request.
- `PodsWithLabelAreRunningOnNode`: A node shutdown is requested and postponed, because virtual machines are still running on the node.
- `NoRunningPodsWithLabel`: No virtual machines are left on the node, there’s nothing to hold the shutdown with, and it continues.

To check the reason, run the following command:

```
d8 k get node <NODE_NAME> -o jsonpath='{range .status.conditions[?
(@.type=="GracefulShutdownPostpone")]}{.reason}{"\n"}{end}'
```

The shutdown delay doesn’t move virtual machines to other nodes, it only keeps the node from shutting down. For this reason, free the node from virtual machines before any work that requires a shutdown or a reboot:

- If the VMs can be migrated, that is, the `Migratable` condition has the `True` status, switch the

node to maintenance mode with `d8 k drain`.

- If a VM can't be migrated, that is, the `Migratable` condition has the `False` status because of local disks or devices passed through from the node, stop it with `d8 v stop <VM_NAME>`, and start it with `d8 v start <VM_NAME>` once the work is done.

  Stopping is available only for the `Manual` and `AlwaysOnUnlessStoppedManually` run policies. Check the VM policy:

  ```
  d8 k -n <NAMESPACE> get vm <VM_NAME> -o jsonpath='{.spec.runPolicy}'
  ```

  With the `AlwaysOn` policy, the stop command is rejected with the `NotApplicableForVirtualMachineRunPolicy` reason. In that case, change the policy first, and restore the previous value once the work is done:

  ```
  d8 k -n <NAMESPACE> patch vm <VM_NAME> --type merge -p '{"spec":
  {"runPolicy":"AlwaysOnUnlessStoppedManually"}}'
  ```

  Where `<NAMESPACE>` is the project namespace, and `<VM_NAME>` is the virtual machine name.

Instead of stopping VMs manually, you can let DP restart such VMs for the duration of the node maintenance. The run policy doesn't have to be changed in that case.

If you do none of this, the node doesn't shut down. Two alerts report this situation. The `D8VirtualizationVirtualMachineHoldsNodeMaintenance` alert lists the VMs that hold the node and wait for an administrator's decision. The `D8VirtualizationNodeEvacuationStuck` alert fires if a VM was evicted from a node but neither migrated nor restarted within 15 minutes.

- Module `virtualization` custom resources
- Module `virtualization` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Application scaling and resource management

Scaling applications and managing pod placement in Deckhouse Platform allows dynamic adaptation of cluster resources to the current load, ensuring high availability of services and efficient resource utilization.

Deckhouse supports all major Kubernetes scaling and workload distribution mechanisms:

- Horizontal Pod Autoscaling (HPA) — automatic adjustment of the number of pod replicas based on resource consumption metrics or external indicators.
- Vertical Pod Autoscaling (VPA) — automatic tuning of requested CPU and memory resources for containers based on actual usage.
- Scaling by metrics — using arbitrary metrics to flexibly manage application scaling through Prometheus.
- Pod redistribution (Descheduler) — automatically evicting pods to optimize workload placement across the cluster.
- Pod priorities (Priority Classes) — managing the eviction order of pods during resource shortages based on their importance.
- Scheduler — configuring the rules and logic for node selection when placing pods.

Deckhouse Platform enables automatic application scaling and efficient resource management to ensure stable and predictable cluster operation.

The following sections provide a detailed description of scaling capabilities, configuration examples, and recommendations for their effective use.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Scaling by metrics

Scaling based on metrics

Metric-based scaling is the process of automatically or manually adjusting resources (e.g., number of pod replicas, allocated CPU/memory) based on defined metrics. These metrics can range from CPU or memory usage to the number of requests per second or the size of a message queue.

Scaling can be based on both standard and custom monitoring metrics. For example, scaling can be triggered by the following metrics:

- Pod CPU — current CPU usage.
- Pod Memory — current memory usage.
- RPS (Ingress) — number of requests per second over 1, 5, or 15 minutes (`rps_1m`, `rps_5m`, `rps_15m`).
- Average CPU usage (Pod) — over 1, 5, or 15 minutes (`cpu_1m`, `cpu_5m`, `cpu_15m`).
- Average memory usage (Pod) — over 1, 5, or 15 minutes (`memory_1m`, `memory_5m`, `memory_15m`).

Configuration

To simplify metric-based scaling configuration, DP offers special resources (`Cluster*Metric` and `*Metric`). You can also configure scaling based on custom metric calculation rules.

To configure scaling based on metrics, follow these steps:

1. Enable the `prometheus-metrics-adapter` module. It allows you to define custom resources that describe metric calculation rules using PromQL queries.

   You can enable the `prometheus-metrics-adapter` module in the Deckhouse web interface or via the following command:

   ```
   d8 system module enable prometheus-metrics-adapter
   ```

2. Define a PromQL query that describes the desired metric (e.g., application request rate or CPU usage over time). This query is registered in the cluster as a metric for HPA.
3. Create a HorizontalPodAutoscaler) resource, specifying the metric name and threshold value. Kubernetes will query the result of your PromQL expression and compare it to the threshold, adjusting the number of replicas as needed (see the HPA configuration documentation for more details).

Example PromQL query:

```
query: sum(rate(ingress_nginx_detail_requests_total{<<.LabelMatchers>>}[2m])) by
(<<.GroupBy>>) OR on() vector(0)
```

In this example:

- `ingress_nginx_detail_requests_total` — the base metric (a request counter, e.g., from the Ingress NGINX controller);
- `rate(...[2m])` — calculates the rate of increase over the past 2 minutes (requests per second);
- `sum(...) by (<<.GroupBy>>)` — aggregates the results by a set of labels (e.g., Ingress name, namespace, etc.);
- `OR on() vector(0)` — a PromQL construct that ensures the result is `0` when there's no data (otherwise, the query might return nothing, which would be ignored).

This PromQL query effectively provides the current requests per second value filtered by specified labels (Ingress, namespace, etc.).

Once an administrator defines a metric using a PromQL query (e.g., in an IngressMetric object or a similar mechanism), it can be referenced in a HorizontalPodAutoscaler (HPA) as shown below:

```
apiVersion: deckhouse.io/v1beta1
kind: IngressMetric
metadata:
  name: mymetric
  namespace: mynamespace
spec:
  query: sum(rate(ingress_nginx_detail_requests_total{<<.LabelMatchers>>}[2m])) by
(<<.GroupBy>>) OR on() vector(0)
---
kind: HorizontalPodAutoscaler
apiVersion: autoscaling/v2
metadata:
  name: myhpa
  namespace: mynamespace
spec:
  # The controller to scale (reference to a Deployment or StatefulSet).
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: myapp
  minReplicas: 1
  maxReplicas: 2
  # Metrics used for scaling.
  metrics:
  - type: Object
    object:
      # The object that owns the metrics in Prometheus.
      describedObject:
        apiVersion: networking.k8s.io/v1
        kind: Ingress
        name: myingress
      metric:
        # The metric registered via a custom resource like IngressMetric or
ClusterIngressMetric.
        # You can also use built-in metrics like rps_1m, rps_5m, or rps_15m provided
by the prometheus-metrics-adapter module.
        name: mymetric
      target:
        # For Object-type metrics, use either `Value` or `AverageValue`.
        type: AverageValue
        # Scaling will occur if the average value of the metric across all pods in the
Deployment differs significantly from 10.
        averageValue: 10
```

i When the metric exceeds (or falls below) the threshold `averageValue: 10`, the system will adjust the number of replicas of `myapp` within the range of 1 to 2.

Configuring metrics using observability module resources

To configure custom metric calculation rules:

1. Make sure the `observability` module is enabled.
2. Create a ClusterObservabilityMetricsRulesGroup or ObservabilityMetricsRulesGroup resource:
   - ClusterObservabilityMetricsRulesGroup: Intended for cluster-wide rules applied to system namespaces.
   - ObservabilityMetricsRulesGroup: Intended for rules that operate within a specific namespace.

Configuration example:

```
apiVersion: observability.deckhouse.io/v1alpha1
kind: ClusterObservabilityMetricsRulesGroup
metadata:
  name: custom-cluster-metrics-mymetric
spec:
  interval: 1m
  rules:
    - record: kube_adapter_metric_ingress_bytes_sent
      expr: |
        sum(ingress_nginx_detail_sent_bytes_sum) by (namespace, ingress)
```

Working with unstable metrics

When dealing with unstable metrics (e.g., metrics that fluctuate and cause excessive scaling), it is recommended to:

- Use PromQL aggregation functions. For example, `avg_over_time()` smooths the metric over a specified time range, helping to avoid sudden spikes:

  ```
  apiVersion: deckhouse.io/v1beta1
  kind: ServiceMetric
  metadata:
    name: rmq-queue-forum-messages
    namespace: mynamespace
  spec:
    query: sum
  (avg_over_time(rabbitmq_queue_messages{<<.LabelMatchers>>,queue=~"send_forum_me
  ssage",vhost="/"}[5m])) by (<<.GroupBy>>)
  ```

- Configure stabilization behavior in the autoscaler. You can increase the stabilization window so that decisions to scale up or down are based on more stable data.

Retrieving metric values

To get a list of available metrics, use the following command:

```
d8 k get --raw /apis/custom.metrics.k8s.io/v1beta1/
```

To retrieve metric values associated with specific objects, use:

```
d8 k get --raw /apis/custom.metrics.k8s.io/v1beta1/namespaces/my-
namespace/services/*/my-service-metric
```

To get values of metrics created via `NamespaceMetric`, use:

```
d8 k get --raw /apis/custom.metrics.k8s.io/v1beta1/namespaces/my-
namespace/metrics/my-ns-metric
```

To retrieve external metrics, use:

```
d8 k get --raw /apis/external.metrics.k8s.io/v1beta1
```

Configuring autoscaling in the Deckhouse Web Interface

In Deckhouse Platform, you can configure node autoscaling settings through the Deckhouse web interface. This allows you to dynamically change the number of nodes depending on the load.

To configure autoscaling in the web interface:

- Open the Deckhouse web interface;
- In the left menu, go to the “Nodes” → “ Node Groups” section;
- Select the desired NodeGroup;
- In the “Autoscaling Parameters” section, the current settings will be displayed.

The following settings are available in the Deckhouse web interface:

- Nodes per zone – sets the minimum and maximum number of nodes that can run in a single zone.
- Desired – the current number of nodes needed for operation.
- Requested – the number of nodes currently scheduled for provisioning.
- Standby – additional reserved nodes.

To modify autoscaling parameters:

- Click the edit icon next to the “Nodes per zone” parameter.
- In the pop-up window, specify the minimum and maximum number of nodes.
- Click “Apply” to save the changes, or “Cancel” to discard them.

When you click “Create based on” in the web interface, a form for configuring autoscaling parameters opens:

1. **Main parameters:**
   - Zones – selection of availability zones where machines will be created. This helps distribute nodes across multiple zones. The default value depends on the selected cloud provider and usually includes all zones in the region.
   - Scaling priority – used if multiple node groups exist with the same priority. If not specified, the system will randomly choose a group for scaling.
   - Number of machines created simultaneously during scale-up – defines how many machines can be added at once during scale-up. For example, if the value is 1, nodes will be added one at a time.
   - Max unavailable instances during RollingUpdate – how many nodes can be unavailable during updates. A value of 0 means rolling updates will occur one by one with no downtime.
2. **Standby nodes and resources:**
   - Number of standby nodes out of total nodes – you can specify an exact number (e.g., 2–6) or a percentage (e.g., 15%). A standby node is a pre-provisioned node ready to receive workloads immediately. This speeds up scale-up by several minutes.
   - Resources reserved on standby nodes – the percentage of resources to reserve on standby nodes. Acceptable values: 1% to 80%. For example, if set to 50%, half of the node’s resources will be reserved.
3. **Additional parameters:**
   - Quick Shutdown – enables fast node shutdown, reducing the drain wait time to 5 minutes.

Horizontal pod autoscaling

How Horizontal Scaling (HPA) works

Horizontal Pod Autoscaler (HPA) is a mechanism for automatically adjusting (up or down) the number of pod replicas (in Deployments or StatefulSets) based on metrics retrieved via the Kubernetes API. HPA monitors application load by checking current metrics (e.g., CPU, memory, or custom Prometheus metrics), and adjusts the number of replicas as needed to maintain a desired level of performance or to optimize resource usage.

Available metric types for HPA

Horizontal scaling in DP can be based on any available metrics, such as:

1. Pod CPU and memory usage.
   - Configured using the HorizontalPodAutoscaler resource.
     For example, you can define a Resource-type metric with `averageUtilization = 70` for CPU, so that the application scales up when average CPU usage reaches 70%.
2. DP object metric (Ingress, Service) or pod-based metrics (sum or average across all pods of a controller).

    - Enables scaling based on metrics attached to DP objects (e.g., Ingress, Service), or metrics aggregated from pods (sum or average per controller). Resources like ServiceMetric and IngressMetric are used for this.
3. Any other metrics, including external data (such as Amazon SQS metrics, cloud load balancers, SaaS services, etc.).
    - Useful when the metric source is outside the cluster. Metric calculation rules are configured using the ClusterObservabilityMetricsRulesGroup resource (for cluster-wide metrics) and the ObservabilityMetricsRulesGroup resource (for namespaced metrics) and require enabling the `observability` module.

HPA recommendations

If metrics fluctuate, wrap the metric in an aggregation function (e.g., `avg_over_time()`) or increase the stabilization window (`spec.behavior.scaleUp.stabilizationWindowSeconds`) to avoid rapid scaling of pods.

HPA limitations

1. By default, HPA handles scaling up and scaling down differently:
    - Scaling up:
        - Happens immediately (`spec.behavior.scaleUp.stabilizationWindowSeconds = 0`).
        - Limit — within 15 seconds, the number of pods can double. If there were fewer than 4 pods, up to 4 new pods can be added.
    - Scaling down:
        - Takes up to 5 minutes (`spec.behavior.scaleDown.stabilizationWindowSeconds = 300`).
        - Multiple “proposals” for a new number of replicas are collected, and the highest one is selected to avoid frequent downsizing.
        - There are no limits on how many pods can be removed at once.
2. Only one HPA per controller. You cannot assign multiple HPAs to the same Deployment (or StatefulSet) — they will conflict.

How to enable or disable HPA

HPA does not require separate activation in DP. However, if you want to scale based on metrics other than CPU and memory, you must enable the `prometheus-metrics-adapter` module. See how to enable it in the documentation.

HPA configuration

To configure HPA, follow these steps:

1. Define the controller (Deployment or StatefulSet) to scale.
2. Set scaling limits (`minReplicas` and `maxReplicas`):

   ```
   minReplicas: 1
   maxReplicas: 10
   ```

3. Configure metrics:

   ```
   metrics:
   - type: Resource
     resource:
       name: cpu
       target:
         type: Utilization
         averageUtilization: 70
   ```

4. Optionally, set the `stabilizationWindowSeconds` to delay scaling decisions and limit the pod growth rate:

   Example for scaling up:

```
behavior:
 scaleUp:
   stabilizationWindowSeconds: 300
```

Example for scaling down:

```
behavior:
 scaleDown:
   stabilizationWindowSeconds: 300
```

HPA configuration examples

Scaling based on CPU and memory

Scaling occurs when the average CPU or memory usage across all pods exceeds the specified percentage:

```
apiVersion: autoscaling/v2
kind: HorizontalPodAutoscaler
metadata:
  name: app-hpa
  namespace: app-prod
spec:
  # Specifies the controller to scale (reference to a Deployment or StatefulSet).
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: app
  # Scaling boundaries for the controller.
  minReplicas: 1
  maxReplicas: 10
  # If the application tends to have short CPU usage spikes,
  # you can delay the scaling decision to confirm it's necessary.
  # By default, scaling up happens immediately.
  behavior:
    scaleUp:
      stabilizationWindowSeconds: 300
  metrics:
  # CPU and memory-based scaling.
  - type: Resource
    resource:
      name: cpu
      target:
        # Scaling happens when the average CPU utilization across all pods in
scaleTargetRef exceeds this value.
        # For metrics of type: Resource, only target type: Utilization is available.
        type: Utilization
        # Example: if each pod requests 1 core, scaling occurs when average usage
exceeds 700m.
        averageUtilization: 70
  - type: Resource
    resource:
      name: memory
      target:
        # Scaling based on memory usage exceeding a certain percentage.
        type: Utilization
        # Example: if each pod requests 1 GiB, scaling occurs when average usage
exceeds 800 MiB.
        averageUtilization: 80
```

Scaling based on object metrics

If the `rmq-queue-forum-messages` metric (number of messages in RabbitMQ) exceeds 42, the HPA increases the number of replicas in the `myconsumer` Deployment:

```
apiVersion: deckhouse.io/v1beta1
kind: ServiceMetric
metadata:
  name: rmq-queue-forum-messages
  namespace: mynamespace
spec:
  query: sum
(rabbitmq_queue_messages{<<.LabelMatchers>>,queue=~"send_forum_message",vhost="/"})
by (<<.GroupBy>>)
---
kind: HorizontalPodAutoscaler
apiVersion: autoscaling/v2
metadata:
  name: myhpa
  namespace: mynamespace
spec:
  # Specifies the controller to scale (reference to a Deployment or StatefulSet).
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: myconsumer
  minReplicas: 1
  maxReplicas: 5
  metrics:
  - type: Object
    object:
      describedObject:
        apiVersion: v1
        kind: Service
        name: rmq
      metric:
        name: rmq-queue-forum-messages
      target:
        type: Value
        value: 42
```

Scaling based on external metrics

The `mymetric` metric is sourced from an external system (e.g., SQS). Scaling is triggered when the metric value exceeds 100:

```
kind: HorizontalPodAutoscaler
apiVersion: autoscaling/v2
metadata:
  name: myhpa
  namespace: mynamespace
spec:
  # Specifies the controller to scale (reference to a Deployment or StatefulSet).
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: myapp
  minReplicas: 1
  maxReplicas: 2
  metrics:
  # Using external metrics for scaling.
  - type: External
    external:
      metric:
        # This is the metric registered in Prometheus as kube_adapter_metric_mymetric,
        # but used here without the 'kube_adapter_metric_' prefix.
        name: mymetric
        selector:
          # Use label selectors to narrow down the metric query.
          matchLabels:
            namespace: mynamespace
            ingress: myingress
      target:
        # Only `type: Value` is supported for External metrics.
        type: Value
        # Scaling is triggered if the metric value exceeds 10.
        value: 10
```

Vertical pod autoscaling

How Vertical Scaling (VPA) works

Vertical Pod Autoscaler (VPA) automates container resource management and significantly improves application efficiency. VPA is useful in scenarios where the exact resource requirements of an application are unknown in advance. When VPA is enabled and the appropriate operating mode is set, the requested resources are determined based on actual usage metrics gathered from the monitoring system. It is also possible to configure the system to only recommend resource settings without applying them automatically.

If the application load changes depending on time of day, user requests, or other factors, VPA automatically adjusts the allocated resources. This helps prevent outages due to lack of resources or excessive CPU and memory consumption.

For details on VPA operating modes, its components and limitations, refer to Architecture.

How to enable or disable VPA

You can enable VPA in the following ways:

1. Via a ModuleConfig resource (e.g., ModuleConfig/vertical-pod-autoscaler). Set the `spec.enabled` parameter to `true` or `false`:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: vertical-pod-autoscaler
   spec:
     enabled: true
   ```

2. Via the `d8` command (run inside the `d8-system/deckhouse pod`):

   ```
   d8 system module enable vertical-pod-autoscaler
   ```

3. Through the Deckhouse web interface:

   - Go to the “Deckhouse → Modules” section;
   - Find the vertical-pod-autoscaler module and click on it;
   - Toggle the “Module enabled” switch.

The `vertical-pod-autoscaler` module has no required configuration — it can be enabled and used with default settings.

After creating a VerticalPodAutoscaler resource, you can check VPA recommendations using the following command:

```
d8 k describe vpa my-app-vpa
```

In the `status` section, you’ll see the following parameters:

- `Target`: The recommended resource amount for the pod.
- `Lower Bound`: The minimum recommended resource amount for the application.
- `Upper Bound`: The maximum recommended resource amount for the application.
- `Uncapped Target`: The resource value based on extreme metrics without considering historical data.

VPA configuration

1. Create the VPA module configuration.

   To configure VPA, you need to create a configuration file for the module. Example configuration:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: vertical-pod-autoscaler
   spec:
     version: 1
     enabled: true
     settings:
       nodeSelector:
         node-role/system: ""
       tolerations:
       - key: dedicated.deckhouse.io
         operator: Equal
         value: system
   ```

2. Apply the VPA configuration file using `d8 k apply -f <your-config-file-name>`.

For more details on VPA resource limits configuration, see the documentation.

Module configuration example

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: vertical-pod-autoscaler
spec:
  version: 1
  enabled: true
  settings:
    nodeSelector:
      node-role/system: ""
    tolerations:
    - key: dedicated.deckhouse.io
      operator: Equal
      value: system
```

Pod restart on configuration change

Deckhouse Platform can automatically restart Pods when certain ConfigMap or Secret resources are modified. This functionality is based on the Reloader project and is controlled via annotations added to Pod controllers (Deployment, DaemonSet, StatefulSet).

> Reloader is not designed to be highly available.

The following annotations allow you to control pod restarts.

Supported annotations

Annotation	Applies to objects	Purpose	Example values
`pod-reloader.deckhouse.io/auto`	Deployment, DaemonSet, StatefulSet	Automatically restarts Pods when any related ConfigMap or Secret changes (used as a volume or environment variable)	`"true"`, `"false"`
`pod-reloader.deckhouse.io/search`	Deployment, DaemonSet, StatefulSet	Restarts only when resources annotated with `pod-reloader.deckhouse.io/match: "true"` are changed	`"true"`, `"false"`
`pod-reloader.deckhouse.io/configmap-reload`	Deployment, DaemonSet, StatefulSet	Specifies particular `ConfigMap` resources that should trigger a restart when changed	`"some-cm"`, `"some-cm1,some-cm2"`
`pod-reloader.deckhouse.io/secret-reload`	Deployment, DaemonSet, StatefulSet	Specifies particular `Secret` resources that should trigger a restart when changed	`"some-secret"`, `"some-secret1,some-secret2"`

Annotation	Applies to objects	Purpose	Example values
`pod-reloader.deckhouse.io/match`	ConfigMap, Secret	Marks resources to be tracked when `pod-reloader.deckhouse.io/search: "true"` is used	`"true"`, `"false"`

⚠ The `pod-reloader.deckhouse.io/search` annotation must not be used together with `pod-reloader.deckhouse.io/auto: "true"`. In this case, both `pod-reloader.deckhouse.io/search` and `pod-reloader.deckhouse.io/match` annotations will be ignored. To ensure correct behavior, set `pod-reloader.deckhouse.io/auto: "false"` or remove it.

The `pod-reloader.deckhouse.io/configmap-reload` and `pod-reloader.deckhouse.io/secret-reload` annotations do not work when `pod-reloader.deckhouse.io/auto: "true"` is present. To ensure correct behavior, disable `auto`.

Usage examples

Tracking all changes in all attached resources

Connected resources can be used either as environment variables or mounted as volumes.

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
  labels:
    app: nginx
  annotations:
    pod-reloader.deckhouse.io/auto: "true"
spec:
  template:
    spec:
      containers:
        - name: nginx
          env:
            - name: SECRET_WORD
              valueFrom:
                secretKeyRef:
                  name: nginx-secret-value
                  key: extra
          volumeMounts:
            - name: pages
              mountPath: "/usr/share/nginx/pages"
      volumes:
        - name: pages
          configMap:
            name: nginx-pages
---
apiVersion: v1
kind: Secret
type: Opaque
metadata:
  name: nginx-secret-value
---
apiVersion: v1
kind: ConfigMap
metadata:
  name: nginx-pages
```

Tracking changes in specific resources

Indicates that only those Secrets or ConfigMaps with the annotation `pod-reloader.deckhouse.io/match: "true"` should be monitored. This is useful when a pod uses many resources, but restarts are required only upon changes to specific ones.

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
  annotations:
    pod-reloader.deckhouse.io/search: "true"
spec:
  template:
    spec:
      containers:
        - name: nginx
          env:
            - name: SECRET_WORD
              valueFrom:
                secretKeyRef:
                  name: nginx-secret-value
                  key: extra
---
apiVersion: v1
kind: Secret
type: Opaque
metadata:
  name: nginx-secret-value
  annotations:
    pod-reloader.deckhouse.io/match: "true"
```

Tracking changes in resources from the list

Explicitly specifies a list of ConfigMaps that should trigger a pod restart when changed.

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
  annotations:
    pod-reloader.deckhouse.io/configmap-reload: "nginx-config,nginx-pages"
spec:
  template:
    spec:
      containers:
        - name: nginx
          volumeMounts:
            - name: pages
              mountPath: "/usr/share/nginx/pages"
            - name: config
              mountPath: "/etc/nginx/templates"
      volumes:
        - name: pages
          configMap:
            name: nginx-pages
        - name: config
          configMap:
            name: nginx-config
---
apiVersion: v1
kind: ConfigMap
metadata:
  name: nginx-pages
---
apiVersion: v1
kind: ConfigMap
metadata:
  name: nginx-config
```

Enabling or disabling pod restart

You can enable or disable the pod restart functionality in the following ways:

1. Using a `ModuleConfig` resource (e.g., `ModuleConfig/pod-reloader`). Set the `spec.enabled` field to `true` or `false`:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: pod-reloader
   spec:
     enabled: true
   ```

2. Using the `d8` command (in the `d8-system/deckhouse` pod):

   ```
   d8 system module enable pod-reloader
   ```

3. Through the Deckhouse web interface:
   - Go to the “Deckhouse → Modules” section;
   - Find the `pod-reloader` module and click on it;
   - Toggle the “Module enabled” switch.

Configuration

The pod restart mechanism works out of the box and does not require any mandatory configuration. By default, it is enabled in the Default and Managed module bundles and disabled in the Minimal bundle.

If needed, its behavior can be adjusted in the settings of the pod-reloader module (ModuleConfig `pod-reloader`).

Available parameters:

Parameter	Type	Description	Default Value
`reloadOnCreate`	boolean	Restart on ConfigMap or Secret creation, not only on modification	`true`
`nodeSelector`	object	Limits the nodes where the component can run (equivalent to `spec.nodeSelector`)	Not set
`tolerations`	array	Allows scheduling on tainted nodes (equivalent to `spec.tolerations`)	Not set

Scheduler

Pod scheduling

General overview of the scheduler

The scheduler is a component responsible for assigning pods to cluster nodes based on available resources and specified rules. It selects the most suitable node for running each pod, considering many factors such as CPU and memory availability, data locality, network topology, node labels, and application-specific requirements.

The scheduler operates in multiple stages, each involving different plugins. These plugins evaluate nodes against specific criteria and help determine the optimal placement for a pod.

Main tasks of the scheduler:

- Filtering — determines which nodes meet the pod’s requirements.
- Scoring — assigns scores to nodes based on various criteria (the higher the score, the better the node).
- Binding — assigns the pod to the best node based on scoring results.

Plugins may participate in one or multiple stages. For example, one plugin might be used only during filtering, while another can be involved in both filtering and scoring.

Examples of plugins:

- ImageLocality (phase: Scoring) — prefers nodes that already have the required container images. This helps reduce deployment time since images do not need to be pulled from a remote repository.
- TaintToleration (phases: Filtering, Scoring) — implements the taints and tolerations mechanism. It helps avoid placing pods on unsuitable nodes or, conversely, forces placement on specific nodes (e.g., those with dedicated resources).
- NodePorts (phase: Filtering) — checks if the node has free ports required by the pod. This is especially important for services using fixed NodePorts, as a node cannot host multiple pods using the same port.

For the complete list of plugins, refer to the Kubernetes documentation.

Pod scheduling phases

The process of assigning pods to nodes in DP involves several key phases. The scheduler analyzes available nodes, applies various filtering and scoring criteria, and then selects the most suitable node to run the pod.

In the Filtering phase, filtering plugins are activated. These plugins evaluate all available nodes and select only those that meet certain conditions (e.g., taints, nodePorts, nodeName, unschedulable, and others).

If the nodes are distributed across different availability zones, DP alternates between zones during selection to avoid placing all pods in a single zone. For example, if the nodes are distributed like this:

```
Zone 1: Node 1, Node 2, Node 3, Node 4
Zone 2: Node 5, Node 6
```

The selection will occur in the following order:

```
Node 1, Node 5, Node 2, Node 6, Node 3, Node 4
```

It is important to note that the scheduler does not evaluate all nodes in the cluster — only a subset is considered to optimize the scheduling process. The number of nodes evaluated depends on the size of the cluster:

- In small clusters (≤50 nodes), all nodes are evaluated.
- In medium clusters (~100 nodes), about 50% of nodes are evaluated.
- In very large clusters (~5000 nodes), only 10% of nodes are evaluated.
- The minimum threshold is 5% of nodes when there are more than 5000.

After the filtering phase, the scoring phase begins. During this stage, each node from the filtered list is scored by various scoring plugins that analyze its characteristics and how well it matches the pod's requirements.

Each plugin evaluates a node based on its specific criteria and assigns it a score. These scores are then aggregated to produce an overall ranking.

Key factors considered during scoring include:

- Node load (`pod capacity`) — available CPU and memory are taken into account. Nodes with more free resources receive higher scores.
- Container image locality (ImageLocality) — nodes that already have the required container images are preferred, as this speeds up pod deployment.
- Affinity and anti-affinity rules — nodes that satisfy required placement (or avoidance) rules based on other pods get higher priority.
- Storage availability (`volume provisioning`) — nodes with the necessary PersistentVolumes receive a higher score.

After all scores are summed, the node with the highest total score is selected for pod placement.

If multiple nodes receive the same highest score, the selection is made randomly to avoid inefficient and predictable load distribution.

How to modify or extend scheduler logic

The scheduler in DP can be flexibly configured and extended using custom plugins. This allows its behavior to be adapted to specific cluster requirements, such as considering custom metrics, special workload distribution rules, or node prioritization.

Each such plugin is implemented as a webhook and must meet the following requirements:

- TLS usage – The plugin must be accessed over a secure TLS connection.
- Availability – The plugin must be deployed as a service inside the cluster and accessible via HTTP(S).
- Support for standard verbs – The plugin must support standard scheduler operations:
  - `filterVerb = filter` – participates in node filtering before pod placement.
  - `prioritizeVerb = prioritize` – participates in node scoring during the Scoring phase.
- Node cache capability – It is expected that all extender plugins support caching node data (`nodeCacheCapable: true`) to improve performance.

To connect an extender plugin, use the KubeSchedulerWebhookConfiguration resource. This resource

defines the configuration for an external webhook used by the kube-scheduler and enables more advanced scheduling conditions in the cluster, such as:

- Placing application pods closer to data storage nodes,
- Prioritizing nodes based on their current state (e.g., network load or storage subsystem health),
- Segmenting nodes into zones, etc.

Example of connecting an external scheduler plugin via webhook:

```
apiVersion: deckhouse.io/v1alpha1
kind: KubeSchedulerWebhookConfiguration
metadata:
  name: sds-replicated-volume
webhooks:
- weight: 5
  failurePolicy: Ignore
  clientConfig:
    service:
      name: scheduler
      namespace: d8-sds-replicated-volume
      port: 8080
      path: /scheduler
    caBundle: ABCD=
  timeout: 5s
```

✖ If the `failurePolicy: Fail` parameter is used, any failure in the webhook will cause the scheduler to stop functioning entirely, preventing new pods from being scheduled. It is highly recommended to thoroughly test any custom scheduler plugins before deploying them in a production environment.

Additional pod placement mechanisms

Deckhouse Platform provides flexible mechanisms for managing pod placement within a cluster. These mechanisms help optimize load balancing, improve fault tolerance, and separate system and user workloads.

Main placement configuration options:

- Using node labels (`NodeGroup.spec.nodeTemplate.labels`).
  Allows explicitly targeting specific nodes for pods using `spec.nodeSelector` or `spec.affinity.nodeAffinity`.
- Configuring taints and tolerations.
  Enables limiting pod scheduling to specific nodes, preventing them from being placed on unsuitable hosts.
- Using custom toleration keys (`settings.modules.placement.customTolerationKeys`).
  Allows control over the scheduling of critical Deckhouse components (e.g., CNI and CSI) on dedicated nodes.

1. Using `nodeSelector` — allows you to explicitly specify which nodes pods should be scheduled on. This is done by labeling the desired nodes and referencing those labels in the pod's `spec.nodeSelector`. Example:

   Suppose you have a node named `kube-system-1` that is intended for monitoring services. Label the node:

   ```
   d8 k label node kube-system-1 node-role/monitoring=""
   ```

   Now, to deploy pods only on this node, add a `nodeSelector` to the Deployment:

   ```
   nodeSelector:
    node-role/monitoring: ""
   ```

2. Using taints and tolerations — unlike `nodeSelector`, taints are used to prevent pods from being scheduled on a node unless they have a matching toleration. This ensures that only specific

services run on a given node. Example:

Suppose you have a node named `kube-frontend-1` that is dedicated exclusively to Ingress controllers. Apply a taint to the node:

```
d8 k taint node kube-frontend-1 node-role/frontend="":NoExecute
```

Now, only pods with the appropriate toleration will be allowed to run on this node:

```
tolerations:
- effect: NoExecute
  key: node-role/frontend
```

This mechanism prevents unintended pods from being scheduled on nodes that are meant for specific purposes.

3. Using `customTolerationKeys` — Deckhouse supports the `customTolerationKeys` mechanism, which explicitly defines allowed toleration keys. This is useful when you need to run system services (such as CNI, CSI, etc.) on specific nodes. Example:

   ```
   customTolerationKeys:
   - dedicated.example.com
   - node-dedicated.example.com/master
   ```

   This mechanism allows:

   - Divide nodes into zones — for example, dedicating some for Ingress controllers and others for system services (Prometheus, VPN, CoreDNS).
   - Isolate critical applications from system components, avoiding resource contention.

Scheduler profiles

The scheduler supports multiple profiles that define different strategies for distributing pods across nodes in the cluster. Depending on the selected profile, pods will be scheduled with different load balancing logic.

- `default-scheduler` — the default profile that attempts to evenly distribute pods across nodes, preferring less loaded ones.
- `high-node-utilization` — a profile that places pods on more heavily loaded nodes. This can be useful in scenarios where workload consolidation is needed, allowing underutilized nodes to be shut down or repurposed.

To select a scheduler profile, specify it in the `spec.schedulerName` field of the Pod manifest. Example:

```
apiVersion: v1
kind: Pod
metadata:
  name: scheduler-example
  labels:
    name: scheduler-example
spec:
  schedulerName: high-node-utilization
  containers:
  - name: example-pod
    image: registry.k8s.io/pause:2.0
```

Pod redistribution

DP analyzes the state of the cluster every 15 minutes and evicts pods that match the conditions described in active scheduling strategies. Evicted pods go through the standard scheduling process again, taking the current cluster state into account. This mechanism allows workloads to be redistributed based on the selected strategy and frees up resources on certain nodes when necessary.

Considering pod Priority Classes

DP defines a set of priority classes that determine the importance of pods and the order in which they

are evicted during workload redistribution.

If the cluster lacks resources, lower-priority pods may be evicted in favor of higher-priority ones. This ensures that critical services remain operational even when nodes are overloaded.

How DP considers pod priority

Deckhouse Platform uses the pod priority mechanism to determine which pods should be evicted when resources are insufficient. The higher the pod’s priority, the lower the chance it will be evicted during redistribution.

This mechanism is controlled by the `descheduler` module, where you can define a priority threshold using the `spec.priorityClassThreshold` parameter. This threshold limits eviction to only those pods with a priority below the specified value.

You can set the threshold in two ways:

- By class name: Use `priorityClassThreshold.name` to evict only pods with a priority lower than the specified priority class.
- By numeric value: Use `priorityClassThreshold.value` to evict pods with a priority lower than the specified integer value.

Example:

```
apiVersion: deckhouse.io/v1alpha2
kind: Descheduler
metadata:
  name: custom
spec:
  priorityClassThreshold:
    name: high-priority
```

Which pods are not evicted

- DP does not evict a pod in the following cases:
  - The pod is in the `d8-*` or `kube-system` namespace;
  - The pod has the `priorityClassName` set to `system-cluster-critical` or `system-node-critical`;
  - The pod is using local storage;
  - The pod is managed by a DaemonSet;
  - Evicting the pod would violate a Pod Disruption Budget (PDB);
  - There are no available nodes to reschedule the evicted pod.

If multiple pods match the eviction criteria, DP applies additional logic:

1. Pods with the lowest priority (`BestEffort`) are evicted first;
2. Then `Burstable` pods are considered;
3. `Guaranteed` pods are evicted last, and only if absolutely necessary.

DP provides fine-grained control over which pods and nodes are subject to eviction:

- `spec.podLabelSelector` — limits evicted pods by label;
- `spec.namespaceLabelSelector` — filters namespaces whose pods can be considered for eviction;
- `spec.nodeLabelSelector` — selects target nodes by label.

Each of these fields supports standard `matchExpressions` and `matchLabels` syntax, allowing you to use operators like `In`, `NotIn`, `Exists`, and `DoesNotExist` with desired label values.

How to enable or disable pod eviction

To enable the pod redistribution feature, you need to enable the `descheduler` module.

You can do this in one of the following ways:

1. Using a ModuleConfig resource (e.g., `ModuleConfig/descheduler`). Set the `spec.enabled` field to `true` or `false`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: descheduler
spec:
  enabled: true   # or false to disable
```

2. Using the `d8` command (in the `d8-system/deckhouse` pod):

```
d8 system module enable descheduler
# or to disable:
d8 system module disable descheduler
```

3. Through the Deckhouse web interface:
   - Go to the “Deckhouse → Modules” section;
   - Find the `descheduler` module and click on it;
   - Toggle the “Module enabled” switch.

The module does not require mandatory configuration. You can enable it without additional settings — it will work with the default values.

Descheduling strategies

The `spec.strategies` parameter lists the strategies you want to enable or configure. Each strategy has an `enabled` flag (default is `false`).

Below is a list of the main strategies available in DP.

HighNodeUtilization — concentrates workloads on fewer nodes by evicting pods from underutilized nodes so they can be rescheduled elsewhere. Requirements:

- Specific `descheduler` module configuration — `MostAllocated`;
- (Optional) cluster autoscaling must be enabled — to allow unused nodes to be shut down.

This strategy is enabled using the `spec.strategies.highNodeUtilization.enabled` parameter.

The `thresholds` parameter defines the resource usage levels below which a node is considered underutilized. If usage (CPU, memory, etc.) falls below *all* threshold values, the node is deemed underutilized, and DP will attempt to evict pods from it.

Example:

```
---
apiVersion: deckhouse.io/v1alpha2
kind: Descheduler
metadata:
  name: high-node-utilization
spec:
  strategies:
    highNodeUtilization:
      enabled: true
      thresholds:
        cpu: 50
        memory: 50
```

If any of these resource types is not specified, all its thresholds default to 100 to avoid nodes going from underutilized to overutilized For example, If the memory threshold is not specified in thresholds, it defaults to 100.

```
thresholds:
  cpu: 50
```

> **i** In GKE (Google Kubernetes Engine), it is not possible to configure `MostAllocated` by default, but you can use the `optimize-utilization` strategy instead.

LowNodeUtilization — more evenly distributes workloads across nodes. This strategy identifies underutilized nodes and evicts pods from overutilized ones, assuming that evicted pods will be rescheduled on the underutilized nodes.

Enable the strategy via `spec.strategies.lowNodeUtilization.enabled`.

- An **underutilized** node is one where all resources are below the thresholds set in `strategies.lowNodeUtilization.thresholds`.
- An **overutilized** node exceeds at least one of the values in `strategies.lowNodeUtilization.targetThresholds`.

Nodes with resource usage between `thresholds` and `targetThresholds` are considered optimally utilized and will not have pods evicted.

Example:

```
---
apiVersion: deckhouse.io/v1alpha2
kind: Descheduler
metadata:
  name: low-node-utilization
spec:
  strategies:
    lowNodeUtilization:
      enabled: true
      thresholds:
        cpu: 20
      targetThresholds:
        cpu: 50
```

RemoveDuplicates — prevents multiple pods from the same controller (ReplicaSet/ReplicationController/StatefulSet/Job) from running on the same node simultaneously (DaemonSets are excluded). If, for any reason, 2 or more pods from the same controller end up on a single node, this strategy will evict the “extra” pods to redistribute them more evenly across the cluster.

This situation can occur after temporary node failures — when pods are rescheduled to other nodes, and once the original node is back online, the pods remain concentrated on the fallback node.

Enable the strategy using the `strategies.removeDuplicates.enabled` parameter.

Example:

```
spec:
  strategies:
    removeDuplicates:
      enabled: true
```

RemovePodsHavingTooManyRestarts — evicts pods having too many restarts from nodes. Pods become eviction candidates when the total number of restarts across all containers, including init containers, exceeds the `podRestartThreshold` threshold. This strategy is useful for evicting pods in the `CrashLoopBackOff` state or with repeated failures, as well as for freeing up resources and allowing fresh pods to be scheduled on potentially healthier nodes.

Enable the strategy using the `strategies.removePodsHavingTooManyRestarts.enabled` parameter.

Example:

```
spec:
  strategies:
    removePodsHavingTooManyRestarts:
      enabled: true
```

RemovePodsViolatingInterPodAntiAffinity — evicts any pods that violate `inter-pod affinity/anti-affinity` rules. For example, if `pod2` and `pod3` have an `anti-affinity` rule against `pod1`, but all three end up on the same node, this strategy will evict `pod1` so that `pod2` and `pod3` can continue operating according to their scheduling constraints.

Enable the strategy using the `strategies.removePodsViolatingInterPodAntiAffinity.enabled` parameter.

Example:

```
spec:
  strategies:
    removePodsViolatingInterPodAntiAffinity:
      enabled: true
```

RemovePodsViolatingNodeAffinity — this strategy evicts pods that no longer comply with their defined `node affinity` rules. `Node affinity` defines which nodes are suitable for a pod at scheduling time:

1. `requiredDuringSchedulingIgnoredDuringExecution`:
   - A pod with this rule must be scheduled only on a node that satisfies the specified conditions (e.g., a specific label).
   - If the node later no longer satisfies the condition (e.g., the label is removed), and there is another suitable node in the cluster, DP will evict the pod so it can be rescheduled on a valid node.
2. `preferredDuringSchedulingIgnoredDuringExecution`:
   - A pod with this preference may run on a node that doesn’t fully match the affinity, if no better option is available.
   - If a more suitable node appears later in the cluster, DP may evict the pod so it can be restarted under better placement conditions.

This strategy helps ensure pods continue to align with their node affinity rules and do not remain in suboptimal locations when better options become available.

Enable the strategy using the `spec.strategies.removePodsViolatingNodeAffinity.enabled` parameter.

Example:

```
spec:
  strategies:
    removePodsViolatingNodeAffinity:
      enabled: true
      nodeAffinityType:
        - requiredDuringSchedulingIgnoredDuringExecution
        - preferredDuringSchedulingIgnoredDuringExecution
```

RemovePodsViolatingTopologySpreadConstraint — ensures that pods violating topology spread constraints are evicted from nodes. It evicts the minimum number of pods required to balance topology domains to within each constraint’s `maxSkew`. This is useful for rebalancing pods across zones after a zone outage recovery.

Enable the strategy using the `strategies.removePodsViolatingTopologySpreadConstraint.enabled` parameter.

Example:

```
spec:
  strategies:
    removePodsViolatingTopologySpreadConstraint:
      enabled: true
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Priority classes

Deckhouse Platform creates a set of priority classes (PriorityClass) in the cluster and assigns them to its components. Applications and virtual machines (VMs) can use these classes by setting the `priorityClassName` field. The scheduler takes pod priority into account: if resources are insufficient, pods with lower priority are preempted first.

For example, if a pod with the `production-low` class cannot be scheduled due to insufficient resources, the scheduler first preempts pods with a lower priority, such as `develop`, then `cluster-low`, and so on. If `priorityClassName` is not set, the pod is assigned the `develop` class.

The priority class of a VM is passed to its `virt-launcher` pod, so the scheduler uses the same rules to choose which VMs to preempt as it does for pods.

Available priority classes

The table lists the priority classes that Deckhouse Platform creates in the cluster, in descending priority order (the higher the value, the higher the priority). Choose a class based on the environment and workload criticality.

> ✖ Do not use the `system-node-critical`, `system-cluster-critical`, `cluster-medium`, or `cluster-low` priority classes, as they are reserved for critical cluster components.

Priority class	Description	Value
`system-node-critical`	Cluster components that must be present on the node. Also fully protected from eviction by the kubelet. Examples: `node-exporter`, `csi`, and others.	2000001000
`system-cluster-critical`	Cluster components without which the cluster cannot operate correctly. MutatingWebhooks and Extension API servers must use this priority class. Also fully protected from eviction by the kubelet. Examples: `kube-dns`, `kube-proxy`, `cni-flannel`, `cni-cilium`, and others.	2000000000
`production-high`	Stateful applications whose absence in a production environment leads to complete service unavailability or data loss. Examples: `PostgreSQL`, `Memcached`, `Redis`, `MongoDB`, and others.	9000

Priority class	Description	Value
`cluster-medium`	Cluster components that affect monitoring (alerts, diagnostics) and autoscaling. Without monitoring, you cannot assess the scope of an incident; without autoscaling, applications cannot get the resources they need. Examples: `deckhouse`, `node-local-dns`, `grafana`, `upmeter`, and others.	7000
`production-medium`	Main stateless applications in production that serve end users.	6000
`deployment-machinery`	Cluster components used for building and deploying workloads to the cluster.	5000
`production-low`	Production applications (cron jobs, admin panels, batch processes) that can be unavailable for some time. If batch or cron jobs must not be interrupted, assign them `production-medium`.	4000
`staging`	Staging environments for applications.	3000
`cluster-low`	Cluster components that are not required for operation but are desirable. Examples: `dashboard`, `cert-manager`, `prometheus`, and others.	2000
`develop` (default)	Development environments for applications. Default class if no other class is specified.	1000
`standby`	Not intended for applications. Used for system purposes to reserve nodes.	-1

Creating additional priority classes

In addition to the classes that Deckhouse Platform creates in the cluster, you can create an additional priority class by specifying a name and a numeric priority value.

The following example creates the `critical-applications` priority class with priority `8000`. Pods that use this priority class are preempted before pods with the `production-high` priority class (and higher), but after pods with the `cluster-medium` priority class (and lower).

Create a file `critical-applications.yaml` with the following content:

```
apiVersion: scheduling.k8s.io/v1
kind: PriorityClass
metadata:
  name: critical-applications
value: 8000
globalDefault: false
description: "Priority for critical applications"
```

A PriorityClass resource manifest uses the following fields:

- `metadata.name` — the priority class name referenced by the `priorityClassName` field in pod specifications.
- `value` — numeric priority. The higher the value, the higher the priority.
- `globalDefault` — specifies whether this class is assigned to pods that do not explicitly set

`priorityClassName`.
- `description` — class description.

⚠ Be careful with the `globalDefault: true` field. If you enable it for an additional class, that class will be assigned to pods that do not explicitly specify `priorityClassName`, which may cause unexpected preemption of system components.

Apply the manifest to the cluster:

```
d8 k apply -f critical-applications.yaml
```

Verify that the priority class was created:

```
d8 k get priorityclass critical-applications
```

Example output:

```
NAME                    VALUE   GLOBAL-DEFAULT   AGE   PREEMPTIONPOLICY
critical-applications   8000    false            7s    PreemptLowerPriority
```

i Do not create additional classes with values above 1,000,000 to avoid disrupting critical system components.

Preemption mechanism

How it works

The scheduler makes preemption decisions based on numeric priority values. The workload type (Deployment, StatefulSet, DaemonSet, VM, or standalone pod) does not affect preemption decisions. The scheduler compares pod priority values regardless of the workload type: a higher-priority pod can preempt a lower-priority pod to free resources on the node.

Preemption does not occur when priorities are equal. If a new pod has the same priority as existing pods, the scheduler does not preempt them. The new pod remains `Pending` until sufficient resources become available.

For practical scenarios and step-by-step demonstrations, see Using priority classes.

Protecting a pod from eviction

The only way to protect a pod from preemption is to assign it a sufficiently high priority. However, even with a high priority, the pod will be preempted if another pod with an even higher priority appears in the cluster.

To reduce the risks associated with preemption, combine the following three mechanisms:

1. Specifying a high-priority class in the `priorityClassName` field — reduces the likelihood that the pod will be selected for preemption.
2. Using a PodDisruptionBudget (PDB) — limits how many replicas can be disrupted at the same time. During preemption, the scheduler treats PDB constraints as best-effort rather than strict requirements (unlike planned operations such as draining a node, where PDB is a hard constraint).
3. `terminationGracePeriodSeconds` — gives the application time to flush buffers and close connections before forced termination. This helps preserve data integrity when a pod must be terminated, including cases where the PDB cannot be honored.

i Without the `terminationGracePeriodSeconds` parameter on a pod, an immediate termination may lead to loss of data that was not written to disk and, for example, to database corruption.

Do not create a PodDisruptionBudget for VMs: it does not affect VM eviction. The time for a graceful guest operating system (OS) shutdown is set by the `.spec.terminationGracePeriodSeconds` parameter in the VM specification (60 seconds by default).

Differences between priority classes and other resource management

mechanisms

Priority classes (PriorityClass) serve a different purpose from other resource management mechanisms:

Mechanism	Purpose	Difference from priority classes
ResourceQuota	Limits resource consumption in a namespace	Limits total resource consumption within a namespace; does not determine preemption order.
LimitRange	Default limits and requests for pods	Sets minimum and maximum values; does not affect preemption.

Unlike ResourceQuota and LimitRange, priority classes determine which pods take precedence when resources are insufficient; they do not limit resource consumption.

Operations and diagnostics

If a pod does not start despite available resources in the cluster, the issue is often related to pod placement rather than its priority class.

Possible cluster-level causes:

- Available CPU and memory are distributed across multiple nodes, and no single node has enough resources to accommodate the pod, even after preemption.
- No eligible pods can be preempted because all pods on the target node have equal or higher priority. How to check — see the Practical check when no suitable pods are available user section.
- No nodes satisfy the pod's scheduling requirements, for example because of taints that the pod does not tolerate.
- The pod limit per node (`Capacity.pods`) has been reached. Preemption cannot resolve this condition because replacing one pod with another does not reduce the total pod count.

What you can do:

1. Add worker nodes or redistribute workloads if available resources are spread across different nodes.
2. Free resources on the overloaded node by removing or relocating less critical pods.
3. Review the density of DaemonSet and system pods on the node.
4. If needed, assign the application a higher priority class from Available priority classes.

Additional resources

- Using priority classes

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Network

Unlike basic Kubernetes installations, Deckhouse Platform (DP) handles network configuration through modules and custom resources, which simplifies and standardizes the setup process.

The platform supports:

- Management of incoming and outgoing traffic.
- Configuration of inter-cluster communication.
- Management of network policies and routing.
- DNS management within the Kubernetes cluster.

Configuring and managing incoming traffic

Incoming traffic is managed using Ingress controllers. These controllers route user requests to the appropriate applications and services based on rules defined in Ingress resources. In DP, traffic can be

managed at both the network level (NLB – Network Load Balancer) and the application level (ALB – Application Load Balancer).

Managing outgoing traffic

DP administrators can configure and manage outgoing traffic to ensure correct processing and routing of all outgoing data.

Configuring outgoing traffic enables connection control and filtering, which is especially important for secure integrations with external APIs and services. This can be achieved by defining policies that allow or block specific traffic flows.

Outgoing traffic management is implemented using the Egress Gateway feature (provided by the `cni-cilium` module) as well as Istio tools (via the `istio` module).

Internal network configuration

DP provides a wide range of options for managing the internal network. Administrators can configure pod-to-pod and pod-to-node communication, as well as traffic encryption using various technologies and tools.

Configuring inter-cluster communication

DP supports two approaches to organizing communication between independent and codependent clusters:

- Multicluster — combines clusters to share resources, balance loads, and improve fault tolerance. Ideal for distributed teams and infrastructure spread across regions.
- Federation — centralized management of multiple independent clusters with unified policies and synchronized configurations. Effective for large organizations and complex systems.

For more information on configuring inter-cluster communication, refer to Inter-cluster communication.

Network policies

Network policies in DP describe rules that regulate interactions between objects within the cluster and define ingress and egress traffic for those objects. They isolate pods, protect against internal cluster attacks, and control access to external services and filter incoming and outgoing connections.

The section includes the following pages:

- Kubernetes NetworkPolicy — isolation model, selectors, default policies, API limitations.
- CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy — Cilium extensions, entities, L7 rules, FQDN rules, audit mode.
- Host firewall on nodes — protecting nodes with CiliumClusterwideNetworkPolicy and `nodeSelector`.
- Common policy examples — recipes for typical tasks.
- Diagnostics and observability — verifying and debugging policies.

Virtual machine networking

Virtual machines get their addresses from separate subnets listed in the `virtualMachineCIDRs` parameter of the virtualization settings. Which subnets to choose, how they differ from the pod and service networks, and how a machine gets its address is described in Virtual machine networking.

Additional resources

- Module `istio` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Internal network configuration

In Deckhouse Platform, networking is configured using CNI plugins. The recommended option is Cilium, which suits most use cases. Other supported CNIs include Flannel and Simple Bridge, typically used with cloud providers.

Network parameters are specified during the deployment of the DP cluster:

- Address ranges for Pods and Services are defined.
- The network operation mode for Cilium is selected (this can be changed later).

Internal network operation modes

The operation mode is set via the `tunnelMode` parameter in the `cni-cilium` module settings. Two modes are supported:

- Classic
- VXLAN tunnel

The appropriate mode depends on the cluster network setup:

- If all nodes are on the same network, either mode can be used.
- If nodes are on different networks, using VXLAN is recommended to create a virtual isolated network over the existing one. This allows communication across different network segments.

Performance differences between the modes are minimal. The table below outlines their characteristics:

Parameter	Classic mode	VXLAN tunnel mode
Network type	For nodes in the same network	Suitable for nodes in different networks
Traffic isolation	Not provided	Provided
Infrastructure usage	Direct routing	Virtual network over existing infrastructure
Changes to MTU	No changes	MTU is reduced due to encapsulation
Additional routing	Intermediate hop is added	Not required

Mode configuration

The internal network mode is configured via the ModuleConfig resource named `cni-cilium`.

Example configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cni-cilium
spec:
  version: 1
  enabled: true
  settings:
    tunnelMode: VXLAN
```

For more details on configuring the `cni-cilium` module, refer to the module documentation.

⚠ After changing the operation mode, reboot all nodes. Otherwise, Pod availability issues may occur.

Services

Services in DP are implemented either using the selected CNI plugin or through `kube-proxy`.

They provide access to groups of Pods performing the same function and balance traffic between them. Each Service object defines:

- A logical group of endpoints (Pods).

- A routing method for reaching them.

Supported service types

- **ClusterIP**: Creates an internal IP address selected from the Service network. All traffic sent to this IP is forwarded to the Pods specified in the selector. This ensures load balancing.

  You can also disable IP assignment in this service type. In that case, the service will not be assigned an IP address from the service network, and it will resolve to the Pod IPs. Load balancing will be done using DNS (round-robin).

- **NodePort**: Opens the specified port on each cluster node and forwards incoming traffic to the Pods. For security reasons, DP only listens on the node's internal IP. This behavior can be overridden by adding the annotation `node.deckhouse.io/nodeport-bind-internal-ip: "false"` to a node group.
- **LoadBalancer**: Created in the cloud provider where DP is deployed and accepts external traffic. In bare-metal clusters, similar functionality is implemented using the `metalLb` module.
- **ExternalName**: A DNS record for accessing the service (acting as a CNAME).

Configuring the service network with kube-proxy

When using Flannel or Simple Bridge, the `kube-proxy` module is required for services to function. It replaces the default kubeadm components (DaemonSet, ConfigMap, RBAC) with its own configuration.

By default, for security reasons, when using services of NodePort type, connections are only accepted on the node's InternalIP. This behavior can be changed by adding the following annotation to the node: `node.deckhouse.io/nodeport-bind-internal-ip: "false"`.

Example annotation for a NodeGroup:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: myng
spec:
  nodeTemplate:
    annotations:
      node.deckhouse.io/nodeport-bind-internal-ip: "false"
```

⚠ After adding, removing, or changing this annotation, you must manually restart all kube-proxy Pods.

When the `cni-cilium` module is enabled, the `kube-proxy` module is automatically disabled.

Additional resources

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Encrypting traffic between pods

To encrypt traffic between pods in Deckhouse Platform (DP), you can use mTLS provided by Istio (via the `istio` module).

mTLS (mutual TLS) enables mutual authentication between services using TLS certificates: for all outgoing requests, the server certificate is verified; for incoming requests, the client certificate is checked. Once verification is successful, the sidecar proxy identifies the remote node and can use this information for authorization or other application-level purposes.

Each service receives a unique identifier in the format `<TrustDomain>/ns/<Namespace>/sa/<ServiceAccount>`.

Where:

- `TrustDomain` is the cluster domain.
- `ServiceAccount` is the account name (either `default` or a custom one).

This identifier is used as the verifiable name in TLS certificates.

The settings can be overridden at the namespace level.

mTLS configuration example

1. Enable the `istio` module:

   ```
   d8 k create -f -<<EOF
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: istio
   spec:
     version: 2
     enabled: true
   EOF
   ```

2. Create a namespace and add labels:

   ```
   d8 k create namespace test-istio-mtls
   d8 k label namespace test-istio-mtls istio-injection=enabled
   d8 k label namespace test-istio-mtls security.deckhouse.io/pod-policy=privileged
   ```

3. Apply a policy that defines the mTLS mode. Available modes:

   - `PERMISSIVE` (default): Allows encrypted traffic between pods, but also permits unencrypted traffic.
   - `STRICT`: Only encrypted traffic is allowed.

   Example of applying `PERMISSIVE` mode:

   ```
   d8 k -n test-istio-mtls create -f -<<EOF
   apiVersion: security.istio.io/v1beta1
   kind: PeerAuthentication
   metadata:
     name: default
   spec:
     mtls:
       mode: PERMISSIVE
   EOF
   ```

4. Create a Deployment:

   - If using a public registry:

     ```
     d8 k -n test-istio-mtls create deployment webserver --image=docker.io/library/nginx:1.26-alpine --port 80
     ```

   - If using an all-in-one image (replace with your registry address):

     ```
     d8 k -n test-istio-mtls create deployment webserver --image=registry.company.network/localrepo/all-in-one-image:0.1 --port 80 -- /bin/sh -c 'nginx -g "daemon off;"'
     ```

5. Expose the Deployment:

```
d8 k -n test-istio-mtls expose deployment webserver --port=80
```

6. Get the Pod IP or the associated node name. It will be required to run `tcpdump` on the respective node:

   ```
   d8 k -n test-istio-mtls get pods -l app=webserver -o wide
   ```

   Example output:

   ```
   NAME                         READY   STATUS     RESTARTS   AGE   IP
   NODE                                 NOMINATED NODE   READINESS GATES
   webserver-76d6c9b8c-9mdtb    2/2     Running    0          48m   10.111.1.122
   test-worker-e36e4712-5948b-sp9t8          <none>           <none>
   ```

7. Access the node via SSH as root and run `tcpdump`:

   ```
   tcpdump -A -v -i any host 10.111.1.122 and port 80
   ```

8. Create a Deployment client in the same namespace so that it is part of the mesh network:
   - If using a public registry image:

     ```
     d8 k -n test-istio-mtls create deployment client --image=docker.io/library/alpine:3.21 --
     /bin/sh -c "sleep infinity"
     ```

   - If using an all-in-one image (replace with your registry address):

     ```
     d8 k -n test-istio-mtls create deployment client --
     image=registry.company.network/localrepo/all-in-one-image:0.1 -- /bin/sh -c "sleep
     infinity"
     ```

9. After the Pod is created, make a request to the `webserver` service:

   ```
   d8 k -n test-istio-mtls exec -ti deployments/client -- wget -S --spider --timeout 1
   webserver`
   ```

   The `tcpdump` output will show only encrypted traffic:

```
10.111.91.68.http > 10.111.91.167.54204: Flags [P.], cksum 0xd7c7 (incorrect -> 0xe83a), seq
1:3033, ack 518, win 134, options [nop,nop,TS val 3160034944 ecr 2239691194], length 3032: HTTP

...
```

10. Create a namespace without the `istio-injection=enabled` label and make a request to the `webserver.test-istio-mtls` service (a request is made from a Pod that is not part of the mesh network):

    ```
    d8 k create namespace test-istio-mtls-without-injection
    ```

11. Add a Deployment:

    - If using a public registry image:

      ```
      d8 k -n test-istio-mtls-without-injection create deployment alpine --
      image=docker.io/library/alpine:3.21 -- /bin/sh -c "sleep infinity"
      ```

    - If using an all-in-one image (replace with your registry address):

      ```
      d8 k -n test-istio-mtls create deployment client --
      image=registry.company.network/localrepo/all-in-one-image:0.1 -- /bin/sh -c "sleep
      infinity"
      ```

12. After the Pod is created, make a request to the `webserver.test-istio-mtls` service:

    ```
    d8 k -n test-istio-mtls-without-injection exec -ti deployments/alpine -- wget -S --spider --
    timeout 1 webserver.test-istio-mtls`.
    ```

    The `tcpdump` output will show only unencrypted (plain text) requests and responses:

```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring cluster network stack visualization

To visualize network interactions in the cluster between pods, services, and external resources, as well as to monitor activity and identify network issues, use the `cilium-hubble` module.

Once you enable the module, the network stack visualization becomes available through the Hubble web interface.

Switching CNI from Flannel or Simple bridge to Cilium

> This guide is applicable to Deckhouse Platform version 1.75 and earlier.
>
> For DP version 1.76 and later, use the Switching CNI in the cluster guide.

> ⚠ The migration requires a **full cluster downtime**: all pods and nodes will be restarted. Estimated time to complete is **about 1 hour**.

To perform the migration, follow these steps:

1. Enable the `cni-cilium` module:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: cni-cilium
   spec:
     version: 1
     settings:
       tunnelMode: VXLAN
     enabled: true
   ```

2. Wait for the Cilium components to start:

   ```
   d8 k -n d8-cni-cilium get pods
   ```

   Example output:

```
NAME                          READY STATUS  RESTARTS    AGE
agent-5zzfv                   2/2   Running 5 (23m ago) 26m
agent-gqb2b                   2/2   Running 5 (23m ago) 26m
agent-wtv4p                   2/2   Running 5 (23m ago) 26m
operator-856d69fd49-mlglv 2/2   Running 0           26m
safe-agent-updater-26qpk  3/3   Running 0           26m
safe-agent-updater-qlbrh  3/3   Running 0           26m
safe-agent-updater-wjjr5  3/3   Running 0           26m
```

If the Cilium agent pods do not transition to the `Ready` state:

- Save the `d8-kube-proxy` manifest:

  ```
  d8 k -n kube-system get ds d8-kube-proxy -oyaml > d8-kube-proxy.yaml
  ```

- Run the recovery actions:

  ```
  d8 k delete validatingadmissionpolicies.admissionregistration.k8s.io label-
  objects.deckhouse.io
  d8 k -n kube-system delete ds d8-kube-proxy
  d8 k -n d8-cni-cilium delete po -l app=agent
  ```

- If Cilium startup still takes more than 5 minutes, restart `kube-proxy`:

  ```
  d8 k -n kube-system delete pod -l k8s-app=kube-proxy
  ```

3. Save the DaemonSet manifest:

   ```
   d8 k -n d8-cni-simple-bridge get ds simple-bridge -o yaml > simple-bridge.yaml
   # or
   d8 k -n d8-cni-flannel get ds flannel -o yaml > flannel.yaml
   ```

4. Disable `cni-simple-bridge` or `cni-flannel`. Perform this step only after the Cilium pods have reached the `Ready` state:

   ```
   d8 k -n d8-system exec -it svc/deckhouse-leader -- deckhouse-controller module disable cni-
   simple-bridge
   # or
   d8 k -n d8-system exec -it svc/deckhouse-leader -- deckhouse-controller module disable cni-
   flannel
   ```

5. Delete the `validating webhook` (if present):

   ```
   d8 k delete validatingwebhookconfigurations.admissionregistration.k8s.io d8-deckhouse-validating-
   webhook-handler-hooks
   ```

6. Delete the namespace of the old CNI (if it was not removed automatically):

   ```
   d8 k delete ns d8-cni-simple-bridge
   # or
   d8 k delete ns d8-cni-flannel
   ```

7. (Optional) Clean up artifacts of the old CNI. If required, remove the interface and flush iptables rules:

```
ip link delete cni0

iptables -t filter -F
iptables -t filter -X
iptables -t nat -F
iptables -t nat -X
iptables -t mangle -F
iptables -t mangle -X
iptables -t raw -F
iptables -t raw -X
iptables -P INPUT ACCEPT
iptables -P FORWARD ACCEPT
iptables -P OUTPUT ACCEPT
```

8. Restart all pods:

```
d8 k delete pods -A --all --wait=false
```

9. Configure internal LoadBalancers (if used). For all TargetGroups that belong to the internal load balancer, set:

```
Preserve client IP addresses = Off
```

10. Reboot the cluster nodes one by one, including the master nodes.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Incoming traffic balancing

This section describes the approaches to balancing incoming traffic in Deckhouse Platform (DP):

- NLB (Network Load Balancer) — operates at the network level, routing traffic based on IP addresses and ports without inspecting request contents.
- ALB (Application Load Balancer) — operates at the application level, analyzing HTTP(S) headers, paths, and domains. It supports SSL termination and content-based routing.

Network-level load balancing (NLB)

NLB-based load balancing can be implemented in two ways:

- Using an external load balancer provided by a cloud provider.
- Using the built-in `metallb` balancer, which works in both cloud and bare-metal clusters.

Application-level load balancing (ALB)

For application-level traffic balancing, DP provides following solutions:

- Ingress NGINX Controller (via the `ingress-nginx` module).
- Kubernetes Gateway API (`alb` module).
- Istio (via the `istio` module).

Difference between the Kubernetes Gateway API and an API gateway

Kubernetes Gateway API and an API gateway serve different purposes:

- The Kubernetes Gateway API is a set of Kubernetes resources (a specification) that describe how inbound traffic is routed to services. It is a configuration interface implemented by controllers, and the successor to the Ingress API.
- An API gateway is an architectural component (or product) that aggregates several application APIs behind a single entry point and centralizes cross-cutting functions such as authentication,

authorization, and request rate limiting for API consumers.

In other words, the Kubernetes Gateway API describes how to configure traffic routing, while an API gateway is a type of infrastructure that handles that traffic. Some API gateways can be configured through the Kubernetes Gateway API. The `alb` module is an implementation of the Kubernetes Gateway API.

Role separation in the Gateway API model

When using the `alb` module, responsibilities are typically split as follows:

- Cluster administrator — deploys cluster-scoped gateway infrastructure with ClusterALBInstance.
- Namespace administrator — deploys namespaced gateway infrastructure with ALBInstance and configures how traffic is accepted with ListenerSet (hostname, TLS, ports).
- Application developers — configure routing to applications with HTTPRoute and other route objects.

In a typical cluster-wide gateway scenario, the namespace administrator creates the ListenerSet, and application developers create the HTTPRoute. The same person may perform both roles if they have the required permissions.

Choosing an ALB implementation

The table below lists the criteria for choosing an ALB implementation.

Criterion	Ingress NGINX	Gateway API	Istio
Publishing API	Ingress + annotations	Gateway, ListenerSet, routes	Gateway, VirtualService, DestinationRule
Protocols	HTTP/HTTPS, gRPC (Ingress)	HTTP/HTTPS, gRPC, TLS, TCP, UDP	HTTP/HTTPS, gRPC, TCP (Istio Gateway)
Role separation	IngressClass + Ingress	ClusterALBInstance/ALB Instance → ListenerSet → routes	IngressIstioController + Istio Gateway
Service mesh	No	Optional (sidecar on the gateway proxy)	Yes
Typical use case	Classic Ingress, minimal change	New apps, multitenancy, gradual migration from Ingress	Canary, mTLS, tracing, advanced routing

Comparison of the ingress-nginx and alb modules

Both modules solve the same task — receiving and routing external traffic to applications — but rely on different standards: `ingress-nginx` uses the Ingress API with annotations, while `alb` uses the Kubernetes Gateway API. The modules can be used in a cluster simultaneously. The table below compares their capabilities in the current versions.

Service domains (web interfaces of DP components and modules via `publicDomainTemplate`) and application domains (routes owned by application developers) are configured differently. Details are in Publishing service domains.

Capability	**`ingress-nginx`**	**`alb`**
Routing standard	Ingress API with annotations	Kubernetes Gateway API
Proxy implementation	nginx	Envoy Proxy
Lifecycle stage	General Availability	Preview
Development	Maintenance mode: the upstream Ingress NGINX project no longer develops new features, while DP provides security updates	Actively developed
Minimum DP version	Available in all supported versions	1.76
DP editions	All editions	All editions

Capability	ingress-nginx	alb
Role separation model	Cluster administrator, namespace administrator	Cluster administrator, namespace administrator, application developers
Multiple independent entry points	Multiple Ingress controllers selected via `ingressClass`	Multiple Gateway objects selected via `gatewayName`; cluster-scoped and namespaced gateways
HTTP/HTTPS (HTTP/1.1, HTTP/2, HTTP/3)	Yes	Yes (enabling HTTP/3)
WebSocket	Yes	Yes
gRPC	Yes	Yes
FastCGI	Yes	No
TCP	No	Yes (TCPRoute)
UDP	No	Yes (UDPRoute)
TLS passthrough	Yes	Yes (TLSRoute)
Proxy Protocol	Yes	Yes
Traffic ingress methods	`LoadBalancer`, `HostPort`, and `HostWithFailover` inlets	`LoadBalancer` and `HostPort` inlets
Automatic TLS certificate issuance (cert-manager)	Yes	Yes
HTTPS policy tuning (TLS versions, ciphers, HSTS)	Yes	TLSv1.2/1.3 by default; HSTS via a response-header annotation
WAF	ModSecurity at the controller or Ingress level	ModSecurity/Coraza at the route level, OWASP CRS preset
External authentication	Yes	Yes
IP allowlist	Yes	Yes
Basic authentication	Yes	Yes
Request rate limiting	Yes	Yes
Session affinity	Yes	Yes
GeoIP	Geo-based request statistics in metrics	Adding GeoIP fields to headers based on MaxMind databases
Prometheus metrics and Grafana dashboards	Yes, detailed by namespace, vhost, Ingress resource, and location	Yes: Envoy Proxy metrics and dashboards for requests, routes, and upstreams
OpenTelemetry tracing	Yes	Yes (configuration)

Next steps

To publish an application, follow these steps:

1. Choose an ALB implementation based on the criteria in the table above: Ingress NGINX, Gateway API, or Istio.
   - Istio — when you need service-mesh traffic management (canary routing, mTLS between Pods).
   - Gateway API — when you need a model with role separation and protocols beyond classic Ingress.
   - Ingress NGINX — when you need a mature Ingress-based ALB.
2. Enable and configure the corresponding module. For Gateway API, complete the “Steps to take before enabling and configuring ALB in a cluster”.
3. Publish applications using the ALB user guides (Gateway API, Ingress NGINX, or Istio).
4. To move from Ingress NGINX to Gateway API, follow Migrating from ingress-nginx to alb.

Balancing with MetalLB

The `metallb` module implements support for LoadBalancer-type services in Deckhouse Platform (DP) clusters. It is suitable for both bare-metal clusters and cloud environments where built-in load balancers by providers are unavailable.

Two operating modes are supported:

- **Layer 2**: An enhanced version of the standard L2 mode in MetalLB, allowing multiple public addresses to be used for services.
- **BGP**: Fully based on the MetalLB solution and available only in DP Enterprise Edition.

Layer 2 mode

How it works

In Layer 2 mode, one or more cluster nodes receive traffic for a service from the public network. From the network layer's perspective, each of these nodes has multiple IP addresses assigned to its network interface. This is implemented by the module responding to ARP requests (for IPv4) and NDP requests (for IPv6).

The main advantage of this mode is universality. It works in any Ethernet network without requiring specialized hardware.

Advantages over classic MetalLB

In classic MetalLB (L2 mode), when creating a LoadBalancer service, load balancing is achieved by having a single node in the cluster reply to ARP requests for the public IP. This means:

- Only one node handles all incoming traffic for the given IP at a time.
- The leader node becomes a bottleneck with no horizontal scaling.
- If the leader node fails, all active connections are dropped during the switchover to the new node.

The `metallb` module removes these limitations. It provides the MetalLoadBalancerClass resource, which lets you:

- Bind a group of nodes to an IP address pool using `nodeSelector`.
- Create a standard LoadBalancer Service and specify the name of the target MetalLoadBalancerClass.
- Define the number of IP addresses for L2 announcement via an annotation.

This approach means:

- The application receives multiple public IPs, which must be added as A records in DNS.
- To scale, add more load balancer nodes. Associated Services will be created automatically — only adding the IPs to the application domain's A records is required.
- If one balancer fails, only part of the traffic is rerouted, without a complete connection drop.

Behavior comparison

Feature	Classic MetalLB (L2)	New module with MetalLoadBalancerClass
Traffic handling	Single node (leader)	Multiple nodes
Scalability	No	Yes
Fault tolerance	All connections dropped	Part of the traffic is rerouted smoothly
Number of public IPs	One	Multiple (configurable)
DNS configuration	One A record	Multiple A records

Example of using MetalLB in L2 LoadBalancer mode

1. Enable the `metallb` module:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: metallb
   spec:
     enabled: true
     version: 2
   ```

2. Deploy the application to expose:

   ```
   d8 k create deploy nginx --image=nginx
   ```

3. Create a MetalLoadBalancerClass resource:

   ```
   apiVersion: network.deckhouse.io/v1alpha1
   kind: MetalLoadBalancerClass
   metadata:
     name: ingress
   spec:
     addressPool:
       - 192.168.2.100-192.168.2.150
     isDefault: false
     l2:
       # Network interfaces that announce the assigned IP addresses.
       interfaces:
         - eth1
     nodeSelector:
       # Selects nodes that run the L2 load balancer.
       node-role.kubernetes.io/loadbalancer: ""
     type: L2
   ```

   In this example, `spec.nodeSelector` selects nodes with the `node-role.kubernetes.io/loadbalancer` label. Make sure the nodes intended to announce the Service IP addresses have this label.

   ⚠ If the `spec.l2.interfaces` parameter is not set or contains an empty list, the assigned IP addresses are announced from all network interfaces of the selected nodes. Specify the interfaces to announce the addresses from.

   If the selected nodes have taints with custom keys, allow the `speaker` to run on them as described in the Running speakers on nodes with custom taints section.

4. Create a Service resource with the annotation and name MetalLoadBalancerClass:

> **i** When creating a Service resource, you can omit the annotations `network.deckhouse.io/l2-load-balancer-external-ips-count` and `network.deckhouse.io/load-balancer-ips` from the examples below. In this case, the service will automatically be assigned 1 random address from the pool.

```
apiVersion: v1
kind: Service
metadata:
  name: nginx-deployment
  annotations:
    network.deckhouse.io/l2-load-balancer-external-ips-count: "3"
spec:
  type: LoadBalancer
  # Selects the MetalLoadBalancerClass named ingress.
  # Can be omitted if the cluster has a MetalLoadBalancerClass with isDefault:
true
  # and BGP LoadBalancer mode is not used.
  loadBalancerClass: ingress
  ports:
    - port: 8000
      protocol: TCP
      targetPort: 80
  selector:
    app: nginx
```

If you need to assign specific IP addresses from the pool to the service...

> **i** If the service needs to allocate specific IP addresses from the pool, use the annotation `network.deckhouse.io/load-balancer-ips`. If there is more than one desired address, there must also be an annotation `network.deckhouse.io/l2-load-balancer-external-ips-count`, which must specify the number of addresses allocated from the pool (it must not be less than the number of addresses listed in `network.deckhouse.io/load-balancer-ips`).

```
apiVersion: v1
kind: Service
metadata:
  name: nginx-deployment
  annotations:
    # The number of addresses that will be allocated from the pool declared in
MetalLoadBalancerClass.
    network.deckhouse.io/l2-load-balancer-external-ips-count: "3"
    # A list of addresses from the pool declared in MetalLoadBalancerClass that will
be allocated to the service.
    network.deckhouse.io/load-balancer-ips:
"192.168.2.102,192.168.2.103,192.168.2.104"
spec:
  type: LoadBalancer
  # Selects the MetalLoadBalancerClass named ingress.
  # Can be omitted if the cluster has a MetalLoadBalancerClass with isDefault: true
  # and BGP LoadBalancer mode is not used.
  loadBalancerClass: ingress
  ports:
    - port: 8000
      protocol: TCP
      targetPort: 80
  selector:
    app: nginx
```

As a result, the LoadBalancer Service will be assigned the configured number of addresses:

```
d8 k get svc
```

Example output:

```
NAME                    TYPE           CLUSTER-IP      EXTERNAL-IP
PORT(S)          AGE
nginx-deployment        LoadBalancer   10.222.130.11
192.168.2.100,192.168.2.101,192.168.2.102   8000:30544/TCP   11s
```

The obtained `EXTERNAL-IP` can be set as A records for the application domain:

```
curl -s -o /dev/null -w "%{http_code}" 192.168.2.100:8000
curl -s -o /dev/null -w "%{http_code}" 192.168.2.101:8000
curl -s -o /dev/null -w "%{http_code}" 192.168.2.102:8000
```

Example output:

```
200
```

BGP mode

In BGP mode, `metallb` provides LoadBalancer-type services in Kubernetes clusters deployed on physical infrastructure. Service IP addresses are announced directly to routers (or top-of-rack switches) via the BGP protocol.

How it works

Configuration

- Define an IP address pool available for Service allocation.
- Specify BGP session parameters: the Kubernetes cluster Autonomous System (AS) number, router (peer) IP addresses, peer AS numbers, and passwords for authentication (if needed).
- For each IP pool, define specific announcement parameters, such as community strings.

Establishing BGP sessions

- On each Kubernetes node running `metallb`, the `speaker` component establishes BGP sessions with the configured routers.
- Route information is exchanged between `metallb` and the routers.

Assigning IP addresses to Services

- When a LoadBalancer Service is created, `metallb` selects a free IP address from the configured pool and assigns it to the Service.
- The `controller` component tracks Service changes and manages IP address assignments.

Announcing IP addresses

- After assigning an IP address, the `speaker` component on one of the nodes (leader for the Service) announces it via the established BGP sessions.
- Routers receive the announcement and update their routing tables to direct traffic to the corresponding node.

Traffic distribution

- Routers use Equal-Cost Multi-Path (ECMP) protocols or other load balancing algorithms to distribute traffic between nodes announcing the same Service IP.
- Once delivered to the node, incoming traffic is forwarded to the Service pods using the CNI mechanisms (iptables/IPVS, eBPF, etc.).

Benefits of using BGP

- BGP is supported by most network equipment.
- The network can include multiple routers and many nodes.
- Traffic balancing via ECMP.

- If a node stops announcing an IP, routers automatically redirect traffic to other nodes with the same IP.

Drawbacks of using BGP

- More complex to configure than ARP/GARP announcements (Layer 2 mode).
- Routers must support BGP and ECMP.

Example of using MetalLB in BGP LoadBalancer mode

1. Enable the `metallb` module and configure the required parameters:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: metallb
   spec:
     enabled: true
     version: 3
   ---
   apiVersion: network.deckhouse.io/v1alpha1
   kind: MetalLoadBalancerPool
   metadata:
     name: mypool
   spec:
     addresses:
       - 192.168.219.100-192.168.219.200
   ---
   apiVersion: network.deckhouse.io/v1alpha1
   kind: MetalLoadBalancerBGPPeer
   metadata:
     name: myrouter
   spec:
     peerAddress: 172.18.18.10
     peerASN: 64601
     myASN: 64600
     holdTime: 3s
   ---
   apiVersion: network.deckhouse.io/v1alpha1
   kind: MetalLoadBalancerConfiguration
   metadata:
     name: defaults
   spec:
     mode: BGP
     nodeSelector:
       node-role.deckhouse.io/metallb: ""
     bgp:
       peerNames:
         - myrouter
     advertisements:
       - poolNames:
           - mypool
   ```

   In this example, `spec.nodeSelector` selects nodes with the `node-role.deckhouse.io/metallb` label. Make sure the nodes intended to run the `speaker` pods have this label.

   If the selected nodes have taints with custom keys, allow the `speaker` to run on them as described in the Running speakers on nodes with custom taints section.

2. Configure BGP peering on the network equipment.

Running speakers on nodes with custom taints

The `speaker` pods announce Service IP addresses and run as a DaemonSet on the nodes selected by

the `nodeSelector` parameter: of MetalLoadBalancerClass in Layer 2 mode and of MetalLoadBalancerConfiguration in BGP mode. The `speaker` pods tolerate only the following taints known to DP:

- `node-role.kubernetes.io/master`
- `node-role.kubernetes.io/control-plane`
- `node.deckhouse.io/etcd-arbiter`
- `dedicated.deckhouse.io` and `dedicated` with any value
- `DeletionCandidateOfClusterAutoscaler` and `ToBeDeletedByClusterAutoscaler`

If a selected node has a taint with any other key, the `speaker` is not scheduled on it, and the IP addresses are not announced from that node.

To run the `speaker` on such nodes, follow these steps:

1. Add the taint key to the `customTolerationKeys` parameter of the `global` ModuleConfig. The key must match the taint key set on the nodes, for example, in the `spec.nodeTemplate.taints` parameter of NodeGroup. The parameter also allows the other system components (CNI, CSI, monitoring) to run on such nodes.

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: global
   spec:
     version: 3
     settings:
       modules:
         placement:
           customTolerationKeys:
             - dedicated.example.com
   ```

2. Check that the `speaker` pods are running on the tainted nodes.

   For Layer 2 mode:

   ```
   d8 k -n d8-metallb get pods -l app=l2lb-speaker -o wide
   ```

   For BGP mode:

   ```
   d8 k -n d8-metallb get pods -l app=speaker -o wide
   ```

Additional resources

- Global parameters
- Module `metallb` documentation
- Module `node-manager` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

Balancing in clusters on cloud platforms

A list of supported providers:

- Amazon Web Services
- Google Cloud Platform
- Microsoft Azure
- OpenStack
- Huawei Cloud
- VMware Cloud DirectorExperimental
- VMware vSphere

- Yandex Cloud
- zVirtExperimental

Configuring incoming traffic balancing in clusters on cloud platforms involves creating an Ingress controller with specified LoadBalancer parameters. Based on these settings, the cloud provider automatically creates an external load balancer. In the cluster, a Service resource is created through which the external load balancer routes traffic to applications.

Example of creating an Ingress controller for the OpenStack provider

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancerWithProxyProtocol
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
  - effect: NoExecute
    key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
```

Example of creating a ClusterIP-type Service

```
apiVersion: v1
kind: Service
metadata:
  name: backend-resolver-cluster-ip
spec:
  ports:
  - name: http
    port: 8000
    protocol: TCP
  selector:
    app: lab-4-backend
  type: ClusterIP
```

Example for VK Cloud

The following example is relevant when the internal balancer would be used.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: nginx
spec:
  ingressClass: nginx
  inlet: LoadBalancer
  loadBalancer:
    annotations:
      service.beta.kubernetes.io/openstack-internal-load-balancer: "true"
  nodeSelector:
    node.deckhouse.io/group: worker
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

ALB with Ingress NGINX Controller

The `ingress-nginx` module is used to implement ALB using the Ingress NGINX Controller.

> In 2025, Ingress NGINX was placed in maintenance mode, with no plans for active development of new features. Further evolution of inbound traffic load balancing in Kubernetes is focused on the Gateway API.
>
> This does not apply to the module as part of Deckhouse Platform: the module is maintained by the Deckhouse Platform team, including security updates. Details are in “Module support and security”.
>
> Step-by-step migration to Gateway API is in Migrating from ingress-nginx to alb.

The `ingress-nginx` module installs the Ingress NGINX Controller and manages it with custom resources. If there is more than one node available for hosting the Ingress controller, it is deployed in the HA mode, taking into account the infrastructure specifics of both cloud and bare-metal environments, as well as various Kubernetes cluster types.

The module supports running and configuring several Ingress NGINX controllers simultaneously (one of the controllers is the primary one. You can create as many additional controllers as you want). This approach allows you to separate extranet and intranet Ingress resources of applications.

Traffic termination options

Traffic to `ingress-nginx` can be routed in several ways:

- Directly without the use of an external load balancer.
- Using an external LoadBalancer. The following variants are supported:
  - Qrator
  - Cloudflare
  - AWS LB
  - GCE LB
  - ACS LB
  - Yandex LB
  - OpenStack LB

HTTPS termination

The module allows you to manage HTTPS security policies for each of the Ingress NGINX controllers, including:

- HSTS parameters
- Available SSL/TLS versions and encryption protocols

The module is integrated with the `cert-manager` module. Thus, it can get SSL certificates automatically and pass them to Ingress NGINX controllers for further use.

Monitoring and statistics

The current `ingress-nginx` implementation has a Prometheus-based system for collecting statistical data with the following set of metrics:

- Total response time and backend response time separately
- Response codes
- Number of repeated requests (retries)
- Request and response sizes
- Request methods
- `content-types`
- Geography of requests, etc.

The data can be grouped by the:

- `namespace`
- `vhost`
- `ingress` resources
- `location` (in nginx)

All graphs are grouped by Grafana dashboards. From any graph you can open a more detailed view: for example, from a `namespace` statistics view, you can click through to the corresponding `vhost` dashboard for more detail, and continue down the hierarchy.

Statistics

Basic principles of collecting statistics

1. At the `log_by_lua_block` stage, the module calculates the necessary metrics for each request and stores them in a buffer (each NGINX worker has its own buffer).
2. At the `init_by_lua_block` stage, each NGINX worker starts a process that sends data in `protobuf` format via TCP socket to the `protobuf_exporter` every second (developed by Deckhouse Platform).
3. `protobuf_exporter` runs as a sidecar container in the Ingress controller pod, receives `protobuf` messages, parses and aggregates them, and exports metrics for Prometheus.
4. Prometheus scrapes metrics every 30 seconds from both the Ingress controller and the `protobuf_exporter`. This scraped data is what statistics is based on.

Metrics structure and representation

All collected metrics include service labels identifying the controller instance: `controller`, `app`, `instance`, and `endpoint` (visible in `/prometheus/targets`).

- All non-geo metrics exported by `protobuf_exporter` are provided at three detail levels:
  - `ingress_nginx_overall_*`: Top-level aggregated metrics (non-detailed, all metrics have the following labels: `namespace`, `vhost`, `content_kind`).
  - `ingress_nginx_detail_*`: In addition to overall metrics, adds `ingress`, `service`, `service_port`, and `location`.
  - `ingress_nginx_detail_backend_*`: Backend-level metrics. In addition to detail metrics, adds the `pod_ip` label.
- Metrics collected for overall and detail levels:
  - `*_requests_total`: Total requests (extra labels: `scheme`, `method`).
  - `*_responses_total`: Number of responses (extra label: `status`).
  - `*_request_seconds_{sum,count,bucket}`: Response time histogram.
  - `*_bytes_received_{sum,count,bucket}`: Request size histogram.
  - `*_bytes_sent_{sum,count,bucket}`: Response size histogram.
  - `*_upstream_response_seconds_{sum,count,bucket}`: Upstream service response time histogram (total for multiple upstreams).
  - `*_lowres_upstream_response_seconds_{sum,count,bucket}`: Simplified histogram (for visualization; can't be used for quantiles).
  - `*_upstream_retries_{count,sum}`: Number and total of backend retries.
- Metrics collected for overall level:
  - `*_geohash_total`: Request counts per geohash (additional labels: `geohash`, `place`).
- Metrics collected for detail backend level:
  - `*_lowres_upstream_response_seconds`: Simplified response time histogram for overall and detail.
  - `*_responses_total`: Number of responses (additional label: `status_class`, not just `status`).
  - `*_upstream_bytes_received_sum`: Total size of data received from backends.

Load balancing configuration examples

Use the IngressNginxController custom resource to configure load balancing.

- AWS (NLB)
- GCP, Yandex Cloud, and Azure
- OpenStack
- VK Cloud
- Bare metal (HostWithFailover)
- Bare metal with external LB
- MetalLB BGP
- MetalLB L2

Example for AWS (Network Load Balancer)

When setting up the balancer, all available zones in the cluster are used.

Each zone’s balancer receives its own public IP. If a zone has an Ingress controller instance, its IP is added to the load balancer’s domain name as an A record.

If no instances remain in a zone, that IP is removed from DNS.

If only one Ingress controller instance exists in a zone, its IP is temporarily removed from DNS during pod restarts.

Example IngressNginxController with the `LoadBalancer` inlet and AWS NLB annotations:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
 name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancer
  loadBalancer:
    annotations:
      service.beta.kubernetes.io/aws-load-balancer-type: "nlb"
```

Example for GCP, Yandex Cloud, and Azure

IngressNginxController with the `LoadBalancer` inlet:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
 name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancer
```

i In GCP, nodes must have an annotation allowing external connections for NodePort services.

Example for OpenStack

IngressNginxController with the `LoadBalancerWithProxyProtocol` inlet and OpenStack Proxy Protocol annotations:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main-lbwpp
spec:
  inlet: LoadBalancerWithProxyProtocol
  ingressClass: nginx
  loadBalancerWithProxyProtocol:
    annotations:
      loadbalancer.openstack.org/proxy-protocol: "true"
      loadbalancer.openstack.org/timeout-member-connect: "2000"
```

Example for VK Cloud

Use this configuration for an internal cloud balancer (without a public address).

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: nginx
spec:
  ingressClass: nginx
  inlet: LoadBalancer
  loadBalancer:
    annotations:
      service.beta.kubernetes.io/openstack-internal-load-balancer: "true"
  nodeSelector:
    node.deckhouse.io/group: worker
```

Example for bare metal

IngressNginxController with the `HostWithFailover` inlet on frontend nodes:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: HostWithFailover
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
    - effect: NoExecute
      key: dedicated.deckhouse.io
      value: frontend
```

Example for bare metal with external load balancer

Use this configuration with Cloudflare, Qrator, Nginx+, Citrix ADC, Kemp, or other external load balancers.

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: HostPort
  hostPort:
    httpPort: 80
    httpsPort: 443
    behindL7Proxy: true
```

Example for bare metal (MetalLB in BGP LoadBalancer mode)

IngressNginxController with the `LoadBalancer` inlet for use with MetalLB in BGP mode:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancer
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
    - effect: NoExecute
      key: dedicated.deckhouse.io
      value: frontend
```

When using MetalLB, its speaker pods (MetalLB components that announce IP addresses) must run on the same nodes as the Ingress controller pods.

To preserve the real client IP addresses, the Ingress controller Service should be created with `externalTrafficPolicy: Local` to avoid inter-node SNAT. In this configuration, MetalLB speaker will only announce the Service from nodes running target pods.

Example ModuleConfig for the `metallb` module:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: metallb
spec:
  enabled: true
  version: 2
  settings:
    speaker:
      nodeSelector:
        node-role.deckhouse.io/frontend: ""
      tolerations:
        - effect: NoExecute
          key: dedicated.deckhouse.io
          value: frontend
```

Example for bare metal (MetalLB in L2 LoadBalancer mode)

1. Enable the `metallb` module:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: metallb
   spec:
     enabled: true
     version: 2
   ```

2. Create a MetalLoadBalancerClass resource:

   > **i** MetalLB balancers should be placed on the same nodes as Ingress controllers. In a cluster with role separation, frontend nodes are used for this purpose. To deploy Ingress controllers and MetalLB load balancers on frontend nodes, set the label `node-role.deckhouse.io/frontend: ""` in `nodeSelector`.

```
apiVersion: network.deckhouse.io/v1alpha1
kind: MetalLoadBalancerClass
metadata:
  name: ingress
spec:
  addressPool:
    - 192.168.2.100-192.168.2.150
  isDefault: false
  l2:
    # Network interfaces that announce the assigned IP addresses.
    interfaces:
      - eth1
  nodeSelector:
    # Selects nodes that run the L2 load balancer.
    node-role.deckhouse.io/frontend: ""
  type: L2
```

3. Create an IngressNginxController resource:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: main
spec:
  ingressClass: nginx
  inlet: LoadBalancer
  loadBalancer:
    loadBalancerClass: ingress
    annotations:
      # Number of addresses to allocate from the pool defined in
MetalLoadBalancerClass.
      network.deckhouse.io/l2-load-balancer-external-ips-count: "3"
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  tolerations:
    - effect: NoExecute
      key: dedicated.deckhouse.io
      value: frontend
      operator: Equal
```

> **i**
>
> When creating an ingress controller, you can also specify certain IP addresses from the pool that will be assigned to its Service. Use the annotation `network.deckhouse.io/load-balancer-ips`.
>
> If you need more than one address, also set `network.deckhouse.io/l2-load-balancer-external-ips-count` to the number of addresses allocated from the pool. That value must not be less than the number of addresses listed in `network.deckhouse.io/load-balancer-ips`.
>
> A configuration example is provided in the Creating a Service and assigning it specific IP addresses from the pool section.

Deckhouse Platform will create a LoadBalancer Service with the specified number of IPs:

```
d8 k -n d8-ingress-nginx get svc
```

Example output:

```
NAME                    TYPE           CLUSTER-IP      EXTERNAL-IP
PORT(S)                       AGE
main-load-balancer      LoadBalancer   10.222.130.11
192.168.2.100,192.168.2.101,192.168.2.102   80:30689/TCP,443:30668/TCP   11s
```

Example of segregating access between public and administrative zones

In many applications, the same backend serves both the public part and the administrative interface. For example:

- `https://example.com` is the public zone;
- `https://admin.example.com` is the administrative zone, access to which must be restricted (`ACL`, `mTLS`, `IP whitelist`, and so on).

For this scenario, offload administrative traffic to a separate Ingress controller (with a dedicated Ingress class if necessary) and restrict access to it by using the `spec.acceptRequestsFrom` parameter.

- Single Ingress controller
- Separate Ingress controllers

Specifics of using a single Ingress controller

The example below shows a single Ingress controller serving requests from both the public zone and the administrative interface.

Example of Ingress resource configuration for this case:

```
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: admin-ingress
  annotations:
    nginx.ingress.kubernetes.io/whitelist-source-range: "1.2.3.4/32"
spec:
  ingressClassName: nginx # The Ingress resource for administrative traffic is
associated with the same Ingress controller as the Ingress resource for public
traffic.
  rules:
    - host: admin.example.com
      http:
        paths:
          - path: /
            pathType: Prefix
            backend:
              service:
                name: backend
                port:
                  number: 80
---
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: public-ingress
spec:
  ingressClassName: nginx # The Ingress resource for public traffic is associated
with the same Ingress controller as the Ingress resource for administrative traffic.
  rules:
    - host: example.com
      http:
        paths:
          - path: /
            pathType: Prefix
            backend:
              service:
                name: backend
                port:
                  number: 80
```

With processing and forwarding of X-Forwarded-* headers enabled, the backend can rely on the `x-forwarded-host` header when making authorization decisions. In the example above, public Ingress traffic can reach the administrative zone via `x-forwarded-host`. Therefore, requests to the Ingress controller must come only from trusted sources.

Using separate Ingress controllers

To avoid that situation, do the following:

- Configure access rules at the Ingress resource level.
- Use separate Ingress controllers.
- Restrict which source addresses are allowed to connect to the Ingress controllers.

Example of Ingress resource configuration for this case:

```
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: admin-ingress
  annotations:
    nginx.ingress.kubernetes.io/whitelist-source-range: "1.2.3.4/32"
spec:
  ingressClassName: admin-nginx # The Ingress resource for administrative traffic is
associated with a separate Ingress controller.
  rules:
    - host: admin.example.com
      http:
        paths:
          - path: /
            pathType: Prefix
            backend:
              service:
                name: backend
                port:
                  number: 80
---
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: public-ingress
spec:
  ingressClassName: public-nginx # The Ingress resource for public traffic is
associated with a separate Ingress controller.
  rules:
    - host: example.com
      http:
        paths:
          - path: /
            pathType: Prefix
            backend:
              service:
                name: backend
                port:
                  number: 80
```

Example of an Ingress controller that serves administrative Ingress resources and accepts connections only from specified subnets:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: admin
spec:
  ingressClass: admin-nginx
  inlet: HostPort
  acceptRequestsFrom:
    - 1.2.3.4/32
    - 10.0.0.0/16
  hostPort:
    httpPort: 80
    httpsPort: 443
    behindL7Proxy: true
```

In this example:

- The Ingress controller is exposed on node ports through the `HostPort` inlet.
- The `acceptRequestsFrom` parameter allows connections to the controller only from the listed

subnets.
- Even if an external load balancer or client can set its own `X-Forwarded-*` header values, the decision whether to allow the connection to reach the controller is made based on the actual source address, not on headers.
- Administrative Ingress resources (in this example `admin-ingress`) are served by this controller according to the configured Ingress class.

Example of an Ingress controller that serves Ingress resources for public traffic:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: public
spec:
  ingressClass: public-nginx
  inlet: HostPort
  hostPort:
    httpPort: 8080
    httpsPort: 8443
    behindL7Proxy: true
```

Module support and security

The `ingress-nginx` module is covered by Deckhouse Platform maintenance for the entire platform support lifecycle, regardless of the upstream project's development status. The Deckhouse Platform team tracks CVEs in the controller and its dependencies — NGINX, Lua modules, and base images — and delivers fixes in platform releases.

For compliance with PCI DSS expectations regarding vendor support and vulnerability remediation timelines, Flant is the responsible vendor of the module. Deckhouse Platform certification with FSTEC of Russia also covers vulnerability management processes and the release of security updates.

ALB with Kubernetes Gateway API

To implement an Application Load Balancer (ALB) using the Kubernetes Gateway API, the `alb` module is used.

The `alb` module implements an Application Load Balancer and allows you to publish applications through Kubernetes Gateway API. It deploys and configures the infrastructure for receiving and routing external requests, and also verifies the user configuration of the Gateway API.

> **i** ALBs created using the Kubernetes Gateway API can be used in a cluster alongside ALBs created using the Ingress NGINX Controller. Details are in "Using with other modules and third-party solutions".

Overview and scheme

The module is built on the Kubernetes Gateway API — an API for inbound traffic routing that extends the Ingress API model. A ClusterALBInstance or ALBInstance creates a managed Gateway. A ListenerSet bound to that Gateway describes handlers for incoming requests. Routes direct traffic to application services.

The module supports:

- A single declarative API for HTTP/HTTPS, gRPC, TCP, UDP, and TLS passthrough.
- A separation of responsibilities between the cluster administrator (ClusterALBInstance or ALBInstance), the namespace administrator (ALBInstance and ListenerSet — hostname, TLS, ports), and application developers (routes).
- Request-handling features: per-route WAF, external authentication, IP allowlists, rate limiting, session affinity, GeoIP, BackendTLSPolicy, Proxy Protocol, and HTTP/3.

Kubernetes Gateway API and an API gateway serve different purposes. The Kubernetes Gateway API is a set of Kubernetes resources that describe how inbound traffic is routed to services. An API gateway is an architectural component that aggregates application APIs behind a single entry point. The `alb` module is an implementation of the Kubernetes Gateway API.

For a capability comparison with `ingress-nginx`, open the “Comparison of the ingress-nginx and alb modules” section.

Object roles

Gateway API separates responsibilities between cluster and namespace administrators and application developers:

- Cluster administrator — manages traffic infrastructure through ClusterALBInstance or ALBInstance (cluster-wide Gateway).
- Namespace administrator — manages ALBInstance and ListenerSet (hostname, TLS, ports) within a namespace.
- Application developers — define routes (HTTPRoute, GRPCRoute, TLSRoute, TCPRoute, UDPRoute).

Why ListenerSet

ListenerSet is a Gateway API extension. The ListenerSet object describes system and user traffic handlers: hostname, TLS mode, port, and protocol. Each ListenerSet is linked to a parent Gateway through `spec.parentRef`. Routes are then attached to it.

Each Gateway object creates two default listeners: `d8-http` (port `80`) and `d8-https` (port `443`). They are intended for service tasks such as gateway availability checks or cert-manager HTTP-01 challenges. They are not recommended for publishing applications. Use ListenerSet for that purpose instead.

ClusterALBInstance and ALBInstance

When creating a Gateway managed object for publishing user applications, the custom resources ClusterALBInstance (a cluster-scoped object) and ALBInstance (a namespaced object) are used.

The characteristics and differences between them are described in the table:

	ClusterALBInstance	**ALBInstance**
Purpose	Deploy a cluster-wide Gateway object	Deploy a local Gateway object

	ClusterALBInstance	**ALBInstance**
Typical use case	- Common entry point (cluster-wide gateway). - System gateway for publishing web interfaces of Deckhouse Platform (DP) service components and other modules (may require “Steps before enabling”). - Platform gateway	Dedicated gateway for an application or team in a dedicated namespace
Supported inlet types	`LoadBalancer`, `HostPort`	`LoadBalancer`, `ClusterIP`
Proxy implementation	Envoy Proxy	Envoy Proxy
Deployment type	DaemonSet	Deployment
Placement of ListenerSet objects and routes	In any user namespace	In the same namespace as the ALBInstance object (required)
Access level	Cluster administrator	Namespace administrator

Creating a ClusterALBInstance object or an ALBInstance object results in creation of a managed Gateway object in the cluster. At the same time:

- Each Gateway object is served by at least one Envoy Proxy instance.
- Traffic reaches it through a Service of type `LoadBalancer` or directly by using `HostPort` parameters.
- Several ClusterALBInstance or ALBInstance objects may point to the same Gateway object through the `gatewayName` field. In that case, they describe one shared gateway. The request handling infrastructure may still differ depending on settings. You can think of `gatewayName` as an analog of `ingressClass` for IngressNginxController objects. The resulting configuration comes from the instance with the earliest `creationTimestamp` (that is, the one created first). The others get `conflictPorts: true` in status, with `conflictPortsOwner` naming the controlling instance.

Validating configuration

In addition to Gateway API infrastructure configuration, user settings are validated before being applied to prevent conflicts. This allows detecting conflicts between identical traffic handlers in different ListenerSet objects when they point to the same Gateway object.

Inlets

An inlet defines how external traffic reaches the Envoy Proxy that serves the Gateway object:

- `LoadBalancer` — traffic is accepted through a Service of type `LoadBalancer` (cloud providers or bare metal with MetalLB). Available for both ClusterALBInstance and ALBInstance.
- `HostPort` — traffic is accepted on node ports without an external load balancer. Available for ClusterALBInstance only.
- `ClusterIP` — traffic is accepted through a Service of type `ClusterIP`, without an external entry point (for example, for internal traffic). Available for ALBInstance only.

The inlet mapping table for migration from `ingress-nginx` is in “Inlet configuration”. More examples are in “Examples for different environments”.

How to configure ALB

Publishing an application includes enabling the module, creating a managed Gateway, a ListenerSet, and routes.

Steps before enabling

Before enabling and configuring ALB in a DP cluster, do the following:

- Verify that the requirements for the `alb` module are met.
- If you need to publish service domains — web interfaces of DP service components and other modules — set the global parameter `publicDomainTemplate`. Without this parameter, system HTTPRoute, Gateway, and ListenerSet objects for service domains will not work correctly, and the web interfaces will not be published. If you do not need to publish service domains, you can leave this parameter unset. Details are in “Publishing service domains”.
- Check API version compatibility in “Alongside third-party Gateway API implementations” if such solutions are already used in the cluster.

- On bare metal, for the `LoadBalancer` inlet prepare an external load balancer or the `metallb` module. The `HostPort` inlet is available for ClusterALBInstance only and does not require MetalLB.

Enabling the module and creating a Gateway

Enable the `alb` module as described in Enabling the module.

Create a ClusterALBInstance or ALBInstance resource. This creates and configures the managed Gateway object.

> ⚠ Manual modification of Gateway objects managed by the module is not allowed.

- ClusterALBInstance
- ALBInstance

Example of a ClusterALBInstance manifest for creating a cluster-wide gateway:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: public-gw
spec:
  gatewayName: public-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
```

Example of a minimal working ALBInstance configuration for publishing a gateway in a namespace:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ALBInstance
metadata:
  name: app-gw
  namespace: prod
spec:
  gatewayName: app-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
```

After the ALBInstance reaches the `Ready` state, create ListenerSet and HTTPRoute objects in the same namespace. Next steps are in “Publishing an application with ListenerSet and HTTPRoute” .

Creating a ListenerSet

The ListenerSet object describes system and user traffic handlers: hostname, TLS mode, port, and protocol. Each ListenerSet is linked to a parent Gateway through `spec.parentRef`. Routes are then attached to it.

Placement of ListenerSet objects depends on the type of Gateway object in use:

- For ClusterALBInstance, ListenerSet objects may be placed in any namespace.
- For ALBInstance, ListenerSet objects must be placed in the same namespace as the parent ALBInstance.

In both cases, place the ListenerSet in the same namespace as the associated HTTPRoute, GRPCRoute, and TLSRoute objects. In that case, you do not need additional setup such as creating a ReferenceGrant.

In ListenerSet, use ports `80` and `443` for HTTP/HTTPS. These are Gateway API listener ports. They are not the same as the `hostPort.httpPort` and `hostPort.httpsPort` parameters of the HostPort inlet, which set ports on the node.

TCPRoute and UDPRoute objects that use TCP and UDP ports from `additionalPorts` attach directly to the corresponding Gateway listener.

An example of a ListenerSet manifest for managing the reception of incoming HTTP and HTTPS requests through a cluster-wide gateway:

```
apiVersion: gateway.networking.k8s.io/v1
kind: ListenerSet
metadata:
  name: app-listeners
  namespace: prod
spec:
  parentRef:
    name: public-gw  # The name of the Gateway object from the ClusterALBInstance
status, provided by the administrator.
    namespace: d8-alb
  listeners:
    - name: app-http
      port: 80 # In ListenerSet, use port 80 for HTTP. This is not the HostPort inlet
httpPort on the node.
      protocol: HTTP
      hostname: app.example.com
    - name: app-https
      port: 443 # In ListenerSet, use port 443 for HTTPS. This is not the HostPort
inlet httpsPort on the node.
      protocol: HTTPS
      hostname: app.example.com
      tls:
        mode: Terminate
        certificateRefs:
          - name: app-tls   # Reference to the secret with the TLS certificate.
            namespace: prod
```

Creating routes

The following route types are used to route incoming requests:

- HTTPRoute: For routing HTTP/HTTPS/TLS requests. HTTPRoute objects support extended settings through annotations that complement the current Gateway API specification.
- GRPCRoute: For routing gRPC traffic.
- TLSRoute: For TLS passthrough routing.
- TCPRoute: For routing TCP traffic. For TCP ports from `additionalPorts`, attach TCPRoute directly to the Gateway listener, not to a ListenerSet.
- UDPRoute: For routing UDP traffic. For UDP ports from `additionalPorts`, attach UDPRoute directly to the Gateway listener, not to a ListenerSet.

An example of creating an HTTPRoute for HTTP and HTTPS traffic, and other publishing scenarios, are in “Publishing an application with ListenerSet and HTTPRoute” .

Publishing service domains

⚠ If you need to publish service domains, set the global parameter `publicDomainTemplate` — without it, system HTTPRoute/Gateway/ListenerSet objects for service domains will not work correctly, and the web interfaces of DP service components and other modules will not be published. If you do not need to publish service domains, you can leave this parameter unset.

To provide access to the DP cluster’s service domains, specify a default gateway. Create a ClusterALBInstance with the desired inlet type and configuration, and set `spec.defaultDeckhouseGateway: true` on it.

Example of a ClusterALBInstance manifest with `spec.defaultDeckhouseGateway: true`:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: public-gw
spec:
  gatewayName: public-gw
  defaultDeckhouseGateway: true
  inlet:
    type: LoadBalancer
    loadBalancer: {}
```

After applying the changes, check the ClusterALBInstance status:

```
d8 k get clusteralbinstances
```

The ClusterALBInstance must reach the `Ready` state and create the managed Gateway. After that, ListenerSet and HTTPRoute objects appear in the corresponding system namespaces.

> **i** Currently, not all DP modules are available through the Gateway API. Do not disable the `ingress-nginx` module or delete related objects until the required web interfaces are published through the Gateway API and validated.

After you configure the default gateway, run the following command to see which modules have **already** published service HTTPRoute objects through the Gateway API in this cluster. The command shows the actual route inventory, not a full platform capability matrix:

```
d8 k get httproutes -A -l heritage=deckhouse -o json \
  | jq -r '
["MODULE","GATEWAY API SUPPORT"],
(.items
  | map(.metadata.labels.module // "UNKNOWN")
  | unique[]
  | ["d8-" + ., "yes"])
| @tsv
' \
  | column -t -s $'\t'
```

Selecting the default DP gateway when using multiple ClusterALBInstances

A cluster can have multiple cluster-scoped gateways simultaneously, each marked as the default gateway (with the `spec.defaultDeckhouseGateway: true` flag set for the corresponding ClusterALBInstance). In that case, the default gateway is the Gateway object created by the ClusterALBInstance object with the earliest `creationTimestamp` (that is, the one created first).

If no ClusterALBInstance object is marked as the default gateway, DP allows the Gateway object created by the `alb` module for the instance named `main` to be used as the default gateway.

Changing the default DP gateway

If DP system domains need to move to another Gateway object, complete these steps:

1. Create a new ClusterALBInstance object that describes the required settings and set `spec.defaultDeckhouseGateway: true` on it.
2. In the current ClusterALBInstance object that provides the default DP gateway, set `spec.defaultDeckhouseGateway: false`.
3. Check that all system ListenerSet objects now point to the new Gateway object in `spec.parentRef`.

Examples for different environments

This section describes traffic reception in different environments and operations on an already deployed ALB. Full CR field reference: ClusterALBInstance and ALBInstance. Additional examples are also

available in the `alb` module examples.

- Cloud provider
- Bare metal with MetalLB
- Bare metal with HostPort
- External L7 balancer

Example ClusterALBInstance with the `LoadBalancer` inlet for a cloud provider:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: main
spec:
  gatewayName: public-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
```

To configure the cloud load balancer, specify the required Service annotations in `spec.inlet.loadBalancer.serviceAnnotations`. For example, for a Network Load Balancer in AWS:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: main
spec:
  gatewayName: public-gw
  inlet:
    type: LoadBalancer
    loadBalancer:
      serviceAnnotations:
        service.beta.kubernetes.io/aws-load-balancer-type: "nlb"
```

To accept traffic on bare metal using the MetalLB load balancer, enable the `metallb` module and create a MetalLoadBalancerClass object with an address pool. Place MetalLB balancers on the same nodes as the Envoy Proxy pods of the `alb` module (typically frontend nodes labeled `node-role.deckhouse.io/frontend`):

```
apiVersion: network.deckhouse.io/v1alpha1
kind: MetalLoadBalancerClass
metadata:
  name: alb
spec:
  addressPool:
    - 192.168.2.100-192.168.2.150
  isDefault: false
  l2:
    # Network interfaces that announce the assigned IP addresses.
    interfaces:
      - eth1
  nodeSelector:
    node-role.deckhouse.io/frontend: ""
  type: L2
```

Then create a ClusterALBInstance object and set `spec.inlet.loadBalancer.loadBalancerClass`:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: main
spec:
  gatewayName: public-gw
  inlet:
    type: LoadBalancer
    loadBalancer:
      loadBalancerClass: alb
      serviceAnnotations:
        # Number of addresses allocated from the pool declared in
MetalLoadBalancerClass.
        network.deckhouse.io/l2-load-balancer-external-ips-count: "1"
```

Example ClusterALBInstance with the `HostPort` inlet for bare metal without an external load balancer:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: main
spec:
  gatewayName: public-gw
  inlet:
    type: HostPort
    hostPort:
      httpPort: 80
      httpsPort: 443
```

To place Envoy Proxy pods only on dedicated nodes, set `nodeSelector` and `tolerations` on the ClusterALBInstance.

If the `alb` module runs behind an external L7 balancer (for example, Cloudflare or Qrator), enable `useProxyProtocol` to receive real client addresses. Additionally, use `spec.originalIPDetection` to restrict the list of subnets allowed to provide headers with the client address.

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: main
spec:
  gatewayName: public-gw
  inlet:
    type: HostPort
    hostPort:
      httpPort: 80
      httpsPort: 443
  useProxyProtocol: true
  originalIPDetection:
    setRealIPFrom:
      - 10.0.0.0/16
```

⚠ Proxy Protocol and HTTP/3 cannot be enabled at the same time: if both parameters are set, the `alb` module controller rejects the configuration as conflicting.

Changing the inlet while keeping the current Gateway

To change the inlet used for an existing Gateway object, complete these steps:

1. Create a new ClusterALBInstance object or ALBInstance object with a different name but the same `spec.gatewayName`, using the required inlet type.

2. Check that the new traffic path works correctly.
3. Delete the obsolete ClusterALBInstance object or ALBInstance object.

Because `gatewayName` does not change, the Gateway object stays the same. In most cases, the ListenerSet object and routes do not need to be rewritten.

Opening an additional TCP/UDP port on the cluster-wide gateway

If a dedicated TCP/UDP port is needed in addition to the default HTTP/HTTPS listeners, add the `spec.inlet.additionalPorts` field to the corresponding ClusterALBInstance object, for example:

```
spec:
  gatewayName: public-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
    additionalPorts:
      - port: 9000
        protocol: TCP
```

The controller adds a corresponding TCP/UDP traffic handler to the managed Gateway object with a section name (`sectionName`) like `tcp-port-9000`. To attach a TCPRoute to it, specify the Gateway name and the matching `sectionName` in the route:

```
apiVersion: gateway.networking.k8s.io/v1alpha2
kind: TCPRoute
metadata:
  name: app-tcp
  namespace: prod
spec:
  parentRefs:
    - name: public-gw
      namespace: d8-alb
      sectionName: tcp-port-9000
      port: 9000
  rules:
    - backendRefs:
        - name: tcp-svc
          port: 9000
```

> **i** If a TCPRoute or UDPRoute object is created in a namespace different from the Gateway object namespace, create a ReferenceGrant object in the Gateway's namespace that allows references from the route's namespace.

UDPRoute examples and application publishing steps are in "Working with GRPCRoute, TLSRoute, TCPRoute, and UDPRoute objects".

Separating public and administrative zones

You can run separate Gateway objects for public and administrative traffic. This lets you assign each zone its own entry point and access policy. This approach is similar to using a separate Ingress NGINX Controller and IngressClass for the administrative zone.

Create a dedicated Gateway object for each zone and restrict administrative traffic with `spec.acceptRequestsFrom`. The decision is based on the real connection address, not on request headers.

Example of creating two ClusterALBInstance objects — for the public and administrative zones:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: public
spec:
  gatewayName: public-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
---
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: admin
spec:
  gatewayName: admin-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
  acceptRequestsFrom:
    - 1.2.3.4/32
    - 10.0.0.0/16
```

Then create separate ListenerSet objects and routes for each gateway. Application publishing examples are in “Publishing an application with ListenerSet and HTTPRoute” .

Namespaced publishing (ALBInstance)

Example of a minimal working ALBInstance configuration for publishing a gateway in a namespace:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ALBInstance
metadata:
  name: app-gw
  namespace: prod
spec:
  gatewayName: app-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
```

After the ALBInstance reaches the `Ready` state, create ListenerSet and HTTPRoute objects in the same namespace. Next steps are in “Publishing an application with ListenerSet and HTTPRoute” .

Issuing TLS certificates with cert-manager

The `alb` module uses `cert-manager` to automatically issue TLS certificates. The `d8-http` and `d8-https` listeners serve HTTP-01 challenges when issuing a certificate. To issue a certificate for an application, create a Certificate object that stores the certificate in a Secret, and reference that Secret from `certificateRefs` in the corresponding ListenerSet.

Certificate example that creates the `app-tls` Secret for a ListenerSet:

```
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: app-tls
  namespace: prod
spec:
  secretName: app-tls
  issuerRef:
    name: letsencrypt
    kind: ClusterIssuer
  dnsNames:
    - app.example.com
```

Certificates are issued by the `cert-manager` module. If the `alb` module is used alongside `ingress-nginx`, use a separate ClusterIssuer for each ALB type, as described in “Alongside ingress-nginx”.

Using with other modules and third-party solutions

ALBs implemented using the Kubernetes Gateway API in a DP cluster can be used in conjunction with ALBs implemented using the Ingress NGINX Controller, as well as with ALBs based on third-party Gateway API solutions. For a step-by-step cutover, see Migrating from ingress-nginx to alb.

Alongside ingress-nginx

ALBs implemented using the Kubernetes Gateway API can run in a cluster alongside “ALB with Ingress NGINX Controller”. In that case, use a separate ClusterIssuer object for each ALB type so that certificate settings and lifecycles are managed independently. The same external hostname must not be served by both ALBs at once without an explicit split at the DNS or external load balancer layer.

> **i** For the DP gateway, a ClusterIssuer object is automatically created by default. This same ClusterIssuer object is used to issue certificates for system domains.

Alongside third-party Gateway API implementations

Use of third-party Gateway API implementations is supported, provided that the cluster uses the following Gateway API object storage versions compatible with the `alb` module controller:

- BackendTLSPolicy: v1;
- GatewayClass: v1;
- Gateway: v1;
- ListenerSet: v1;
- GRPCRoute: v1;
- HTTPRoute: v1;
- ReferenceGrant: v1beta1;
- TCPRoute: v1alpha2/v1;
- UDPRoute: v1alpha2/v1;
- TLSRoute: v1.

During startup, the `alb` module controller checks the currently stored versions of Gateway API objects. If it detects a mismatch between the installed and required versions, it stops and does not proceed. If a given Gateway API object type is completely absent from the cluster, the controller automatically creates the required CRD version and then continues startup.

To manually verify version compatibility of the installed Gateway API objects in the cluster, use:

```
declare -A want=(
    [gatewayclasses.gateway.networking.k8s.io]=v1
    [gateways.gateway.networking.k8s.io]=v1
    [grpcroutes.gateway.networking.k8s.io]=v1
    [httproutes.gateway.networking.k8s.io]=v1
    [listenersets.gateway.networking.k8s.io]=v1
    [referencegrants.gateway.networking.k8s.io]=v1beta1
    [tcproutes.gateway.networking.k8s.io]="v1|v1alpha2"
    [udproutes.gateway.networking.k8s.io]="v1|v1alpha2"
    [tlsroutes.gateway.networking.k8s.io]=v1
    [backendtlspolicies.gateway.networking.k8s.io]=v1
)

for crd in "${!want[@]}"; do
    got="$(
       d8 k get crd "$crd" \
         -o jsonpath='{.spec.versions[?(@.storage==true)].name}' \
         2>/dev/null || true
    )"
    if [[ -n "$got" && "$got" =~ ^(${want[$crd]})$ ]]; then
         echo "$crd OK storage=$got"
    else
         echo "$crd FAILED cluster=${got:-MISSING} expected=${want[$crd]}"
    fi
done | sort
```

Otherwise, the module only configures and manages Gateway objects associated with its designated GatewayClass, which minimizes the risk of conflicts when third-party Gateway API implementations are present.

Enabling HTTP/3

By default the gateway accepts HTTP/1.1 and HTTP/2. To enable HTTP/3, set `spec.enableHTTP3: true` on the ClusterALBInstance or ALBInstance:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: public-gw
spec:
  gatewayName: public-gw
  enableHTTP3: true
  inlet:
    type: LoadBalancer
    loadBalancer: {}
```

⚠ You cannot enable `enableHTTP3` and `useProxyProtocol` at the same time: if both parameters are set, the `alb` module controller rejects the configuration as conflicting.

Keep the following in mind:

- HTTP/3 uses QUIC over UDP. Make sure the load balancer and network rules allow UDP on the HTTPS port (usually `443`), not only TCP.
- For the `LoadBalancer` inlet, confirm that the cloud or MetalLB load balancer accepts UDP on the required port.
- Clients must support HTTP/3. From a workstation, verify with:

```
curl -vk --http3 https://app.example.com/
```

If `curl` was built without HTTP/3, use a QUIC-capable client or check UDP port reachability and Envoy Proxy logs.

Using GeoIP and GeoLite2

The `alb` module supports adding GeoIP fields to HTTP request headers based on MaxMind GeoIP/GeoLite2 databases.

Currently, the following database editions can be used:

- GeoIP2-Anonymous-IP;
- GeoIP2-City;
- GeoIP2-ISP;
- GeoIP2-ASN;
- GeoLite2-ASN;
- GeoLite2-City.

> **i** The current GeoIP integration supports using up to 4 databases simultaneously.

Choose how GeoIP databases are obtained:

- Downloading databases from MaxMind
- Local mirror

To use GeoIP and download databases directly from MaxMind servers, first create a Secret containing the license key, for example:

```
d8 k -n prod create secret generic geoip-license \
  --from-literal=licenseKey='<MAXMIND_LICENSE_KEY>'
```

> **i** When configuring GeoIP for ClusterALBInstance, the Secret can be placed in any namespace, but it is recommended to use `d8-alb`.
>
> For ALBInstance objects, the Secret must reside in the same namespace as the ALBInstance object.

After creating the Secret, reference it in the `spec.geoIP.licenseKeySecretRef` parameter of a ClusterALBInstance or ALBInstance object, for example:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ALBInstance
metadata:
  name: main
  namespace: prod
spec:
  envoyLogLevel: Warning
  gatewayName: custom-gateway
  geoIP:
    licenseKeySecretRef:
      name: geoip-license
```

To use GeoIP and download databases from a local mirror, specify the mirror URL in `spec.geoIP.maxmindMirror.url`, for example:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ALBInstance
metadata:
  name: main
  namespace: prod
spec:
  envoyLogLevel: Warning
  gatewayName: custom-gateway
  geoIP:
    maxmindMirror:
      url: "https://local.geoip:8443"
```

You can also use a URL pointing to a local caching GeoIP server in another namespace, for example:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ALBInstance
metadata:
  name: main
  namespace: prod
spec:
  envoyLogLevel: Warning
  gatewayName: custom-gateway
  geoIP:
    maxmindMirror:
      url: "http://geoproxy-cluster.d8-alb.svc:8080/download"
```

Using GeoIP Headers

Once GeoIP is configured in the namespace where ClusterALBInstance or ALBInstance proxies reside, a caching and update server for GeoIP databases is started. Envoy Proxy pods are then restarted sequentially so they can fetch GeoIP databases from the local GeoIP server.

To add GeoIP fields to HTTP request headers, specify the names of the HTTP headers in `spec.geoIP.headers`, for example:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ALBInstance
metadata:
  name: main
  namespace: prod
spec:
  envoyLogLevel: Warning
  gatewayName: custom-gateway
  geoIP:
    headers:
      city: geoip_city
      country: geoip_country
    licenseKeySecretRef:
      name: geoip-license
    maxmindEditionIDs:
      - GeoLite2-City
```

GeoIP databases are updated once per day, both on the caching server and in each individual Envoy Proxy pod using the caching server.

PVC settings for GeoIP components are controlled by the `storageClass` module parameter.

Configuring OpenTelemetry tracing

The `alb` module supports exporting OpenTelemetry traces from Envoy Proxy.

To enable export, set the OpenTelemetry Collector endpoint in `spec.openTelemetry.tracing.url` — using the `http://`, `https://`, or `grpc://` scheme, with the host, port, and, if needed, a path (for example, for OTLP/HTTP).

The `randomSamplingPercentage` parameter sets the share of requests that Envoy Proxy randomly selects for tracing (25% by default).

When using TLS, explicitly set the `sni` parameter if the OpenTelemetry Collector is behind a proxy or load balancer that selects upstreams based on Server Name Indication.

Configure TLS in `spec.openTelemetry.tracing.tls`.

Configuring OpenTelemetry tracing TLS

If OpenTelemetry tracing must send data over TLS, create a Kubernetes Secret with the CA certificate and reference it from `spec.openTelemetry.tracing.tls.caSecretName`.

For ClusterALBInstance and the default DP gateway, place the Secret in the `d8-alb` namespace. For

ALBInstance, place the Secret in the same namespace as the ALBInstance object. The Secret must contain the `cacert` key. Additional Subject Alternative Names for verifying the OpenTelemetry Collector certificate are set with `subjectAltNames`, and `insecureSkipVerify` disables this verification.

```
apiVersion: v1
kind: Secret
metadata:
  name: otel-tracing-ca
  namespace: d8-alb
type: Opaque
stringData:
  cacert: |
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----
---
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterALBInstance
metadata:
  name: proxy-gw
spec:
  gatewayName: proxy-gw
  inlet:
    type: LoadBalancer
    loadBalancer: {}
  openTelemetry:
    tracing:
      url: https://otel-collector.monitoring.svc.cluster.local:4318/v1/traces
      tls:
        sni: otel-collector.monitoring.svc.cluster.local
        caSecretName: otel-tracing-ca
```

Diagnostics and verification

Use this section to check that the gateway is ready and to answer common first-setup questions. More scenarios are in the “alb module FAQ”.

- After creating a ClusterALBInstance or ALBInstance, wait for the `Ready` state and take the Gateway name and namespace from `status`. Field descriptions are in ClusterALBInstance status and ALBInstance status:

  ```
  d8 k get clusteralbinstance
  d8 k -n <NAMESPACE> get albinstance
  d8 k -n d8-alb get gateway
  ```

- With the LoadBalancer inlet, get the address from the load balancer Service (usually in the `d8-alb` namespace) and point DNS for the ListenerSet hostname to it:

  ```
  d8 k -n d8-alb get svc
  ```

- Check whether the same hostname is used for two ALBs. The `alb` and `ingress-nginx` modules can run in the same cluster, but the same external hostname must not be served by both ALBs at once without an explicit split at the DNS or external load balancer layer.
- Check for a conflict between ListenerSet objects. If two ListenerSet objects with identical handlers point to the same Gateway, the controller rejects the conflicting configuration. Change the hostname, port, or protocol, or remove the duplicate ListenerSet.
- For troubleshooting, you can inspect the configuration that the controller and the proxy configurator pushed into the Envoy Proxy instance that serves the Gateway object.

  1. Select an Envoy Proxy pod for the required Gateway object:

```
d8 k -n d8-alb get pods -l alb.deckhouse.io/gateway=shared-gateway
```

2. Get the configuration through the following command (replace `<ENVOY_PROXY_POD_NAME>` with the Envoy Proxy pod name from the previous step):

   ```
   d8 k -n d8-alb exec -it <ENVOY_PROXY_POD_NAME> -- pilot-agent request GET /config_dump
   ```

   If only one section of the configuration is needed, the required section may be requested explicitly:

   ```
   d8 k -n d8-alb exec -it <ENVOY_PROXY_POD_NAME> -- pilot-agent request GET /config_dump?
   resource=dynamic_listeners
   d8 k -n d8-alb exec -it <ENVOY_PROXY_POD_NAME> -- pilot-agent request GET /config_dump?
   resource=dynamic_route_configs
   d8 k -n d8-alb exec -it <ENVOY_PROXY_POD_NAME> -- pilot-agent request GET /config_dump?
   resource=dynamic_active_clusters
   ```

This makes it easy to check whether the expected traffic handlers, virtual hosts, and upstream clusters appeared after changes to the ListenerSet object or Route object.

Migrating from ingress-nginx to alb

This guide describes migration from the `ingress-nginx` module to the `alb` module. Within this migration, application publishing transitions from the Ingress API to the Gateway API.

The guide covers model differences, preparing `alb` module infrastructure with ClusterALBInstance or ALBInstance and a managed Gateway, migrating applications to the Gateway API, migrating Deckhouse Platform (DP) system interfaces, switching traffic to the `alb` module, and rolling back if needed.

Procedure:

1. Preparing alb module infrastructure.
2. Migrating DP interfaces — only if system interfaces currently use Ingress and must move to the Gateway API.
3. Migrating application publishing.
4. Switching traffic to the alb module.
5. Cleanup.

Reasons to move to the Gateway API

Main reasons to move from the Ingress API to the Gateway API:

- Active maintenance of the upstream Ingress NGINX project used by DP has ended. Further upstream development of features, fixes, and integrations is no longer expected. For new application publishing scenarios, use the Gateway API.
- Unlike the Ingress API, the Gateway API describes routes with protocol-specific resources, configures traffic entry points explicitly, controls route attachment, and manages cross-namespace access through dedicated resources. Complex traffic configurations can be defined

with API resources instead of relying mainly on controller-specific annotations.
- The Gateway API separates responsibilities by role. Cluster and network administrators manage traffic infrastructure and Gateway objects through ClusterALBInstance or ALBInstance. Namespace administrators configure traffic reception through ListenerSet objects (hostname, TLS, ports). Application developers define routing with HTTPRoute and other route resources. This separation supports delegated configuration, validation, and gradual migration.

Model comparison

This section compares how administrators define traffic infrastructure, how DP provisions it, and how application routing configuration is translated into data-plane configuration.

Ingress API and ingress-nginx

The diagram below shows the resource model and traffic flow through the `ingress-nginx` module.

HTTP and HTTPS traffic processing through the `ingress-nginx` module is configured as follows:

1. A cluster administrator creates a cluster-scoped IngressNginxController object.
2. The IngressNginxController specifies the name of the IngressClass it uses. If the name is omitted, `nginx` is used.
3. DP reconciles the object and provisions the required infrastructure, including the IngressClass. Multiple IngressNginxController objects can use the same IngressClass.
4. By default, DP resources are published through the IngressClass named `nginx`. A different class can be selected in the DP global configuration.
5. Network administrators or application development teams create Ingress objects that select the required IngressClass explicitly or implicitly.
6. The resulting nginx configuration combines infrastructure settings from IngressNginxController with the Ingress objects selected by the IngressClass.

Gateway API and alb

The diagram below shows the resource model and traffic flow through the `alb` module.

HTTP, HTTPS, gRPC, TLS, TCP, and UDP traffic processing through the `alb` module is configured as follows:

1. A cluster administrator creates a cluster-scoped ClusterALBInstance object.
2. The ClusterALBInstance specifies infrastructure parameters and the mandatory `gatewayName`, which identifies the managed Gateway.
3. The `alb` module controller reconciles the object and provisions the managed Gateway and the required traffic-processing infrastructure. Multiple ClusterALBInstance objects can use the same `gatewayName` and therefore the same Gateway.

4. If a default DP Gateway is configured, DP modules create their ListenerSet, HTTPRoute, and other Gateway API resources for that Gateway.
5. Network administrators or application development teams create Gateway API resources and attach them to the managed Gateway.
6. The resulting Envoy Proxy configuration combines infrastructure settings from ClusterALBInstance with the configuration represented by the Gateway API resources attached to the Gateway.

Key architectural differences

The table highlights the following architectural differences:

Parameter	Ingress API and ingress-nginx	Gateway API and alb
Resource relationships	Infrastructure and routing rules are associated indirectly through an IngressClass	Resources form an explicit graph using `parentRefs` and other typed references, with the Gateway as the root
Separation of responsibilities	IngressNginxController defines infrastructure, while Ingress combines application routing with controller-specific configuration	Cluster and network administrators manage instances and gateways, namespace administrators manage ListenerSet objects, and application developers manage HTTPRoute and other route resources
Configuration model	An Ingress combines most HTTP/HTTPS routing configuration in one object and controller-specific annotations	Listeners, routes, backends, and policies are represented by separate, composable objects
Shared configuration and entry points	Multiple IngressNginxController objects that use the same IngressClass consume the same set of Ingress rules while providing separate entry points	Multiple ClusterALBInstance objects with the same `gatewayName` provide separate entry points backed by the same Gateway configuration
Cross-namespace references	An Ingress, its backend Service, and its TLS Secret generally reside in the same namespace	Controlled cross-namespace references are supported through ReferenceGrant
Protocol support	Ingress primarily models HTTP and HTTPS traffic	Dedicated route types model HTTP, gRPC, TCP, TLS, and UDP traffic
Extensibility	Additional behavior is commonly configured through implementation-specific annotations	More behavior is expressed through structured, validated API resources and policies
Lifecycle and ownership	Infrastructure and routing configuration have limited delegation and attachment controls	Gateway infrastructure can remain stable while application development teams independently create, update, and remove routes
Route attachment	Selecting an IngressClass provides a broad association between an Ingress and controllers	Gateway objects and listeners explicitly control which routes may attach to them

⚠ Multiple ClusterALBInstance objects can refer to the same Gateway, but Gateway-level settings such as `additionalPorts` can conflict. Use compatible Gateway-level settings on every instance associated with the same Gateway.

Consistent with the Gateway API conflict-resolution model, the `alb` module builds the final configuration from the oldest ClusterALBInstance. Conflicting settings from newer instances are ignored and reported in their status.

Step 1. Preparing alb module infrastructure

On this step, choose the `alb` module instance type (ClusterALBInstance or ALBInstance), configure the inlet, and prepare TLS certificates for the Gateway API entry point.

Choosing ALBInstance or ClusterALBInstance

When choosing the instance type, keep the following in mind:

- Use ClusterALBInstance for a shared or platform-level Gateway, for publishing DP system interfaces, or when the `HostPort` inlet is required.
- To publish DP system interfaces, follow Publishing service domains.
- Use ALBInstance for a Gateway dedicated to an application or team and managed within its namespace. ALBInstance supports the `LoadBalancer` and `ClusterIP` inlets; for migration from `ingress-nginx`, `LoadBalancer` is the relevant one.
- A detailed comparison is in ClusterALBInstance and ALBInstance.

Inlet configuration

In IngressNginxController, the inlet type combines the method of accepting traffic with optional behaviors such as Proxy Protocol and SSL passthrough. The `alb` module configures these concerns separately:

- ClusterALBInstance supports the `LoadBalancer` and `HostPort` inlet types.
- ALBInstance supports the `LoadBalancer` and `ClusterIP` inlet types.
- Proxy Protocol is enabled by the `spec.useProxyProtocol` parameter. It can be enabled or disabled on an existing instance without restarting the Envoy Proxy Pod objects or recreating the instance.
- TLS passthrough is configured with a TLS listener and a TLSRoute, rather than with a dedicated inlet type.

Use the following mapping when selecting an inlet for the `alb` module:

IngressNginxController inlet	alb module configuration	Migration notes
`LoadBalancer`	ClusterALBInstance or ALBInstance with `spec.inlet.type: LoadBalancer`	The controller provisions a Service of type `LoadBalancer`
`LoadBalancerWithProxyProtocol`	`LoadBalancer` inlet with `spec.useProxyProtocol: true`	Configure the external load balancer to send Proxy Protocol. Proxy Protocol and HTTP/3 cannot be enabled simultaneously: the `alb` module controller rejects such a configuration as conflicting
`LoadBalancerWithSSLPassthrough`	`LoadBalancer` inlet with a TLS listener and TLSRoute	TLS passthrough is part of the Gateway API routing configuration and is not an inlet variant
`HostPort`	ClusterALBInstance with `spec.inlet.type: HostPort`	`HostPort` is not supported by ALBInstance
`HostPortWithProxyProtocol`	ClusterALBInstance with the `HostPort` inlet and `spec.useProxyProtocol: true`	Proxy Protocol and HTTP/3 cannot be enabled simultaneously
`HostPortWithSSLPassthrough`	ClusterALBInstance with the `HostPort` inlet, a TLS listener, and TLSRoute	TLS passthrough is configured independently of the inlet
`HostWithFailover`	No direct equivalent	Use a ClusterALBInstance with the `LoadBalancer` inlet backed by MetalLB. Follow “Example for bare metal with the MetalLB load balancer” and validate load-balancer failover before switching traffic

> ⚠ During migration, the `ingress-nginx` module with a `HostPort` or `HostWithFailover` inlet and the `alb` module with a `HostPort` inlet cannot use the same host ports on the same nodes. Select separate node sets or a different set of host ports for one of the controllers.

Map related inlet parameters as follows:

IngressNginxController	ClusterALBInstance or ALBInstance
`spec.loadBalancer.annotations`	`spec.inlet.loadBalancer.serviceAnnotations`
`spec.loadBalancer.loadBalancerClass`	`spec.inlet.loadBalancer.loadBalancerClass`
`spec.loadBalancer.httpPort`, `httpsPort`	`spec.inlet.loadBalancer.httpPort`, `httpsPort`
`spec.loadBalancer.sourceRanges`	`spec.inlet.loadBalancer.loadBalancerSourceRanges`
`spec.hostPort.httpPort`, `httpsPort`	`spec.inlet.hostPort.httpPort`, `httpsPort`
`spec.acceptRequestsFrom`	`spec.acceptRequestsFrom`
`spec.*.behindL7Proxy`, `realIPHeader`, `acceptClientIPHeadersFrom`	`spec.originalIPDetection.realIPHeader`, `setRealIPFrom`

When migrating these parameters, consider the following:

- Copy only service annotations supported by the target load balancer implementation.
- Set `spec.inlet.loadBalancer.loadBalancerClass` at creation — the parameter is immutable afterward.
- Keep the default HTTP and HTTPS ports as `80` and `443`, or set a port to `0` in the `alb` module to disable the corresponding default listener.
- Configure HostPort parameters for ClusterALBInstance only. Specify at least one port.
- Preserve the required source CIDR restrictions in `spec.acceptRequestsFrom`.
- Configure trusted proxy CIDRs explicitly. Do not trust client-IP headers from arbitrary sources.
- Verify `loadBalancerSourceRanges` behavior with the target load balancer implementation. The value is passed to the `LoadBalancer` Service. Cloud providers may not support or may ignore this parameter.

The inlet type is immutable for both ClusterALBInstance and ALBInstance. To change the inlet, create a new instance with the same `gatewayName`, validate traffic, switch to it, and delete the old instance.

TLS and certificates

> ⚠ When `ingress-nginx` and `alb` are used simultaneously and certificates are issued by Issuer or ClusterIssuer resources with HTTP-01 solvers, use separate Certificate resources and Secret objects for the Ingress API and Gateway API paths. Otherwise certificate issuance or renewal may conflict.

DP provisions a Gateway-specific ClusterIssuer with a Let’s Encrypt HTTP-01 solver for the default DP Gateway. Separate Certificate and Secret objects are required only for Issuer and ClusterIssuer resources with HTTP-01 solvers. This does not apply to resources configured exclusively with DNS-01 solvers.

Instructions for configuring an HTTP-01 issuer with the Gateway API solver are in “Adding a custom HTTP-01 ClusterIssuer or Issuer for ALB”.

To finish preparing the infrastructure, do the following:

1. Create a ClusterALBInstance or ALBInstance with the selected inlet and the parameters from the tables above.
2. Wait until the instance and the managed Gateway are ready.
3. Prepare separate Certificate resources and Secret objects for the Gateway API path when Issuer or ClusterIssuer resources with HTTP-01 solvers are used at the same time.

Step 2. Migrating DP interfaces

If DP system interfaces are published through Ingress and must move to the Gateway API, follow Publishing service domains.

> **i** Not every DP module publishes service HTTPRoute objects through the Gateway API yet. The `jq` command from that section shows which modules already do this in your cluster — it lists the routes actually published, not the full set of capabilities the platform supports.

If you do not need to migrate DP interfaces, continue with step 3.

Step 3. Migrating application publishing

The list of Gateway API resources supported by the `alb` module and ownership details for managed Gateway objects are in “Supported Gateway API resources”.

Converting Ingress to Gateway API

To convert Ingress resources to Gateway API resources, do the following:

1. Confirm that the target ALBInstance or ClusterALBInstance was created in step 1 and is ready.
2. Obtain the managed Gateway namespace and name from the instance status.
3. Convert each Ingress and its related configuration into the appropriate ListenerSet, route, and policy resources for that Gateway. The built-in conversion tool produces a draft, but not every `ingress-nginx` feature has a direct Gateway API equivalent.
4. Review and adjust the generated manifests before applying them.
5. Apply the resources:

   ```
   d8 k apply -f gateway-api.yaml
   ```

6. Verify Gateway, ListenerSet, and route statuses before switching traffic.

Using the built-in ingress2gateway tool

The gateway controller provides an HTTP endpoint that accepts a single object, a Kubernetes List object, or a YAML payload containing multiple documents. The converter reads the following input resources:

- Ingress — the resources selected for conversion.
- Service — used to resolve named backend ports and service metadata.
- DexAuthenticator — used to resolve `spec.applicationDomain` when an `ingress-nginx` external-auth configuration contains nginx variables such as `$host`.

Pass all related resources as input so the converter can preserve the supported parts of their configuration. The endpoint is disabled by default and listens only inside gateway controller Pod objects.

1. Temporarily enable `migrations.ingress2Gateway.enabled` in the `alb` module configuration and wait for the gateway controller to restart:

   ```
   d8 k patch moduleconfig alb --type merge \
     --patch '{"spec":{"settings":{"migrations":{"ingress2Gateway":
   {"enabled":true}}}}}'
   d8 k -n d8-alb rollout status deployment/gateway-controller
   ```

2. Forward the endpoint from a gateway controller Pod:

   ```
   d8 k -n d8-alb port-forward deployment/gateway-controller 8082:8082
   ```

3. In another terminal, export all recognized resource types and send the resulting Kubernetes List directly to the converter:

```
converter_url='http://127.0.0.1:8082/ingress2gateway'
converter_url="${converter_url}?gateway=<GATEWAY_NAMESPACE>/<GATEWAY_NAME>"
converter_url="${converter_url}&scope=<SCOPE>&ingress-class=<INGRESS_CLASS>"

d8 k get ingress,service,dexauthenticator \
  --all-namespaces --output yaml | \
  curl --fail-with-body --silent --show-error --request POST \
    --header 'Content-Type: application/yaml' \
    --data-binary @- \
    --output gateway-api.yaml \
    "$converter_url"
```

In the URL, query parameter names are lowercase: `gateway`, `scope`, and `ingress-class`. In the example, their values are placeholders in angle brackets and uppercase:

- `<GATEWAY_NAMESPACE>` — namespace of the managed Gateway from the instance status in step 1;
- `<GATEWAY_NAME>` — name of the managed Gateway from the same status.

  The `<GATEWAY_NAMESPACE>/<GATEWAY_NAME>` pair is the value of the `gateway` parameter. Use the default value `d8-alb/public-gw` only if it matches your Gateway.
- `<SCOPE>` — `cluster` for the cluster-scoped model, or `namespaced` for a Gateway in an application namespace (as with ALBInstance). If the parameter is omitted, `cluster` is used;
- `<INGRESS CLASS>` — IngressClass of the source Ingress resources. If the parameter is omitted, `nginx` is used.

> **i** The request body is limited to 8 MiB. For large clusters, export only the namespaces and related resources being migrated.

4. Review `gateway-api.yaml` and the conversion diagnostics included as YAML comments, then apply the resources.
5. After completing the conversion, disable the endpoint:

```
d8 k patch moduleconfig alb --type merge \
  --patch '{"spec":{"settings":{"migrations":{"ingress2Gateway":
{"enabled":false}}}}}'
```

Extending Gateway API with annotations

The Gateway API specification does not cover every implementation-specific traffic-management feature required by DP. The `alb` module therefore uses HTTPRoute annotations for options that are not yet represented by standard Gateway API fields.

As the corresponding features become available in the Gateway API, the `alb` module will gradually replace annotation-based configuration with native Gateway API resources and fields.

During migration, use standard Gateway API fields where possible and replace `ingress-nginx` annotations only with supported `alb` annotations — including after you apply `gateway-api.yaml`. The current list is in “Supported HTTPRoute annotations”.

The `ingress2gateway` utility produces a draft of Gateway API resources and **does not** migrate every `ingress-nginx` annotation automatically. After conversion, compare the Ingress with the table below and apply the required settings manually.

Ingress annotation (`ingress-nginx`)	Equivalent in the `alb` module
`nginx.ingress.kubernetes.io/whitelist-source-range`	HTTPRoute annotation `alb.network.deckhouse.io/whitelist-source-range`
`nginx.ingress.kubernetes.io/service-upstream`	HTTPRoute annotation `alb.network.deckhouse.io/service-upstream`

Ingress annotation (`ingress-nginx`)	Equivalent in the `alb` module
`nginx.ingress.kubernetes.io/upstream-vhost`	HTTPRoute `URLRewrite` filter with `hostname` (see publishing with an Istio sidecar)
`nginx.ingress.kubernetes.io/auth-url` / `auth-signin`	HTTPRoute annotations `alb.network.deckhouse.io/auth-url` and `alb.network.deckhouse.io/auth-signin`
`nginx.ingress.kubernetes.io/auth-type: basic` and a Secret	HTTPRoute annotation `alb.network.deckhouse.io/basic-auth-secret`
`nginx.ingress.kubernetes.io/limit-rps`	HTTPRoute annotation `alb.network.deckhouse.io/limit-rps`
`nginx.ingress.kubernetes.io/proxy-body-size`	HTTPRoute annotation `alb.network.deckhouse.io/buffer-max-request-bytes` (value in bytes)
`nginx.ingress.kubernetes.io/proxy-buffer-size`	HTTPRoute annotation `alb.network.deckhouse.io/proxy-buffer-size`
`nginx.ingress.kubernetes.io/proxy-read-timeout` / `proxy-send-timeout`	HTTPRoute annotation `alb.network.deckhouse.io/idle-timeout` (idle timeout, not total request duration)
`nginx.ingress.kubernetes.io/affinity` / cookie	HTTPRoute annotation `alb.network.deckhouse.io/session-affinity`
`nginx.ingress.kubernetes.io/rewrite-target`	HTTPRoute annotation `alb.network.deckhouse.io/rewrite-target` or standard Gateway API filters
`nginx.ingress.kubernetes.io/configuration-snippet` and other nginx snippets	No direct equivalent; redesign the configuration for Gateway API and `alb` annotations

If an Ingress annotation is missing from the table and has no Gateway API field, behavior after migration may differ or disappear. Validate the application on the `alb` module path before switching production traffic.

Step 4. Switching traffic to the alb module

Run `ingress-nginx` and `alb` simultaneously until the `alb` module path has been validated and the rollback window has closed.

Migrate individual domains or namespaces when they can use separate DNS records. Otherwise, switch the shared external entry point by changing DNS records or the backend pool of an external load balancer.

On this step:

- Test the `alb` module without changing DNS with `migrationGateway` when you need validation without a DNS change (`ingress-nginx` version `1.1.0` and later).
- Enable `http01CertificateSolverBridging` when Gateway API path certificates use HTTP-01 while public DNS still points to Ingress.
- Choose the switching method for your current entry point in the subsections below: automatically provisioned load balancer, manually managed load balancer, or HostPort/HostWithFailover.
- Before the final production cutover, complete “Validating the cutover”.

Testing the alb module via the Ingress NGINX Controller

The `spec.migrationGateway` parameter of IngressNginxController enables source-IP-based testing without changing DNS.

Requests from `sourceCIDRs` continue to enter through the existing Ingress NGINX Controller entry point but are proxied to the internal Service of the target `alb` module instance. Other requests continue to use the original Ingress backends.

> **i** The parameter is available in the `ingress-nginx` module version `1.1.0` and later.

Despite its use in this guide for migration to the `alb` module, `migrationGateway` is not specific to the `alb` module.

Its `serviceRef` can point to the entry-point Service of any Gateway API implementation that accepts ordinary HTTP and HTTPS traffic on the configured ports.

Locate the `alb` module configuration Service:

```
d8 k get service --all-namespaces \
  --selector alb.deckhouse.io/configuration-service
```

Example output for a ClusterALBInstance named `main` — a `ClusterIP` Service in the `d8-alb` namespace:

```
NAMESPACE   NAME   TYPE        CLUSTER-IP     EXTERNAL-IP   PORT(S)          AGE
d8-alb      main   ClusterIP   10.222.1.10    <none>        80/TCP,443/TCP   10d
```

For an ALBInstance, the Service is in the ALBInstance's namespace, named `d8-alb-<ALB_INSTANCE_NAME>`.

Configure the source IngressNginxController, using narrow tester CIDRs initially:

```
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: <CONTROLLER_NAME>
spec:
  # Spec fields unrelated to migrationGateway (inlet, ingressClass, and so on) are
omitted.
  migrationGateway:
    sourceCIDRs:
      - <SOURCE_CIDR>
    serviceRef:
      namespace: <SERVICE_NAMESPACE>
      name: <SERVICE_NAME>
      ports:
        http: <HTTP_PORT>
        https: <HTTPS_PORT>
```

where:

- `<CONTROLLER_NAME>` — name of the source IngressNginxController;
- `<SOURCE_CIDR>` — CIDR of clients whose requests are proxied to the `alb` module during testing;
- `<SERVICE_NAMESPACE>` — namespace of the `alb` module configuration Service;
- `<SERVICE_NAME>` — name of the `alb` module configuration Service;
- `<HTTP_PORT>` — HTTP port on the target Service;
- `<HTTPS_PORT>` — HTTPS port on the target Service.

For matching clients, `migrationGateway` forwards requests to the target Service ports and bypasses the backends and location-level behavior from the original Ingress resources. HTTP requests go to the configured HTTP port. For HTTPS, nginx terminates the incoming TLS connection and establishes a new TLS connection to the configured HTTPS port, using the original hostname in the Host header and for SNI. HTTP, HTTPS, and HTTP-based protocol upgrades such as WebSocket are supported. gRPC and non-HTTP protocols are not.

The setting applies to every Ingress served by the controller. Before expanding `sourceCIDRs`, verify every hostname reachable from those addresses and confirm that authentication, redirects, headers, GeoIP behavior, WebSocket connections, and other required policies exist on the `alb` module path.

The `migrationGateway` parameter works by forwarding an already-accepted, and if needed re-encrypted, HTTP or HTTPS request to the target Service, so it is not supported where nginx does not perform this processing:

- With the `HostPortWithSSLPassthrough` and `LoadBalancerWithSSLPassthrough` inlets — with TLS passthrough, nginx does not decrypt traffic and cannot determine which request to forward.
- With the `HostWithFailover` inlet — this inlet always uses Proxy Protocol, and `migrationGateway` does not support sending Proxy Protocol to the target Service.
- With `enableIstioSidecar` — traffic is handled by the Istio sidecar rather than directly by nginx.

The target Service must accept ordinary HTTP and HTTPS without Proxy Protocol — `migrationGateway` does not send it.

If the `alb` module path needs Proxy Protocol in production, disable it for `migrationGateway` testing (`spec.useProxyProtocol: false`). Re-enable it before shifting production traffic and validate the entry point through the load balancer that sends Proxy Protocol.

When a trusted L7 proxy is used in front of the Ingress NGINX Controller, verify real-IP processing before relying on `sourceCIDRs`.

To immediately return selected clients to the original Ingress backends, remove `spec.migrationGateway`:

```
d8 k patch ingressnginxcontroller <CONTROLLER_NAME> --type json \
  --patch '[{"op":"remove","path":"/spec/migrationGateway"}]'
```

where `<CONTROLLER_NAME>` is the name of the source IngressNginxController.

Preserving HTTP-01 validation

The `migrationGateway` parameter handles selected application requests.

The `migrations.http01CertificateSolverBridging` parameter keeps cert-manager Gateway API HTTP-01 challenges reachable through the Ingress NGINX Controller while public DNS still points to it.

When Issuer or ClusterIssuer resources with HTTP-01 solvers are used, do the following:

1. Enable bridging before requesting certificates for the Gateway API path:

   ```
   d8 k patch moduleconfig alb --type merge \
     --patch '{"spec":{"settings":{"migrations":{"http01CertificateSolverBridging":
   {"enabled":true,"ingressClassName":"<INGRESS_CLASS>"}}}}}'
   d8 k -n d8-alb rollout status deployment/gateway-controller
   ```

   where `<INGRESS_CLASS>` is the IngressClass that currently receives public traffic on port `80`.

2. Keep the `ingress-nginx` module enabled. The `alb` module controller creates temporary Ingress resources for cert-manager solver HTTPRoute resources, allowing challenges to pass through the Ingress NGINX Controller to the solver Service.

3. Issue certificates for the Gateway API path before the traffic cutover. Test the prepared TLS configuration through `migrationGateway` or by connecting directly to the Gateway API entry-point address with a hostname override, for example using the curl `--resolve` option.

4. After DNS or the external load balancer sends public traffic to the Gateway API entry point, verify HTTP-01 issuance through the Gateway API path and disable bridging:

   ```
   d8 k patch moduleconfig alb --type merge \
     --patch '{"spec":{"settings":{"migrations":{"http01CertificateSolverBridging":
   {"enabled":false}}}}}'
   ```

Choosing the switching method

Choose the switching method based on how external traffic is accepted today: through an automatically provisioned load balancer, a manually managed load balancer, or direct HostPort/HostWithFailover access.

- DNS / provisioned LB
- Manually managed LB
- HostPort or HostWithFailover

Automatically provisioned load balancer

To switch traffic through DNS, do the following:

1. Wait for the `alb` module load balancer and its health checks to become ready.
2. Lower the DNS TTL in advance.
3. Change each application DNS record from the Ingress NGINX Controller address to the Gateway API entry-point address.

When the Ingress NGINX Controller uses a `LoadBalancer` Service provisioned by the Kubernetes cloud provider, the source and target controllers normally have separate load balancer IP addresses or hostnames.

Use weighted DNS records for a gradual switch only if the DNS provider supports them.

A provider-managed load balancer does not normally allow node-by-node migration between two independently managed Service objects.

If MetalLB or another implementation uses a fixed address, the same address cannot be assigned to both Service objects simultaneously. Transfer it only during a coordinated cutover.

Manually managed load balancer

To switch traffic through an external load balancer, do the following:

1. Keep the public DNS record unchanged.
2. Add `alb` module nodes and their configured ports as healthy backends in the external load balancer pool.
3. Shift traffic from Ingress NGINX Controller backends gradually.
4. Remove the old backends only after validation.

This supports node-by-node migration and weighted traffic distribution when the external load balancer provides those features.

When configuring backends, keep the following in mind:

- Configure health checks against `/healthz` on the `alb` module HTTP port.
- Preserve the original protocol and client-address handling: align Proxy Protocol settings for traffic and health checks, or configure trusted forwarded headers for an L7 load balancer.
- If both controllers run on the same nodes, use different host ports. Alternatively, select disjoint node sets.

Direct HostPort or HostWithFailover access

To switch traffic with direct HostPort or HostWithFailover access, do the following:

1. Deploy the `alb` module on a separate node set or use non-conflicting host ports.
2. For a node-by-node switch, add `alb` module node addresses to the DNS pool and remove Ingress NGINX Controller node addresses after each node passes validation.
3. Account for DNS TTLs and client-side caching: when records point to node addresses, DNS pools do not provide deterministic weighting or connection draining.

DNS cannot distinguish controllers that use different ports on the same node address. If clients must continue using ports `80` and `443`, use separate nodes or introduce a load balancer or NAT rule.

`HostWithFailover` has no direct equivalent in the `alb` module. When equivalent failover behavior is required, use the `LoadBalancer` inlet with MetalLB.

Validating the cutover

⚠ Traffic processing can differ between the Ingress NGINX Controller and the `alb` module, including generated and trusted headers, protocol handling, and supported features. Thoroughly test applications through the `alb` module path and, where necessary, adjust them to the traffic-processing behavior of the `alb` module before switching production traffic.

Before shifting production traffic:

- Confirm that the step 3 resources are applied.
- On the target ALBInstance or ClusterALBInstance status, check that `ready: true` and `synced: true`.
- Verify that `conflictPorts`, `conflictBackendTLS`, and `conflictFrontendTLS` are all `false`; if any is `true`, the matching `<CONFLICT>Owner` field names the controlling instance.
- Check the `Accepted` and `Programmed` conditions on the Gateway and ListenerSet status, and `Accepted` on the route status (`d8 k -n <NAMESPACE> get gateway,listenerset,httproute <NAME> -o yaml` — the `status.conditions` section).
- `True` in these conditions means the controller accepted the resource and applied its configuration.
- Test every hostname and protocol through the Gateway API entry-point address or with `migrationGateway`, including TLS certificates, redirects, authentication, long-lived connections, and application-specific policies.

- Verify preservation of the client address, Proxy Protocol or forwarded-header processing, source restrictions, and load balancer health checks.
- If HTTP-01 bridging is still required, keep `http01CertificateSolverBridging` enabled until DNS or the load balancer is switched.
- Confirm that metrics, logs, alerts, and dashboards identify traffic and errors on both controllers.
- Keep Ingress resources, the Ingress NGINX Controller, its external entry point, and valid certificates available throughout the rollback window.
- Choose the switching method above and define rollback criteria.

Rolling back

Define rollback criteria before the cutover. If validation fails:

1. For `migrationGateway` testing, remove `spec.migrationGateway`.
2. For a DNS switch, restore the Ingress NGINX Controller address and wait for the previous DNS TTL to expire.
3. For a manually managed load balancer, restore Ingress NGINX Controller nodes and ports in its backend pool.
4. If public traffic again enters through the Ingress NGINX Controller and the Issuer or ClusterIssuer resources for Gateway API certificates use HTTP-01 solvers, re-enable `http01CertificateSolverBridging`.

Do not delete the old Ingress resources, Ingress NGINX Controller, load balancer, or DNS values until rollback has been tested and the agreed stabilization period has elapsed.

Step 5. Cleanup

After the rollback window closes, do the following:

1. Remove `migrationGateway` if it is still set.
2. Disable `http01CertificateSolverBridging` and `ingress2Gateway` if they are still enabled.
3. Delete Ingress resources and Ingress NGINX Controllers that no longer serve applications or DP system interfaces.
4. Remove unused load balancers, certificates, Secret objects, and DNS records.
5. Restore normal DNS TTLs after confirming that no clients use the old entry point.

> **i** Some DP interfaces may still be published through the Ingress API. Do not disable the `ingress-nginx` module or delete related objects until the required interfaces are published through the Gateway API and validated. Follow “Publishing service domains”.

ALB with Istio

ALB with Istio is implemented via Istio Ingress Gateway or Ingress NGINX. The `istio` module is used for this purpose.

Use this option when you need advanced traffic management in a service mesh, for example canary routing or mTLS. Configuration details are in the `istio` module documentation.

Creating an IngressIstioController and preparing infrastructure is a cluster administrator task. Application publishing with Gateway and VirtualService resources, including canary deployment, is described in “Publishing applications using Istio Ingress Gateway resource”.

Ingress to publish applications

Applications can be published using the Istio Ingress Gateway or through Ingress NGINX with the Istio sidecar enabled.

Istio Ingress Gateway

To publish the application using the Istio Ingress Gateway, follow these steps:

1. Create an IngressIstioController resource.

   The example below creates a controller with the `HostPort` inlet on frontend nodes:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: IngressIstioController
   metadata:
     name: main
   spec:
     # The label selector value used to create the Gateway resource.
     ingressGatewayClass: istio-hp
     inlet: HostPort
     hostPort:
       httpPort: 80
       httpsPort: 443
     nodeSelector:
       node-role.deckhouse.io/frontend: ""
     tolerations:
       - effect: NoExecute
         key: dedicated.deckhouse.io
         operator: Equal
         value: frontend
     resourcesRequests:
       mode: VPA
   ```

2. Create a Secret with the TLS certificate and key for HTTPS. Place it in the `d8-ingress-istio` namespace and give application developers the Secret name and the `ingressGatewayClass` value:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: app-tls-secret
     namespace: d8-ingress-istio # Secret namespace is d8-ingress-istio, not the
   application namespace.
   type: kubernetes.io/tls
   data:
     tls.crt: |
       <TLS_CRT_DATA>
     tls.key: |
       <TLS_KEY_DATA>
   ```

Supported Secret formats are in the Istio guide on key formats.

Application developers then create the Gateway and VirtualService resources. Examples, including canary deployment, are in “Publishing applications using Istio Ingress Gateway resource”.

Ingress NGINX

To publish through Ingress NGINX with an Istio sidecar, enable the `enableIstioSidecar` parameter in the IngressNginxController of the `ingress-nginx` module and share the `ingressClass` name with application developers.

Ingress and Service manifests with the required annotations are in “Publishing applications using Ingress NGINX”.

Ensuring high availability and fault tolerance (keepalived)

In Deckhouse Platform, the `keepalived` module can be used to provide high availability and fault tolerance.

To configure keepalived clusters, custom resources are used.

Module usage examples

Multiple public IP addresses

In the following example, there are three public IP addresses on three front nodes. Each virtual IP address is assigned to a separate VRRP group. Thus, each address “jumps” independently of the others, and if there are three nodes in the cluster with the `node-role.deckhouse.io/frontend: ""` labels, each IP address gets its own master node.

```
apiVersion: deckhouse.io/v1alpha1
kind: KeepalivedInstance
metadata:
  name: front
spec:
  nodeSelector: # Required.
    node-role.deckhouse.io/frontend: ""
  tolerations:  # Optional.
  - key: dedicated.deckhouse.io
    operator: Equal
    value: frontend
  vrrpInstances:
  - id: 1 # The unique cluster ID.
    interface:
      detectionStrategy: DefaultRoute # The card with the default route is used as a
service network one.
    virtualIPAddresses:
    - address: 42.43.44.101/32
      # The interface parameter is omitted since IP addresses are based on the cards
that service VRRP traffic.
  - id: 2
    interface:
      detectionStrategy: DefaultRoute
    virtualIPAddresses:
    - address: 42.43.44.102/32
  - id: 3
    interface:
      detectionStrategy: DefaultRoute
    virtualIPAddresses:
    - address: 42.43.44.103/32
```

In the following example, there is a gateway with a pair of IP addresses for LAN and WAN. In the case of the gateway, the private and public IPs are bind together, and they will “jump” between the nodes in tandem. In the below example, the VRRP traffic is routed through the LAN interface. It can be detected using the NetworkAddress method (assuming that each node has an IP address belonging to this subnet).

```
apiVersion: deckhouse.io/v1alpha1
kind: KeepalivedInstance
metadata:
  name: mygateway
spec:
  nodeSelector:
    node-role.deckhouse.io/mygateway: ""
  tolerations:
  - key: node-role.deckhouse.io/mygateway
    operator: Exists
  vrrpInstances:
  - id: 4 # Since "1", "2", "3" IDs are used in the "front" KeepalivedInstance above.
    interface:
      detectionStrategy: NetworkAddress
      networkAddress: 192.168.42.0/24
    virtualIPAddresses:
    - address: 192.168.42.1/24
      # In this case, we have already detected the local network (above); thus, the
interface parameter can be safely omitted.
    - address: 42.43.44.1/28
      interface:
        detectionStrategy: Name
        name: ens7 # The interface for public IPs is called "ens7" on all nodes,
therefore it needs to be named explicitly.
```

Switching keepalived manually

1. Enter the desired pod using a debug container with a shared process namespace:

   ```
   d8 k debug -n d8-keepalived -it keepalived-<name> --profile=general --target keepalived
   ```

2. Edit the configuration file `vim /proc/1/root/etc/keepalived/keepalived.conf`, replace the value in the `priority` line with <number of keepalived pods + 1> or set a value higher than the current VRRP master (e.g., `255`).

3. Apply settings – send a signal to reload the configuration:

   ```
   kill -HUP 1
   ```

Egress Gateway configuration

Egress Gateway enables centralized management and control of outgoing traffic and provides features such as encryption, routing, and monitoring.

⚠ To use the Egress Gateway, enable the `cni-cilium` module in the cluster.

Egress Gateway usage modes

Basic mode

Pre-configured IP addresses are used on egress nodes.

Virtual IP mode

Egress Gateway lets you dynamically assign additional IP addresses to nodes.

Configuration principle

Configuring an egress gateway requires two custom resources:

1. EgressGateway: Describes the group of nodes, one of which will be selected as the active egress gateway, while the rest will remain in standby mode:
   - Among the group of nodes matching the `spec.nodeSelector` the eligible nodes will be selected. One of them will be assigned as the active gateway. The active node is selected in alphabetical order.

     Attributes of an eligible node:

     - The node is in `Ready` state.
       - The node is not in the maintenance state (not cordoned).
       - The `cilium-agent` on the node is in the `Ready` state.
     - When using EgressGateway in `VirtualIP` mode, an agent is launched on the active node which emulates a “virtual” IP address using the ARP protocol. The status of this agent’s pod is also taken into account when determining the eligibility of a node.
     - Different EgressGateways can use the same nodes for operation. The active node is selected independently for each EgressGateway, which allows for load balancing between them.
2. EgressGatewayPolicy: Describes the policy for routing network requests from pods in the cluster to a specific egress gateway defined using EgressGateway.

Node maintenance

To perform maintenance on a node that is currently the active egress gateway, follow these steps:

1. Remove the node label to exclude it from the egress gateway candidate pool. `<egress-label>` is the label specified in `spec.nodeSelector` of your EgressGateway.

   ```
   d8 k label node <node-name> <egress-label>-
   ```

2. Cordon the node to prevent new pods from starting:

   ```
   d8 k cordon <node-name>
   ```

   After this, Cilium will automatically select a new active node from the remaining candidates. Traffic will continue routing through the new gateway without interruption.

3. After maintenance is complete, return the node to service:

   ```
   d8 k uncordon <node-name>
   d8 k label node <node-name> <egress-label>=<value>
   ```

⚠ Reapplying the label may cause the node to become active egress gateway again (if it is first in alphabetical order among candidates).

To avoid immediate return to the active state, temporarily reduce the number of EgressGateway replicas or adjust selection priorities using additional labels.

Comparison with CiliumEgressGatewayPolicy

The `CiliumEgressGatewayPolicy` implies configuring only one node as an egress gateway. If it fails, there are no failover mechanisms and the network connection will be broken.

Configuration examples

EgressGateway in PrimaryIPFromEgressGatewayNodeInterface mode (basic mode)

```
apiVersion: network.deckhouse.io/v1alpha1
kind: EgressGateway
metadata:
  name: my-egressgw
spec:
  nodeSelector:
    node-role.deckhouse.io/egress: ""
  sourceIP:
    mode: PrimaryIPFromEgressGatewayNodeInterface
    primaryIPFromEgressGatewayNodeInterface:
      # The "public" interface must have the same name on all nodes that matching the
nodeSelector.
     # If the active node fails, traffic will be redirected through the backup node
and
     # the source IP address of the network packets will change.
     interfaceName: eth1
```

EgressGateway in VirtualIPAddress mode

```
apiVersion: network.deckhouse.io/v1alpha1
kind: EgressGateway
metadata:
  name: my-egressgw
spec:
  nodeSelector:
    node-role.deckhouse.io/egress: ""
  sourceIP:
    mode: VirtualIPAddress
    virtualIPAddress:
      # Each node must have all the necessary routes configured to access all
external public services,
     # the "public" interface must be prepared for automatic configuration of the
"virtual" IP as a secondary IP address.
     # In case of failure of the active node, traffic will be redirected through the
backup node and
     # the source IP address of the network packets will not change.
     ip: 172.18.18.242
     # List of network interfaces for Virtual IP.
     interfaces:
     - eth1
```

EgressGatewayPolicy

```
apiVersion: network.deckhouse.io/v1alpha1
kind: EgressGatewayPolicy
metadata:
  name: my-egressgw-policy
spec:
  destinationCIDRs:
  - 0.0.0.0/0
  egressGatewayName: my-egressgw
  selectors:
  - podSelector:
      matchLabels:
        app: backend
        io.kubernetes.pod.namespace: my-ns
```

Inter-cluster cooperation (cluster alliance)

Deckhouse Platform (DP) supports two inter-cluster communication models:

- Multicluster
- Federation

Both models can be implemented using Istio (via the `istio` module). Istio provides deployment of a service mesh for managing and configuring network interactions between applications within a cluster.

Service mesh usage specifics in DP

Available scenarios depend on the platform edition.

Multicluster and federation are available in the Enterprise Edition (EE).

In the Community Edition (CE), Basic Edition (BE), Standard Edition (SE), and Standard Edition+ (SE+), the service mesh can only be used within a single cluster — for example, to implement patterns such as Circuit Breaker, Canary Deployment, and others.

Use case	CE / BE / SE / SE+	EE
Service mesh in one cluster	+	+
Federation	-	+
Multicluster	-	+

Differences between federation and multicluster

Federation connects independent (sovereign) clusters:

- Each cluster has its own namespace and services.
- Inter-cluster communication is configured explicitly. You define which services are accessible externally.

Multicluster tightly connects integrated clusters:

- A shared namespace is used.
- Services from one cluster are available to others as if they were local (unless restricted by authorization policies).

Models for combining multiple clusters (Istio example)

When using Istio, different combination models are possible:

- Network models: Clusters can be in the same or different networks.
- Control plane models: One or multiple service mesh control planes.
- Isolation models: Tenant isolation at the namespace, network, or cluster level.
- Service mesh models: One shared service mesh or multiple meshes.

These parameters can be combined to build an architecture tailored to the requirements of a specific infrastructure.

Problems solved with multicluster and federation

Combining clusters into a federation or multicluster can help solve the following tasks:

- Geographical distribution and GEO load balancing: Clusters serve users closer to their location.
- Fault tolerance: If a cluster or data center fails, traffic automatically switches to others (automatic failover).
- Horizontal scaling: Load distribution across clusters increases overall system performance.
- Environment and resource isolation: Different environments (production, staging, dev) can be placed in separate clusters, with optional interconnection.
- Regulatory compliance: For example, data storage requirements for specific geographic zones.
- Hybrid and multi-cloud infrastructure creation: Combining clusters located in different environments (cloud, different providers, etc.).

Multicluster

Multicluster of Istio funds

Requirements for clusters

- Cluster domains in the `clusterDomain` parameter of the ClusterConfiguration resource must be the same for all multicluster members. The default value is `cluster.local`.
- Pod and Service subnets in the `podSubnetCIDR` and `serviceSubnetCIDR` parameters of the ClusterConfiguration resource must be unique for each multicluster member.

  > - When analyzing HTTP and HTTPS traffic *(in Istio terminology)*, you can identify them and decide on further routing or blocking based on their headers.
  > - At the same time, when analyzing TCP traffic *(in Istio terminology)*, it is possible to identify them and decide on further routing or blocking based only on their destination IP address or port number.
  >
  > If the IP addresses of services or pods in different clusters match, requests from other pods in other clusters may mistakenly fall under the Istio's rules. The intersection of subnets of services and pods is not recommended (source).

By default, pods from different clusters communicate through the Istio ingress gateway (multi-network mode). If the pods of two clusters are directly reachable from each other (flat network), set `spec.enableIngressGateway` to `false` in both clusters, in the IstioMulticluster that describes the other cluster.

> ⚠ Only sidecar-mode workloads can take part in a multicluster. For details, refer to Ambient mesh limitations.

General principles

- Multicluster requires mutual trust between clusters to work. This is achieved by a mutual exchange of root certificates between clusters.
- Istio connects directly to the API server of the neighboring cluster to gather information about its services. The Deckhouse `istio` module establishes the secure communication channel.

Enabling the multicluster

Enabling the multicluster (via the `istio.multicluster.enabled = true` module parameter) results in the following:

- A proxy is added to the cluster to publish access to the API server via the standard Ingress resource:
  - Access through this public address is secured by authorization based on Bearer tokens signed with trusted keys.
  - Deckhouse automatically exchanges trusted public keys during the mutual configuration of the multicluster.
  - The proxy has read-only access to a limited set of resources.
- A service gets added to the cluster. That service exports the following cluster metadata to the outside:
  - Istio root certificate (accessible without authentication).
  - The public API server address (available only for authenticated requests from neighboring clusters).
  - List of public addresses of the `ingressgateway` service (available only for authenticated requests from neighboring clusters).
  - Server public keys to authenticate requests to API server and to private metadata.

Managing the multicluster

To create a multicluster, you need to create a set of IstioMulticluster resources in each cluster that describe all the other clusters.

Example of configuring a multicluster of two clusters

Use the IstioMulticluster resource to configure a multicluster using Istio tools.

Cluster A:

```
apiVersion: deckhouse.io/v1alpha1
kind: IstioMulticluster
metadata:
  name: cluster-a
spec:
  metadataEndpoint: https://istio.k8s-a.example.com/metadata/
```

Cluster B:

```
apiVersion: deckhouse.io/v1alpha1
kind: IstioMulticluster
metadata:
  name: cluster-b
spec:
  metadataEndpoint: https://istio.k8s-b.example.com/metadata/
```

Additional resources

- Module `control-plane-manager` parameters
- Module `istio` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Federation

Federation with Istio (Service Mesh)

Requirements for clusters

- Each cluster must have a unique domain in the `clusterDomain` parameter of the `control-plane-manager` module. Note that none of the clusters should use the domain `cluster.local`, which is the default setting.

  > `cluster.local` can't be used as it's an unmodified alias for the local cluster domain. When specifying `cluster.local` as a principals in the AuthorizationPolicy, it will always refer to the local cluster, even if there is another cluster in the mesh with `clusterDomain` explicitly defined as `cluster.local` (for details, refer to the Istio documentation).

- There are no requirements for unique subnets of modules and services in the `podSubnetCIDR` and `serviceSubnetCIDR` parameters of the `control-plane-manager` module when clusters are operating in a federation.

  > When analyzing traffic, Istio uses:
  >
  > - For HTTP and HTTPS requests — headers.
  > - For TCP requests — destination IP address and port number.
  >
  > Istio operates in the multi-network mode — pods from different clusters can only communicate with each other through the Istio ingress gateway. Direct communication between pods of different clusters is not supported.

> ⚠ Only sidecar-mode workloads can take part in a federation. For details, refer to Ambient mesh limitations.

General principles of federation

- Federation requires mutual trust between clusters. It requires a mutual root certificate exchange: cluster A must trust cluster B, and vice versa.
- Configuring inter-cluster access to services requires exchanging information about public services. In vanilla istio this is done using `ServiceEntry` resources. A `ServiceEntry` describes the public `ingressgateway` address of cluster B so that services in cluster A can reach the `bar` service in cluster B. The module creates ServiceEntries automatically (see below).

Enabling the federation — created services

Enabling federation (via the `istio.federation.enabled = true` module parameter) results in the following:

- The `ingressgateway` service is added to the cluster. Its task is to proxy mTLS traffic coming from outside to application services.
- Another added service exports the following cluster metadata to the outside:
  - Istio root certificate (accessible without authentication).
  - List of public services in the cluster (available only for authenticated requests from neighboring clusters).
  - List of public addresses of the `ingressgateway` service (available only for authenticated requests from neighboring clusters).

Managing the federation

To establish a federation, you must:

- Create a set of IstioFederation resources in each cluster that describe all the other clusters.
  - After successful auto-negotiation between clusters, the IstioFederation resource will be filled with necessary service data in `status.metadataCache.public` and `status.metadataCache.private`.
- Add the `federation.istio.deckhouse.io/public-service: ""` label to each Service resource that is considered public within the federation.
  - In the other federation clusters, corresponding `ServiceEntry` and DestinationRule resources will be created for each such Service, leading to the `ingressgateway` of the original cluster.
  - The label value must be empty. You do not need to label other resources, such as Deployment, Pod, or VirtualService, to publish a service in the federation.

⚠ Federation publishing does not support `ExternalName` services, services without `.spec.ports`, or services with ports missing the `name` field.

Each port name must start with a supported Istio prefix: `http`, `http2`, `https`, `tcp`, `tls`, `grpc`, or `grpc-web`. The module uses the port name to determine the protocol in the generated `ServiceEntry`. If the prefix is not recognized, the port will be handled as TCP.

Example of a public service:

```
apiVersion: v1
kind: Service
metadata:
  name: reviews
  namespace: bookinfo
  labels:
    federation.istio.deckhouse.io/public-service: ""
spec:
  selector:
    app: reviews
  ports:
  - name: http
    port: 9080
    targetPort: 9080
```

To troubleshoot service publishing in the federation, follow these checks:

Check which services are marked as public in the local cluster:

```
d8 k get svc -A -l federation.istio.deckhouse.io/public-service=
```

Check metadata exchange status with remote clusters:

```
d8 k get istiofederation
d8 k get istiofederation <name> -o jsonpath='{.status.conditions}'
```

Check that the remote cluster provided its public services list:

```
d8 k get istiofederation <name> -o
jsonpath='{.status.metadataCache.private.publicServices}'
```

Check that local routing resources were created from the received metadata:

```
d8 k -n d8-istio get serviceentry,destinationrule
```

In the IstioFederation `status.conditions`, the `PublicMetadataExchangeReady`, `PrivateMetadataExchangeReady`, and `DataplaneConnectionReady` conditions should become `True`. If metadata exchange does not work, check the `D8IstioFederationMetadataEndpointDoesntWork` alert and the availability of the remote cluster `spec.metadataEndpoint`.

Example of configuring a federation of two clusters

To set up a federation with Istio, use the IstioFederation custom resource.

Cluster A:

```
apiVersion: deckhouse.io/v1alpha1
kind: IstioFederation
metadata:
  name: cluster-a
spec:
  metadataEndpoint: https://istio.k8s-a.example.com/metadata/
  trustDomain: cluster-a.local
```

Cluster B:

```
apiVersion: deckhouse.io/v1alpha1
kind: IstioFederation
metadata:
  name: cluster-b
spec:
  metadataEndpoint: https://istio.k8s-b.example.com/metadata/
  trustDomain: cluster-b.local
```

Network policies

Network policies restrict how pods communicate with each other, with external systems, and with cluster nodes. In Deckhouse Platform (DP), the implementation depends on the enabled CNI module.

Network policy implementation in DP

The available policy formats and the engine that processes them depend on the enabled CNI module:

- With the `cni-cilium` module, the implementation is built into Cilium and supports three policy formats:
  - the standard NetworkPolicy at L3 and L4;
  - CiliumNetworkPolicy — a namespaced resource with L3–L7 rules;
  - CiliumClusterwideNetworkPolicy — a cluster-scoped resource that also supports `nodeSelector` for protecting nodes (host firewall).
- With the `cni-flannel` module or another CNI without policy support, the `network-policy-engine` module handles enforcement on top of kube-router. Only the standard NetworkPolicy at L3 and L4 is supported. Policies are translated into `iptables` and `ipset` rules on every node.

> ⚠ Do not enable `cni-cilium` and `network-policy-engine` at the same time: Cilium already enforces network policies.

What is available in each engine

When choosing a policy format, consider what each engine supports:

- standard NetworkPolicy (L3/L4, namespaced) — supported by both engines;
- CiliumNetworkPolicy (L3–L7, FQDN, deny rules, namespaced) — only with `cni-cilium`;
- CiliumClusterwideNetworkPolicy (L3–L7, FQDN, deny rules, cluster-scoped) — only with `cni-`

`cilium`;
- node-level host firewall via CiliumClusterwideNetworkPolicy with `nodeSelector` — only with `cni-cilium`;
- policy audit mode (`policyAuditMode`) — only with `cni-cilium`.

Network infrastructure requirements

If the underlying infrastructure restricts network communication between servers, make sure the following conditions are met:

- Pod traffic tunneling is enabled: `tunnelMode` for CNI Cilium, `podNetworkMode` for CNI Flannel. Additionally, allow inter-node communication over the VXLAN port from the platform component network interaction list.
- Traffic between pod subnets (`podSubnetCIDR`) encapsulated in VXLAN is allowed, if the network inspects traffic inside the tunnel.
- Communication with external systems the cluster integrates with (LDAP, SMTP, external APIs) is allowed.
- Local communication inside each cluster node is allowed.
- Inter-node communication is allowed on the ports listed in the platform component network interaction list. Most ports are in the 4200–4299 range; new platform components are assigned ports from the same range when possible.

Sections

- Kubernetes NetworkPolicy — isolation model, selectors, default policies, API limitations.
- CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy — Cilium extensions, entities, L7 rules, FQDN rules, audit mode.

Kubernetes NetworkPolicy

The standard NetworkPolicy resource (`networking.k8s.io/v1`) defines L3/L4 traffic rules for pods (TCP, UDP, optionally SCTP). In DP, these policies are enforced by the `cni-cilium` module or the `network-policy-engine` module, depending on the CNI in use; the mapping between CNI and engine is described in Network policy implementation in DP.

Isolation model

NetworkPolicy describes what is allowed — there are no deny rules. By default, a pod is not isolated: all ingress and egress traffic is allowed. A pod becomes isolated as soon as any policy selects it via `spec.podSelector` and lists the matching direction in `spec.policyTypes`:

- A pod is isolated for ingress when a policy with `policyTypes: [Ingress]` selects it. Only the traffic listed in `ingress` is then allowed.
- A pod is isolated for egress when a policy with `policyTypes: [Egress]` selects it. Only the traffic listed in `egress` is then allowed.
- Reply traffic for allowed connections is always implicit.

Policies are additive: when several policies select the same pod, the resulting allow set is the union of all rules. Order of evaluation does not matter.

For a connection between a source pod and a destination pod, both the source's `egress` and the destination's `ingress` must allow it. If either side denies, the connection does not happen.

Selectors and fields

A policy uses the following selectors and fields:

- `spec.podSelector` — required. Defines which pods the policy applies to. The policy affects pods in the same namespace where it is created. An empty selector `{}` matches every pod in the namespace.
- `spec.policyTypes` — a list with `Ingress`, `Egress`, or both. If omitted, `Ingress` is always set; `Egress` is set only when the policy has egress rules.
- `ingress[].from` and `egress[].to` — sources and destinations (see below).
- `ingress[].ports` and `egress[].ports` — protocols and ports; a single port or a range via `endPort`.

Inside `from` and `to`, four selector types are available:

- `podSelector` — pods in the same namespace as the policy;
- `namespaceSelector` — all pods in the matching namespaces;
- `podSelector` and `namespaceSelector` in the same item — pods with the given labels in namespaces with the given labels;
- `ipBlock` — a CIDR range with an optional `except` list. Use it for cluster-external addresses, since pod IPs are ephemeral.

A complete example that uses every main construct:

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
  name: db-access
  namespace: my-app
spec:
  podSelector:
    matchLabels:
      app: db
  policyTypes:
    - Ingress
    - Egress
  ingress:
    - from:
        - ipBlock:
            cidr: 172.17.0.0/16
            except:
              - 172.17.1.0/24
        - namespaceSelector:
            matchLabels:
              kubernetes.io/metadata.name: frontend
        - podSelector:
            matchLabels:
              role: backend
      ports:
        - protocol: TCP
          port: 6379
  egress:
    - to:
        - ipBlock:
            cidr: 10.0.0.0/24
      ports:
        - protocol: TCP
          port: 5978
```

This policy applies to pods labeled `app: db` in namespace `my-app`. Ingress on TCP/6379 is allowed from three sources: the CIDR `172.17.0.0/16` excluding `172.17.1.0/24`, any pod in namespace `frontend`, and pods labeled `role: backend` in the local namespace. Egress is allowed only on TCP/5978 to subnet `10.0.0.0/24`.

AND vs OR in selectors

A single array item with two selectors means AND (intersection):

```
ingress:
  - from:
      - namespaceSelector:
          matchLabels:
            user: alice
        podSelector:
          matchLabels:
            role: client
```

This allows traffic from pods labeled `role=client` in namespaces labeled `user=alice`.

Two separate array items mean OR (union):

```
ingress:
  - from:
      - namespaceSelector:
          matchLabels:
            user: alice
      - podSelector:
          matchLabels:
            role: client
```

This allows traffic from pods labeled `role=client` in the local namespace, or from any pod in namespaces labeled `user=alice`.

Selecting a namespace by name

The spec has no field that points to a namespace by name. Use the `kubernetes.io/metadata.name` label instead. Kubernetes automatically applies this label to every namespace, and its value equals the namespace name.

```
ingress:
  - from:
      - namespaceSelector:
          matchLabels:
            kubernetes.io/metadata.name: frontend
```

Port ranges

The `endPort` field defines a port range:

```
egress:
  - to:
      - ipBlock:
          cidr: 10.0.0.0/24
    ports:
      - protocol: TCP
        port: 32000
        endPort: 32768
```

Constraints: `endPort` must be greater than or equal to `port`; `endPort` requires `port`; both values must be numeric.

Default policies for a namespace

Apply baseline policies to set the default behavior of a namespace:

- deny all ingress to the namespace’s pods:

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
  name: default-deny-ingress
spec:
  podSelector: {}
  policyTypes:
    - Ingress
```

- deny all egress from the namespace's pods:

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
  name: default-deny-egress
spec:
  podSelector: {}
  policyTypes:
    - Egress
```

- deny both directions: list both values in `policyTypes` without rules.
- allow all ingress or egress: add an empty rule `ingress: [{}]` or `egress: [{}]`.

⚠ A default deny-egress policy blocks DNS too. If the pods use DNS, add a separate policy that allows egress to the kube-dns service in `kube-system` (UDP/53 and TCP/53).

Edge cases

`hostNetwork` pods

NetworkPolicy behavior for pods with `hostNetwork: true` is not defined by the API. Most engines, including Cilium and kube-router, treat such traffic as node traffic; `podSelector` and `namespaceSelector` do not match these pods. To filter such traffic, use `ipBlock` with the node IP or the host firewall on nodes.

Pod lifecycle

After a NetworkPolicy is created, the engine applies it asynchronously. A newly started pod selected by the policy may run for a short time without isolation rules or with partial rules. For critical dependencies, use init containers that wait for the required endpoints.

Existing connections

Behavior on policy changes during an open connection is implementation-defined: some engines tear down the connection, others let it finish. Avoid changing policies, pod labels, or namespace labels while important traffic is in flight.

L4 only

NetworkPolicy is defined for L4 (TCP, UDP, optionally SCTP). Behavior for other protocols (ICMP, ARP) depends on the engine and may differ.

Enforcement without Cilium: the `network-policy-engine` module

In clusters without Cilium, the `network-policy-engine` module enforces policies on top of kube-router. It deploys a DaemonSet in the `d8-system` namespace; kube-router runs as a Network Policy Controller and translates policies into `iptables` and `ipset` rules on every node:

- each policy becomes its own `KUBE-NWPLCY-*` chain;
- each isolated pod gets a `KUBE-POD-SPECIFIC-FW-*` chain;
- source and destination pod IPs are stored in ipsets, which keeps large rule sets compact and updates fast.

Only the standard Kubernetes formats are supported: `networking.k8s.io/NetworkPolicy API`, V1/GA, and beta semantics. Cilium extensions (CiliumNetworkPolicy, CiliumClusterwideNetworkPolicy,

L7 rules, FQDN, deny rules) are not supported by this engine.

Ready-to-use standard policy examples that work with both `network-policy-engine` and `cni-cilium` are available on the Common policy examples page.

API limitations

The Kubernetes NetworkPolicy API does not support the following scenarios (these are API-level limitations, not engine-level):

- L7 rules (HTTP, gRPC, Kafka, DNS-name filtering);
- deny rules — the model is “default deny + explicit allow”;
- selecting services by name;
- forcing all traffic through a shared gateway;
- targeting specific nodes by their Kubernetes identity (only via `ipBlock` with node IPs);
- logging — which connections were allowed or denied;
- blocking loopback or traffic from the pod’s own node.

Some of these tasks are addressed by CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy, available in clusters with `cni-cilium`.

CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy

In clusters with the `cni-cilium` module enabled, two Cilium-specific formats are available in addition to the standard NetworkPolicy:

- CiliumNetworkPolicy — a namespaced resource with L3–L7 rules;
- CiliumClusterwideNetworkPolicy — a cluster-scoped resource with the same rule language and `nodeSelector` support.

Cilium can enforce all three formats at the same time.

> ⚠ When NetworkPolicy, CiliumNetworkPolicy, and CiliumClusterwideNetworkPolicy are all in use, the resulting allow set is harder to reason about. Roll out new policies in audit mode and verify the behavior in Hubble.

How rules are evaluated

When combining rules from NetworkPolicy, CiliumNetworkPolicy, and CiliumClusterwideNetworkPolicy, Cilium follows these principles:

- deny rules take priority over allow rules;
- allow rules from NetworkPolicy, CiliumNetworkPolicy, and CiliumClusterwideNetworkPolicy are merged;
- if at least one policy applies to an endpoint (pod), the default-deny model takes effect for the corresponding traffic direction;
- L7 rules are evaluated only after L3/L4 checks pass.

What CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy add

Compared to the standard NetworkPolicy:

- L7 rules — HTTP, gRPC, Kafka, and DNS protocols;
- FQDN rules in egress — filtering by DNS names;
- deny rules — explicit denial of traffic;
- entities — sources and destinations of traffic such as `kube-apiserver`, `host`, `remote-node`, `world`;
- references to Kubernetes services by name or labels (`toServices`) — egress rules without specifying a CIDR;
- ICMP and ICMPv6 filtering by packet type;
- TLS filtering by Server Name Indication (SNI);
- `nodeSelector` (CiliumClusterwideNetworkPolicy only) — applies a rule to nodes themselves and is the basis for the host firewall on nodes;
- audit mode via `policyAuditMode` — log policy verdicts without enforcing them.

Resource structure

CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy share the same `spec` shape. A minimal example:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: example
  namespace: default
spec:
  endpointSelector:
    matchLabels:
      app: db
  ingress:
    - fromEndpoints:
        - matchLabels:
            app: frontend
      toPorts:
        - ports:
            - port: "5432"
              protocol: TCP
```

Key fields:

- `endpointSelector` — selects pods the policy applies to. Counterpart of `podSelector` in the standard NetworkPolicy.
- `nodeSelector` — selects nodes (CiliumClusterwideNetworkPolicy only). A single policy must use either `endpointSelector` or `nodeSelector`, not both.
- `ingress` and `egress` — rule arrays. Each rule has a peer field (`fromEndpoints`, `fromEntities`, `fromCIDR`, `fromCIDRSet`, `toEndpoints`, `toEntities`, `toCIDR`, `toCIDRSet`, `toFQDNs`, `toServices`) and an optional `toPorts` filter for protocols and ports.
- `ingressDeny` and `egressDeny` — deny rules. They are evaluated before allow rules.

Two special labels are useful in selectors. Cilium attaches them to every pod endpoint automatically:

- `io.kubernetes.pod.namespace` — the namespace where the pod runs. Use it in `fromEndpoints` and `toEndpoints` to reference pods in a specific namespace.
- `k8s-app`, `app`, and other regular pod labels — available without a prefix.

Egress to a Kubernetes service

The `toServices` field describes egress to a Kubernetes service rather than to a pod set. Match the service by name and namespace (`k8sService`) or by labels (`k8sServiceSelector`):

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-egress-to-redis
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: client
  egress:
    - toServices:
        - k8sService:
            serviceName: redis
            namespace: data
```

The policy automatically tracks changes to the service backends and applies the corresponding rules to them.

Entities

Entities are sources and destinations of traffic that make it easier to describe traffic to and from cluster components and infrastructure:

- `host` — the pod's own node, including the host's own traffic;
- `remote-node` — other cluster nodes;
- `kube-apiserver` — the Kubernetes API server (used by host firewall);
- `cluster` — every pod and node in the cluster;
- `world` — anything outside the cluster;
- `health` — Cilium health endpoints;
- `init` — containers that have not yet received an identity;
- `unmanaged` — pods not managed by Cilium;
- `all` — any entity.

An ingress rule that allows the API server to reach pods labeled `app: webhook`:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-apiserver-to-webhook
  namespace: default
spec:
  endpointSelector:
    matchLabels:
      app: webhook
  ingress:
    - fromEntities:
        - kube-apiserver
      toPorts:
        - ports:
            - port: "9443"
              protocol: TCP
```

L4 rules: ICMP and SNI

In addition to ports and protocols, `toPorts` supports more L4 filters.

ICMP and ICMPv6

The `icmps` field allows or denies ICMP messages by packet type:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-icmp-echo
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: probe
  ingress:
    - fromEndpoints:
        - matchLabels:
            app: monitoring
      icmps:
        - fields:
            - type: EchoRequest
              family: IPv4
```

Without an explicit `icmps` rule, ICMP traffic is blocked together with TCP and UDP once L4 filtering is active.

TLS Server Name Indication (SNI)

Egress can be restricted by SNI — the name a client sends in the TLS ClientHello. This filters access to external HTTPS services:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-egress-tls-sni
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: client
  egress:
    - toFQDNs:
        - matchPattern: "*.example.com"
      toPorts:
        - ports:
            - port: "443"
              protocol: TCP
          serverNames:
            - "api.example.com"
            - "static.example.com"
```

When `serverNames` is set, only TLS connections with the listed names are allowed; connections with any other SNI are blocked at the TLS handshake.

L7 rules

CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy can describe allowed application-level operations. L7 rules go inside `toPorts[].rules`:

> ⚠ L7 inspection is performed by the Envoy proxy embedded in the Cilium agent on each node. It adds per-connection latency and node CPU load. Avoid L7 rules on hot paths unless they are required — basic L3/L4 rules are sufficient for the common case.

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-readonly-api
  namespace: default
spec:
  endpointSelector:
    matchLabels:
      app: api
  ingress:
    - fromEndpoints:
        - matchLabels:
            app: client
      toPorts:
        - ports:
            - port: "8080"
              protocol: TCP
          rules:
            http:
              - method: GET
                path: "/api/v1/.*"
```

Clients labeled `app: client` may only call `GET /api/v1/...` on pods labeled `app: api`, port 8080.

Supported protocols: HTTP, gRPC, Kafka, DNS. Details and limitations are described in Layer 7 Examples in the Cilium docs.

Kafka

For Kafka, L7 rules allow specific operations (`apiKey`) and topics:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-kafka-produce
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: kafka
  ingress:
    - fromEndpoints:
        - matchLabels:
            app: producer
      toPorts:
        - ports:
            - port: "9092"
              protocol: TCP
          rules:
            kafka:
              - role: produce
                topic: orders
```

Pods labeled `app: producer` may only publish (`role: produce`) to the `orders` topic. Any other operations, including `consume` and `metadata`, are denied at the Kafka protocol level.

DNS Policy and IP Discovery

When `toFQDNs` is in use, Cilium intercepts DNS responses allowed by `rules.dns` and updates an internal cache that maps DNS names to IP addresses. This cache is what `toFQDNs` rules check when allowing traffic. Therefore:

⚠ When `toFQDNs` is combined with DNS inspection (`rules.dns`), the application's DNS request goes through the Cilium proxy on the node — effectively doubling the resolve path. On high DNS traffic volumes this adds noticeable latency and `cilium-agent` load. Narrow `matchPattern` in `rules.dns` to the minimum required.

- DNS egress must be in the same policy as the FQDN rule, or in any other policy selecting the same pods;
- if a pod is not allowed to make DNS requests, its FQDN rules will not work;
- the TTL and lifetime of cache entries are determined by the Cilium agent based on DNS responses.

FQDN rules

Egress traffic can be restricted by DNS names via `toFQDNs`. For `toFQDNs` to work, DNS requests must be allowed and DNS inspection must be enabled through `rules.dns`. This can be done in the same policy or in any other policy that selects the same pods:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-egress-to-example
  namespace: default
spec:
  endpointSelector:
    matchLabels:
      app: client
  egress:
    - toEntities:
        - cluster
      toPorts:
        - ports:
            - port: "53"
              protocol: UDP
            - port: "53"
              protocol: TCP
          rules:
            dns:
              - matchPattern: "*"
    - toFQDNs:
        - matchName: "api.example.com"
        - matchPattern: "*.cdn.example.com"
      toPorts:
        - ports:
            - port: "443"
              protocol: TCP
```

i The DNS egress rule uses `toEntities: cluster` rather than a label selector targeting `kube-dns` pods. DP deploys a `node-local-dns` DaemonSet alongside the main DNS service, so the actual DNS path from a pod may go through a `node-local-dns` instance. Using `toEntities: cluster` matches any cluster-internal DNS endpoint reliably.

Deny rules

Unlike the standard NetworkPolicy, CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy can explicitly deny traffic without removing broader allow rules:

```
apiVersion: cilium.io/v2
kind: CiliumClusterwideNetworkPolicy
metadata:
  name: deny-egress-to-metadata
spec:
  endpointSelector: {}
  egressDeny:
    - toCIDR:
        - 169.254.169.254/32
```

Deny rules are evaluated before allow rules and override permissions from any other policy.

Default policies via CiliumNetworkPolicy

As with the standard NetworkPolicy, a policy with empty rule lists places the selected endpoints into default-deny mode.

To put a namespace into default-deny mode, create a CiliumNetworkPolicy with empty rule lists:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: default-deny
  namespace: secure
spec:
  endpointSelector: {}
  ingress: []
  egress: []
```

DNS is also subject to network policies, so egress to the cluster DNS service over UDP/53 and TCP/53 must be allowed explicitly:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-dns
  namespace: secure
spec:
  endpointSelector: {}
  egress:
    - toEntities:
        - cluster
      toPorts:
        - ports:
            - port: "53"
              protocol: UDP
            - port: "53"
              protocol: TCP
```

i The DNS egress rule uses `toEntities: cluster` rather than a label selector targeting `kube-dns` pods. DP deploys a `node-local-dns` DaemonSet alongside the main DNS service, so the actual DNS path from a pod may go through a `node-local-dns` instance. Using `toEntities: cluster` matches any cluster-internal DNS endpoint reliably.

Audit mode (`policyAuditMode`)

The module parameter `policyAuditMode` puts Cilium into a mode where policies do not block traffic; they only log verdicts. This makes it safe to roll out large policy sets and verify them in Hubble UI before enforcement.

⚠ In audit mode, no network policy blocks traffic. Do not keep audit mode on permanently — turn it off after the rollout is done.

Recommended order:

1. Set `policyAuditMode: true` in the `cni-cilium` module configuration.
2. Apply the policy set. Apply node policies separately, following the procedure in Host firewall on nodes.
3. Inspect verdicts in Hubble UI and via `hubble observe --type policy-verdict`. Look for `verdict=AUDITED` entries — these connections would be blocked outside audit mode.
4. Adjust policies until the log only contains expected `verdict=ALLOWED` and `verdict=AUDITED` entries.
5. Turn audit mode off (`policyAuditMode: false`).

Once audit mode is off, policies start blocking traffic that is not allowed by any rule.

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Host firewall on nodes

A host firewall is a Cilium mode where network policies apply to cluster nodes themselves rather than to pods. In DP, you configure it through CiliumClusterwideNetworkPolicy with the `nodeSelector` field. Available only in clusters with the `cni-cilium` module.

✖ A bug in host policies can break SSH access, control plane operation, kubelet, or etcd. Always roll out host firewall through `policyAuditMode` and verify verdicts in Hubble before enforcing.

How a host firewall differs from regular policies

A CiliumClusterwideNetworkPolicy with `nodeSelector` applies to a special host endpoint with the label `reserved:host` and filters traffic entering and leaving the node, including `hostNetwork` pods. Pod policies that use `endpointSelector` do not apply to the host endpoint — they target a different entity.

Host policies do not replace infrastructure-level protection (physical firewalls, cloud security groups). They are an additional filter layer inside the cluster.

Safe rollout

Roll out a host firewall in stages, using audit mode:

1. Set `policyAuditMode: true` in the `cni-cilium` module configuration. In audit mode, policies do not block traffic; they only log verdicts.
2. Apply the host policy set. At a minimum: a control plane policy (an example is provided below) and worker-node policies that allow SSH and required service ports.
3. Inspect verdicts in Hubble UI and via `hubble observe --type policy-verdict`. Expected traffic must be `verdict=ALLOWED`; anything in `verdict=AUDITED` would be blocked once audit mode is off.
4. Tune the policies until no unexpected `AUDITED` entries remain. Pay close attention to kubelet, etcd, kube-apiserver, ingress controllers, monitoring, and DNS.
5. Turn audit mode off (`policyAuditMode: false`).

If something breaks after enforcement, the fastest recovery path is to re-enable audit mode or delete

the CiliumClusterwideNetworkPolicy. Detailed recovery steps are in Cilium Emergency Recovery.

Mandatory rules

The host firewall policy set you maintain must explicitly configure the following permissions; otherwise, after audit mode is turned off, parts of the cluster will stop working:

- access from kube-apiserver to kubelet and webhook endpoints (ports 10250, 10255, and component webhook ports);
- inter-node access on etcd ports (2379, 2380), only between control plane nodes;
- access from worker nodes to the API server;
- BGP and service ports if MetalLB or a third-party load balancer is in use;
- platform component ports in the 4200–4299 range, listed in the platform component network interaction list;
- SSH from trusted administrative addresses;
- ICMP echo (optional, useful for diagnostics);
- DNS egress to kube-dns or an external resolver;
- access from monitoring to node-exporter and cilium-agent.

Tested policies for the most common cases are shown below: control plane connectivity, administrative SSH, and worker nodes. Use them as a starting set.

Use entities to describe peers:

- `host` — the node itself;
- `remote-node` — other cluster nodes;
- `kube-apiserver` — the Kubernetes API server;
- `cluster` — every pod and node in the cluster;
- `world` — anything external (combine with `toCIDR`/`fromCIDR` for narrowing).

Example: API server access for the control plane

A CiliumClusterwideNetworkPolicy that binds control plane nodes to the `kube-apiserver` entity and allows etcd traffic between control plane nodes. Without the `kube-apiserver` rule, control plane operations may stutter for up to a minute when `cilium-agent` pods restart, due to a Cilium Conntrack table reset:

```
apiVersion: cilium.io/v2
kind: CiliumClusterwideNetworkPolicy
metadata:
  name: allow-control-plane-connectivity
spec:
  nodeSelector:
    matchLabels:
      node-role.kubernetes.io/control-plane: ""
  ingress:
    - fromEntities:
        - kube-apiserver
    - fromEntities:
        - remote-node
      toPorts:
        - ports:
            - port: "2379"
              protocol: TCP
            - port: "2380"
              protocol: TCP
```

The `fromEntities: kube-apiserver` rule allows all traffic from the API server without port restrictions — this covers kubelet (TCP/10250, TCP/10255) and component webhook endpoints. The `fromEntities: remote-node` rule is scoped to etcd ports (TCP/2379, TCP/2380) and allows replication traffic between control plane nodes.

Example: SSH from administrative networks

Allows inbound SSH (TCP/22) on every node from the listed subnets only:

```
apiVersion: cilium.io/v2
kind: CiliumClusterwideNetworkPolicy
metadata:
  name: allow-ssh-admin
spec:
  nodeSelector: {}
  ingress:
    - fromCIDR:
        - 192.0.2.0/24
        - 198.51.100.10/32
      toPorts:
        - ports:
            - port: "22"
              protocol: TCP
```

Replace the subnets with the ones used for administrative access. Do not leave `fromEntities: [world]` without a narrowing CIDR — that is the same as an open SSH.

Example: baseline for worker nodes

Allows worker nodes to exchange traffic inside the cluster, reach the API server, and resolve DNS:

```
apiVersion: cilium.io/v2
kind: CiliumClusterwideNetworkPolicy
metadata:
  name: allow-worker-baseline
spec:
  nodeSelector:
    matchExpressions:
      - key: node-role.kubernetes.io/control-plane
        operator: DoesNotExist
  ingress:
    - fromEntities:
        - cluster
        - remote-node
  egress:
    - toEntities:
        - kube-apiserver
        - cluster
        - remote-node
```

This is a starting point. Extend the policy with rules for monitoring, ingress controllers, load balancers, and SSH that match your setup.

- Platform component network interaction list
- Diagnostics and observability
- Module `cni-cilium` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Common policy examples

This page collects common scenarios for network policies. Standard NetworkPolicy examples work in

any cluster that supports network policies; CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy examples require the `cni-cilium` module.

The resource shape itself is documented in Kubernetes NetworkPolicy and CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy.

Deny all external ingress to a namespace, allow internal traffic

A baseline policy for a namespace where pods talk to each other but are not reachable from outside:

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
  name: deny-external-ingress
  namespace: my-app
spec:
  podSelector: {}
  policyTypes:
    - Ingress
    - Egress
  ingress:
    - from:
        - podSelector: {}
  egress:
    - {}
```

The empty `egress: [{}]` keeps all egress allowed; ingress is allowed only from pods in the same namespace.

Allow ingress from a specific namespace

Allows pods in the namespace labeled `kubernetes.io/metadata.name: frontend` to call pods labeled `app: api`:

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
  name: allow-frontend-to-api
  namespace: my-app
spec:
  podSelector:
    matchLabels:
      app: api
  policyTypes:
    - Ingress
  ingress:
    - from:
        - namespaceSelector:
            matchLabels:
              kubernetes.io/metadata.name: frontend
      ports:
        - protocol: TCP
          port: 8080
```

Kubernetes sets the `kubernetes.io/metadata.name` label on every namespace automatically.

Allow egress to DNS and one CIDR only

Default-deny egress plus explicit DNS and one external service:

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
  name: restrict-egress
  namespace: my-app
spec:
  podSelector:
    matchLabels:
      app: client
  policyTypes:
    - Egress
  egress:
    - to:
        - namespaceSelector:
            matchLabels:
              kubernetes.io/metadata.name: kube-system
          podSelector:
            matchLabels:
              k8s-app: kube-dns
      ports:
        - protocol: UDP
          port: 53
        - protocol: TCP
          port: 53
    - to:
        - ipBlock:
            cidr: 10.0.0.0/24
      ports:
        - protocol: TCP
          port: 5432
```

Allow specific pods to reach the API server

Through the `kube-apiserver` entity, Cilium tracks the API server IPs automatically — the rule does not need to be updated when addresses change:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: allow-controller-to-apiserver
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: controller
  egress:
    - toEntities:
        - kube-apiserver
      toPorts:
        - ports:
            - port: "443"
              protocol: TCP
```

Allow only GET requests to an API at L7

Clients labeled `app: client` may only call `GET /api/v1/...` on pods labeled `app: api`:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: readonly-api
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: api
  ingress:
    - fromEndpoints:
        - matchLabels:
            app: client
      toPorts:
        - ports:
            - port: "8080"
              protocol: TCP
          rules:
            http:
              - method: GET
                path: "/api/v1/.*"
```

Allow egress to specific DNS names (FQDN)

For FQDN rules, Cilium must observe DNS queries, so the same policy must also allow egress to the cluster DNS with DNS inspection:

```
apiVersion: cilium.io/v2
kind: CiliumNetworkPolicy
metadata:
  name: egress-to-fqdns
  namespace: my-app
spec:
  endpointSelector:
    matchLabels:
      app: client
  egress:
    - toEntities:
        - cluster
      toPorts:
        - ports:
            - port: "53"
              protocol: UDP
            - port: "53"
              protocol: TCP
          rules:
            dns:
              - matchPattern: "*"
    - toFQDNs:
        - matchName: "api.example.com"
        - matchPattern: "*.cdn.example.com"
      toPorts:
        - ports:
            - port: "443"
              protocol: TCP
```

i The DNS egress rule uses `toEntities: cluster` rather than a label selector targeting `kube-dns` pods. DP deploys a `node-local-dns` DaemonSet alongside the main DNS service, so the actual DNS path from a pod may go through a `node-local-dns` instance. Using `toEntities: cluster` matches any cluster-internal DNS endpoint reliably.

Deny access to the cloud metadata service

A cluster-scope deny rule blocks the cloud metadata service for every pod, even when other policies allow this egress:

```
apiVersion: cilium.io/v2
kind: CiliumClusterwideNetworkPolicy
metadata:
  name: deny-egress-to-metadata
spec:
  endpointSelector: {}
  egressDeny:
    - toCIDR:
        - 169.254.169.254/32
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Diagnostics and observability

This page covers commands and techniques for inspecting applied network policies and investigating connectivity issues. Some tools require the `cni-cilium` module — this is noted explicitly.

Inspecting an applied policy

Resource summary:

```
d8 k describe networkpolicy <name> -n <namespace>
d8 k describe ciliumnetworkpolicy <name> -n <namespace>
d8 k describe ciliumclusterwidenetworkpolicy <name>
```

The output shows the selected pods or nodes, the resulting ingress and egress rules, and any validation errors.

List policies that affect a namespace:

```
d8 k get networkpolicy,ciliumnetworkpolicy -n <namespace>
d8 k get ciliumclusterwidenetworkpolicy
```

See which pods are isolated and which policies apply to them (Cilium clusters only):

```
d8 k -n d8-cni-cilium exec ds/agent -- cilium-dbg endpoint list
d8 k -n d8-cni-cilium exec ds/agent -- cilium-dbg endpoint get <endpoint-id>
```

In `cilium-dbg endpoint list`, each pod endpoint shows `POLICY (ingress)` and `POLICY (egress)` status: `Enabled`, `Disabled`, or `Disabled (Audit)` when `policyAuditMode` is on. Example output:

```
ENDPOINT   POLICY (ingress)   POLICY (egress)   IDENTITY   LABELS (source:key[=value])
1847       Enabled            Enabled            15234
k8s:app=client,k8s:io.kubernetes.pod.namespace=netpol-test
2156       Enabled            Disabled           28765
k8s:app=server,k8s:io.kubernetes.pod.namespace=netpol-test
3          Disabled           Disabled           1          reserved:host
```

`POLICY (ingress): Enabled` means at least one ingress policy applies to the pod and default-deny is active for inbound traffic. `POLICY (egress): Disabled` means there are no egress policies and outbound traffic is unrestricted.

Observability via Hubble

Hubble shows policy verdicts in real time and is the primary diagnostic tool in Cilium clusters.

In Hubble UI, connections between pods and services are tagged as `forwarded`, `dropped`, or `audit`. Drop events show which policy blocked the traffic and which rule field matched.

`hubble observe` can filter events by type. In DP, the `hubble` client ships with the agent, so it is convenient to run commands via `d8 k exec` against a cilium-agent pod:

```
d8 k -n d8-cni-cilium exec -it ds/agent -- hubble observe --type policy-verdict --verdict DROPPED
d8 k -n d8-cni-cilium exec -it ds/agent -- hubble observe --type policy-verdict --verdict AUDITED
d8 k -n d8-cni-cilium exec -it ds/agent -- hubble observe --from-pod my-app/client --to-pod my-
app/api
```

> **i** DP does not provide a standalone `d8 hubble` binary. Hubble CLI access is provided by running `exec` into a `cilium-agent` pod, as shown above. The `-it` flag is required for streaming output when `--last` is not specified.

Each agent sees events only for its own node. For cluster-wide event collection, use Hubble UI or export via HubbleMonitoringConfig.

Example output of `hubble observe --type policy-verdict --verdict DROPPED`:

```
Jun 10 12:00:01.234   netpol-test/outsider:52341   ->   netpol-test/server:8080   Policy verdict
INGRESS DENIED
Jun 10 12:00:01.236   netpol-test/outsider:52342   ->   netpol-test/server:8080   Policy verdict
INGRESS DENIED
```

Example output of `hubble observe --type policy-verdict --verdict AUDITED` (with `policyAuditMode` on):

```
Jun 10 12:05:01.101   netpol-test/client:53124   ->   netpol-test/server:8080   Policy verdict   INGRESS
AUDITED
```

The output includes policy and selector identifiers and the specific ingress/egress fields that matched, which makes it easy to find the rule that blocked or allowed the connection.

Continuous flow logs collection

For continuous flow log collection, enable export through the HubbleMonitoringConfig resource. Configuration is described in the cni-cilium examples.

Once export is on, `cilium-agent` writes events to `/var/log/cilium/hubble/flow.log` on every node. For central collection, use the `log-shipper` module with a ClusterLoggingConfig of type `File` that reads this file.

> **⚠** Updating HubbleMonitoringConfig restarts every Cilium agent in the cluster.

Diagnosing FQDN rules

If a `toFQDNs` rule does not allow traffic, inspect the DNS-name to IP cache maintained by `cilium-agent`:

```
d8 k -n d8-cni-cilium exec ds/agent -- cilium-dbg fqdn cache list
```

Example output when DNS requests have been intercepted:

```
Endpoint   Source Namespace   Source Name   FQDN           TTL    ExpirationTime              IPs
1847       netpol-test        client        example.com.   299    2026-06-10T12:05:00.000Z
93.184.216.34
```

The output shows entries with the source, DNS name, resolved IPs, and TTL. If there is no entry for the expected name, the pod either did not make a DNS request, or the DNS request is not allowed by a policy with DNS inspection (`rules.dns`). The cache mechanics are described in DNS Policy and IP Discovery.

Also check policy verdicts for DNS traffic:

```
d8 k -n d8-cni-cilium exec ds/agent -- hubble observe --type policy-verdict --port 53
```

Common mistakes

DNS broken after default-deny egress

A default-deny egress policy also blocks DNS. Add an egress rule to the kube-dns service in the `kube-system` namespace (UDP/53 and TCP/53). For details, refer to Default policies for a namespace.

AND vs OR mixed up

Two selectors in one `from`/`to` array item is AND; two separate items is OR. Refer to AND vs OR in selectors for the correct structure.

Policy does not apply to `hostNetwork` pods

Most engines, including Cilium and kube-router, treat such pods as node traffic. Use the host firewall on nodes to filter such traffic.

FQDN rule does not allow traffic

Cilium must observe DNS to keep the resolved IP set up to date. In any policy with `toFQDNs`, also allow egress to kube-dns and enable DNS inspection via `rules.dns`. For an example, refer to FQDN rules.

Connection drops after a policy change

Behavior for in-flight connections is not defined by the standard — some engines tear them down. Change policies during a maintenance window.

“Policy not applied” checklist

If a policy is created but traffic does not behave as expected, walk through these checks:

1. Which engine is enabled. The standard NetworkPolicy is supported by both engines; CiliumNetworkPolicy, CiliumClusterwideNetworkPolicy, L7, and FQDN require `cni-cilium`. The engine capabilities are listed in What is available in each engine.
2. The selector matches the pods: `d8 k get pods -n <namespace> -l <key>=<value>` should return the expected list.
3. `policyTypes` is correct. With `Ingress` only, egress stays unrestricted; with `Egress` only, ingress stays unrestricted.
4. AND vs OR in selectors. Re-check the array structure — a common cause of overly broad or overly narrow rules.
5. Audit mode. When `policyAuditMode` is on, policies do not block traffic. `cilium-dbg endpoint list` shows this as `Disabled (Audit)`.
6. Eventual consistency. Cilium and kube-router apply policies asynchronously. Wait a few seconds and re-test.
7. Policy status (CiliumNetworkPolicy and CiliumClusterwideNetworkPolicy only). `d8 k get ciliumnetworkpolicy <name> -n <namespace> -o yaml` shows parse and apply errors in `status`.
8. Conflict with a deny rule. Cilium deny rules override any allow rules. Look for policies with `ingressDeny` or `egressDeny` selecting the same endpoint.

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Software-defined networking (SDN)

Deckhouse Platform (DP) supports adding additional software-defined networks (SDN) to the cluster. The functions of additional software-defined networking (hereinafter referred to as additional networks) within DP are implemented using the `sdn` module.

Software-defined networking in DP allow declarative management of additional network segments for application workloads (pods, virtual machines). Instead of manually configuring network interfaces on each cluster node, the administrator describes the desired network state through custom Kubernetes resources, and the `sdn` module automatically configures the necessary network equipment.

DP supports the following features for working with software-defined networks:

- Configuration of network interfaces on nodes. Features such as port aggregation, bridging network interfaces, and configuring VLAN interfaces are supported.
- Additional networks for application workloads. Supports adding additional software-defined networks to the cluster: publicly available in each project (cluster) and available within a single namespace (project network).
- IPAM for additional networks. The mechanism allows you to allocate IP addresses (IPv4 addresses are supported) from pools and assign them to additional network interfaces of pods connected to cluster networks and project networks.
- Underlay networks for hardware device passthrough. This allows DPDK applications and other high-performance workloads to directly access physical network interfaces (PF/VF), bypassing the kernel network stack.
- System networks (service networks at nodes). These are designed for service traffic at the node level and are not used as additional pod networks. They are created on top of the existing underlay networks.

Additional resources

- Module `sdn` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring SDN in a cluster

To use SDN in a DP cluster, you need to prepare the infrastructure for enabling the `sdn` module, as well as perform some preparatory actions after enabling it.

Preparing the infrastructure for enabling the `sdn` module

Before using additional software-defined networks (hereinafter referred to as additional networks) in a cluster, preliminary infrastructure preparation is required:

- **For creating additional networks based on tagged VLANs:**
  - Allocate VLAN ID ranges on the data center switches and configure them on the corresponding switch interfaces.
  - Select physical interfaces on the nodes for subsequent configuration of tagged VLAN interfaces. You can reuse interfaces already used by the DP local network.
- **For creating additional networks based on direct, untagged access to a network interface:**
  - Reserve separate physical interfaces on the nodes and connect them into a single local network at the data center level.

Enabling the `sdn` module

Enable the `sdn` module according to the instructions.

Actions after enabling the sdn module

After enabling the module, NodeNetworkInterface objects will automatically appear in the cluster, reflecting the current state of the nodes.

To check for resources, use the command:

```
d8 k get nodenetworkinterface
NAME                           MANAGEDBY   NODE           TYPE     IFNAME          IFINDEX   STATE
AGE
virtlab-ap-0-nic-1c61b4a68c2a   Deckhouse   virtlab-ap-0   NIC      eth1            3         Up
35d
virtlab-ap-0-nic-fc34970f5d1f   Deckhouse   virtlab-ap-0   NIC      eth0            2         Up
35d
virtlab-ap-1-nic-1c61b4a6a0e7   Deckhouse   virtlab-ap-1   NIC      eth1            3         Up
35d
virtlab-ap-1-nic-fc34970f5c8e   Deckhouse   virtlab-ap-1   NIC      eth0            2         Up
35d
virtlab-ap-2-nic-1c61b4a6800c   Deckhouse   virtlab-ap-2   NIC      eth1            3         Up
35d
virtlab-ap-2-nic-fc34970e7ddb   Deckhouse   virtlab-ap-2   NIC      eth0            2         Up
35d
```

i When discovering node interfaces, the controller affixes the following labels, which are service labels (example):

```
labels:
  network.deckhouse.io/interface-mac-address: fa163eebea7b
  network.deckhouse.io/interface-type: NIC
  network.deckhouse.io/nic-pci-bus-info: 0000-17-00.0
  network.deckhouse.io/nic-pci-type: PF
  network.deckhouse.io/node-name: worker-01
annotations:
  network.deckhouse.io/heritage: NetworkController
```

In this example, each cluster node has two network interfaces: eth0 (DP local network) and eth1 (dedicated interface for additional networks).

Marking interfaces for organizing additional software-defined networks

To enable the configuration of additional software-defined networks, label the dedicated interfaces that are planned to be used for network creation (in the example above, eth1) with an appropriate label:

```
d8 k label nodenetworkinterface virtlab-ap-0-nic-1c61b4a68c2a nic-group=extra
d8 k label nodenetworkinterface virtlab-ap-1-nic-1c61b4a6a0e7 nic-group=extra
d8 k label nodenetworkinterface virtlab-ap-2-nic-1c61b4a6800c nic-group=extra
```

Combining multiple physical interfaces into a channel aggregation interface (bond interface)

To increase bandwidth or redundancy, it is possible to combine several physical interfaces into a bond interface (channel aggregation interface).

i Only network interfaces located on the same physical or virtual host can be combined.

Example configuring a bond interface:

1. Set custom labels on the interfaces intended for aggregation.

   Example of setting the `nni.example.com/bond-group=bond0` label on interfaces:

   ```
   d8 k label nni node-0-nic-fa163efbde48 nni.example.com/bond-group=bond0
   d8 k label nni node-0-nic-fa40asdxzx78 nni.example.com/bond-group=bond0
   ```

2. Prepare the configuration for creating the interface and apply it.

   Configuration example:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: NodeNetworkInterface
metadata:
  name: nni-worker-01-bond0
spec:
  nodeName: worker-01
  type: Bond
  heritage: Manual
  bond:
    bondName: bond0
    memberNetworkInterfaces:
      - labelSelector:
          matchLabels:
            # This is a service label that needs to be combined with the Bond
interface on a specific node.
            network.deckhouse.io/node-name: worker-01
            # Custom label (was added to the interfaces in the previous step).
            nni.example.com/bond-group: bond0
```

3. Check the status of the created Bond interface:

   Get a list of interfaces:

   ```
   d8 k get nni
   ```

   Example output:

   ```
   NAME                    MANAGEDBY   NODE                                    TYPE
   IFNAME      IFINDEX   STATE   AGE
   nni-worker-01-bond0     Manual      worker-01-b23d3a26-5fb4b-5s9fp      Bond
   bond0       76        Up      7m48s
   ...
   ```

   Check the status of the desired interface:

   ```
   d8 k get nni nni-worker-01-bond0 -o yaml
   ```

   Example of interface status:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: NodeNetworkInterface
metadata:
...
status:
  conditions:
  - lastProbeTime: "2025-09-30T09:00:54Z"
    lastTransitionTime: "2025-09-30T09:00:39Z"
    message: Interface created
    reason: Created
    status: "True"
    type: Exists
  - lastProbeTime: "2025-09-30T09:00:54Z"
    lastTransitionTime: "2025-09-30T09:00:39Z"
    message: Interface is up and ready to send packets
    reason: Up

Configuring and connecting additional virtual networks for use in application pods

The Deckhouse Platform provides the ability to declaratively manage additional networks for application workloads (pods, virtual machines). At the same time:

- Each additional network implies a single L2 data exchange domain.
- Within the Pod’s network namespace, an additional network is represented as a tap interface.
- The following modes are currently available for L2 network implementation:
  - **Tagged VLAN**: Communication between Pods on different Nodes uses VLAN-tagged packets and the infrastructure’s network equipment for switching. This method allows to create up to 4096 additional networks within a single cluster.
  - **Direct access to a Node’s network interface**: Communication between Pods on different Nodes uses the local network interfaces of the Nodes.
- From a network management perspective, there are two types of networks:
  - **Cluster network**: A network available in all projects, under administrator management. Example: a public WAN network or a shared network for cross-project traffic.
  - **Project network**: A network available within a Namespace, under user management.

Custom resources ClusterNetwork, Network, and NetworkClass are used to configure and connect additional networks for application pods.

> **i** If the VLAN type was specified in the Network or ClusterNetwork resources, NodeNetworkInterface will also be created for VLAN and Bridge.

> ⚠ Before creating an additional network, mark the interfaces that will be used by it.

Creating a publicly accessible network (cluster)

A custom resource ClusterNetwork is used to create publicly accessible networks across the entire cluster.

Creating a network based on tagged traffic

To create a network based on tagged traffic, follow these steps:

1. Create and apply the ClusterNetwork resource:

   In the `spec.type` parameter, specify the value `VLAN`. Tagged interfaces will be configured on the corresponding network interfaces of the nodes to ensure connectivity via the VLAN provided by the infrastructure.

   Example of a ClusterNetwork manifest for creating a public network based on tagged traffic:

   ```
   apiVersion: network.deckhouse.io/v1alpha1
   kind: ClusterNetwork
   metadata:
     name: my-cluster-network
   spec:
     type: VLAN
     vlan:
       id: 900
     parentNodeNetworkInterfaces:
       labelSelector:
         matchLabels:
           # Manually applied label on NodeNetworkInterface resources.
           nic-group: extra
   ```

2. Check the status of the created resource with the command:

   ```
   d8 k get clusternetworks.network.deckhouse.io my-cluster-network -o yaml
   ```

   Example of the status of a ClusterNetwork resource:

   ```
   apiVersion: network.deckhouse.io/v1alpha1
   kind: ClusterNetwork
   metadata:
   ...
   status:
     bridgeName: d8-br-900
     conditions:
     - lastTransitionTime: "2025-09-29T14:39:20Z"
       message: All node interface attachments are ready
       reason: AllNodeInterfaceAttachmentsAreReady
       status: "True"
       type: AllNodeAttachementsAreReady
     - lastTransitionTime: "2025-09-29T14:39:20Z"
       message: Network is operational
       reason: NetworkReady
       status: "True"
       type: Ready
     nodeAttachementsCount: 1
     observedGeneration: 1
     readyNodeAttachementsCount: 1
   ```

3. Check the connection of the additional network to the interfaces on the nodes .

Creating a network based on direct interface access

To create a network based on direct interface access, use the ClusterNetwork resource. In the `spec.type` parameter, specify the value `Access`. The corresponding network adapters on the nodes will be used directly to provide connectivity.

Example manifest for a network based on direct interface access:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterNetwork
metadata:
  name: my-cluster-network
spec:
  type: Access
  parentNodeNetworkInterfaces:
    labelSelector:
      matchLabels:
        # Manually applied label on NodeNetworkInterface resources.
        nic-group: extra
```

After creating the network, check the connection of the additional network to the interfaces on the nodes.

Creating a project network (user network)

In order for users to be able to create their own dedicated networks based on tagged traffic, it is necessary to first describe the range of tags available to them and define the network interfaces on which they can be configured. To do this, use the custom resource NetworkClass.

Example:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: NetworkClass
metadata:
  name: my-network-class
spec:
  vlan:
    idPool:
    - 600-800
    - 1200
    parentNodeNetworkInterfaces:
      labelSelector:
        matchLabels:
          nic-group: extra
```

Upon user request, the administrator provides them with the name of the created NetworkClass, which is used when creating the project network.

An example of creating a custom network using the NetworkClass resource administrator is described in the section “Creating a project network (user network)”.

Checking the connection of an additional network to interfaces on nodes

After creating ClusterNetwork or Network, the controller will create a NodeNetworkInterfaceAttachment tracking resource to link it to a NodeNetworkInterface.

To obtain a list of NodeNetworkInterfaceAttachment resources and information about a specific resource, use the following commands:

```
d8 k get nnia
d8 k get nnia my-cluster-network-... -o yaml
```

Example NodeNetworkInterfaceAttachment resource:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: NodeNetworkInterfaceAttachment
metadata:
...
  finalizers:
    - network.deckhouse.io/nni-network-interface-attachment
    - network.deckhouse.io/pod-network-interface-attachment
  generation: 1
  name: my-cluster-network-...
...
spec:
  networkRef:
    kind: ClusterNetwork
    name: my-cluster-network
  parentNetworkInterfaceRef:
    name: right-worker-b23d3a26-5fb4b-h2bkv-nic-fa163eebea7b
  type: VLAN
status:
  bridgeNodeNetworkInterfaceName: right-worker-b23d3a26-5fb4b-h2bkv-bridge-900
  conditions:
    - lastTransitionTime: "2025-09-29T14:39:06Z"
      message: Vlan created
      reason: VLANCreated
      status: "True"
      type: Exist
    - lastTransitionTime: "2025-09-29T14:39:06Z"
      message: Bridged successfully
      reason: VLANBridged
      status: "True"
      type: Ready
  nodeName: right-worker-b23d3a26-5fb4b-h2bkv
  vlanNodeNetworkInterfaceName: right-worker-b23d3a26-5fb4b-h2bkv-vlan-900-60f3dc
```

The NodeNetworkInterfaceAttachment status will change to `True` immediately after the corresponding NodeNetworkInterface appears and transitions to the `Up` state.

To check the status of NodeNetworkInterface, use the command:

```
d8 k get nni
```

Example output:

```
NAME                                                MANAGEDBY   NODE
TYPE     IFNAME      IFINDEX   STATE   AGE
...
right-worker-b23d3a26-5fb4b-h2bkv-bridge-900         Deckhouse   right-worker-
b23d3a26-5fb4b-h2bkv   Bridge   d8-br-900   684       Up      14h
right-worker-b23d3a26-5fb4b-h2bkv-nic-fa163eebea7b   Deckhouse   right-worker-
b23d3a26-5fb4b-h2bkv   NIC      ens3        2         Up      19d
right-worker-b23d3a26-5fb4b-h2bkv-vlan-900-60f3dc    Deckhouse   right-worker-
b23d3a26-5fb4b-h2bkv   VLAN     ens3.900    683       Up      14h
...
```

IPAM: IP address pools for additional networks

The IPAM mechanism allows you to automatically allocate and assign **IPv4 addresses** for additional network interfaces of pods connected to cluster networks and project networks.

Principles and features of IPAM in DP

For each required IP address, a object IPAddress (ClusterIPAddress — for cluster networks) is created and used, which references the project network or cluster network. The controller allocates an address

from the pool and stores the result in `status.address`, `status.network`, `status.routes` of the IPAddress (ClusterIPAddress) object. The agent on the node assigns an IP address and routes to the interface inside the pod and sets the `status.conditions[Attached]` and `status.usedByPods` fields of the IPAddress (ClusterIPAddress) object.

Protection against conflicts when reusing IP addresses

To protect against conflicts, a cluster-scoped object IPAddressLease is created, which reserves the IP address. When an IPAddress object is deleted, the corresponding IPAddressLease is marked as `orphaned` (using the `status.orphaningTimestamp` field) and holds the address for the time specified in the `spec.ttl` parameter (to avoid rapid reuse).

Resources and settings for configuring IPAM

The following are used to manage the allocation and assignment of IP addresses:

- Address pools: for cluster networks (resource ClusterIPAddressPool) or project networks (resource IPAddressPool).
- Parameters for enabling IPAM for a specific network: `Network.spec.ipam.ipAddressPoolRef` — for project networks, `ClusterNetwork.spec.ipam.ipAddressPoolRef` — for cluster networks.
- The IPAddress resource is a request (automatic or static) for an address allocation, which is then assigned to the pod interface.

Example of assigning IP addresses to the cluster network

> **i** To allocate an address pool for a cluster network, use the ClusterIPAddressPool resource.

To allocate a pool of addresses and assign them to network interfaces of pods connected to the cluster network, perform the following steps:

1. Create an address pool. To do this, use the ClusterIPAddressPool resource.

   Example:

   ```
   apiVersion: network.deckhouse.io/v1alpha1
   kind: ClusterIPAddressPool
   metadata:
     name: public-net-pool
   spec:
     leaseTTL: 24h
     pools:
       - network: 203.0.113.0/24
         ranges:
           - 203.0.113.10-203.0.113.200
   ```

   > **i** The `spec.pools[].ranges` parameter is optional. If it is not specified, the entire CIDR from `spec.pools[].network` is considered available (except for network/broadcast addresses, see the behavior of `/31` and `/32`).

2. Enable IPAM on the network. To do this, specify the parameters of the lusterIPAddressPool created in the previous step in the `spec.ipam.ipAddressPoolRef` parameter of the ClusterNetwork resource:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterNetwork
metadata:
  name: my-cluster-network
spec:
  type: VLAN
  vlan:
    id: 900
  parentNodeNetworkInterfaces:
    labelSelector:
      matchLabels:
        nic-group: extra
  ipam:
    ipAddressPoolRef:
      kind: ClusterIPAddressPool
      name: public-net-pool
```

After allocating a pool of IP addresses for the cluster network, they can be assigned to the network interfaces of pods connected to this network. For more details, see the section Assigning IP addresses to network interfaces of pods connected to an additional network.

Configuring and connecting underlay networks for hardware device passthrough

This feature is designed for high-performance workloads that require direct access to hardware, such as DPDK applications.

Key features

DP implements the following features for working with underlay networks:

- **Hardware device passthrough**: Physical network interfaces (PF/VF) are directly exposed to pods, bypassing the kernel network stack for maximum performance.
- **SR-IOV configuration**: Automatic configuration of SR-IOV on selected Physical Functions to create Virtual Functions, allowing multiple pods to share the same hardware.
- **DPDK support**: Devices can be bound in different modes suitable for DPDK workloads:
  - **VFIO-PCI**: Explicitly connects a network device to the pod by binding it to the `vfio-pci` driver. The corresponding VFIO device files (e.g., `/dev/vfio/vfio0`) are mounted into the pod for userspace access.
  - **DPDK**: A universal mode that automatically selects the appropriate driver for the network adapter vendor. For Mellanox NICs, the device is bound to the `mlx5_core` driver with both the netdev interface and necessary device files mounted (InfiniBand verbs files, `/dev/net/tun`, and the corresponding sysfs directory). For other vendors, the device is bound via VFIO (same as VFIO-PCI mode).
  - **NetDev**: Only the Linux network interface is passed through to the pod as a standard kernel network device.

Operation modes

The following device allocation modes are supported, which determine how physical interfaces are provided to hosts:

- **Shared mode**: Creates Virtual Functions (VF) from Physical Functions (PF) using SR-IOV, allowing multiple pods to share the same hardware. Each pod receives one or more VFs.
- **Dedicated mode**: Exposes each Physical Function as an exclusive device without SR-IOV. Each pod gets exclusive access to a complete PF, suitable for workloads requiring maximum performance.

Automatic interface grouping

When `autoBonding` is enabled, the controller groups interfaces from multiple matched PFs into a single DRA device. The interfaces are passed through to the pod as separate network interfaces, allowing applications (e.g., DPDK) to handle bonding/aggregation at the application level. Note that this does not create kernel-level bonding interfaces inside the pod.

Procedure for configuring and connecting physical interfaces to application subnets

To create underlay networks for forwarding hardware devices to pods, a custom resource UnderlayNetwork is used. It provides direct connection of physical network interfaces (Physical Functions and Virtual Functions) to pods via Kubernetes Dynamic Resource Allocation (DRA).

Prerequisites for DPDK applications

Before configuring UnderlayNetwork resources, you must prepare the cluster's worker nodes for DPDK applications:

- Configure hugepages.
- Configure Topology Manager.

Configuring hugepages

DPDK applications require hugepages for efficient memory management. Configure hugepages on all worker nodes using NodeGroupConfiguration:

```
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: hugepages-for-dpdk
spec:
  bundles:
    - "*"  # Apply to all OS bundles.
  nodeGroups:
    - "*"  # Apply to all node groups.
  weight: 50  # Before the kubelet is configured and started.
  content: |
    #!/bin/bash
    echo "vm.nr_hugepages = 4096" > /etc/sysctl.d/99-hugepages.conf
    sysctl -p /etc/sysctl.d/99-hugepages.conf
```

This configuration sets `vm.nr_hugepages = 4096` on all nodes, providing 8 GiB of hugepages (4096 pages × 2 MiB per page).

Steps of NodeGroupConfiguration run in the order of `weight` together with the built-in steps, and the kubelet is configured at step 64. The weight is below 64, so hugepages are allocated before the kubelet is configured. The kubelet sees them on its first start, and the per-NUMA memory reservation accounts for them right away.

Configuring Topology Manager

Set the `SingleNumaNode` policy in `topologyManager` of the NodeGroup of worker nodes where DPDK applications will run. The kubelet then gives Guaranteed pods whole physical cores and allocates CPU, memory and devices of a pod from one NUMA node.

Example NodeGroup configuration:

```
apiVersion: deckhouse.io/v1
kind: NodeGroup
metadata:
  name: worker
spec:
  kubelet:
    topologyManager:
      policy: SingleNumaNode
    resourceReservation:
      mode: Auto
  nodeType: Static
```

A DPDK pod gets dedicated CPUs only if it is Guaranteed (requests equal limits) and requests a whole number of CPUs. With SMT enabled, the number of CPUs must be even. The whole pod must fit into one NUMA node.

For details, see How do I give pods dedicated CPUs and NUMA alignment?

Preliminary steps before creating an UnderlayNetwork

Before creating an UnderlayNetwork, ensure that:

1. Physical network interfaces (NICs) are available on the nodes and are discovered as NodeNetworkInterface resources.
2. The interfaces you plan to use are Physical Functions (PF), not Virtual Functions (VF).
3. For Shared mode, the NICs must support SR-IOV.

Checking and configuring network interfaces (NodeNetworkInterface)

First, check which Physical Functions are available on your nodes:

```
d8 k get nni -l network.deckhouse.io/nic-pci-type=PF
```

Example output:

```
NAME                            MANAGEDBY   NODE           TYPE   IFNAME   IFINDEX
STATE   VF/PF   Binding   Driver      Vendor   AGE
worker-01-nic-0000:17:00.0      Deckhouse   worker-01      NIC    ens3f0   3
Up      PF      NetDev    ixgbe       Intel    35d
worker-01-nic-0000:17:00.1      Deckhouse   worker-01      NIC    ens3f1   4
Up      PF      NetDev    ixgbe       Intel    35d
worker-02-nic-0000:17:00.0      Deckhouse   worker-02      NIC    ens3f0   3
Up      PF      NetDev    ixgbe       Intel    35d
worker-02-nic-0000:17:00.1      Deckhouse   worker-02      NIC    ens3f1   4
Up      PF      NetDev    ixgbe       Intel    35d
```

Label the interfaces that will be used for UnderlayNetwork:

```
d8 k label nni worker-01-nic-0000:17:00.0 nic-group=dpdk
d8 k label nni worker-01-nic-0000:17:00.1 nic-group=dpdk
d8 k label nni worker-02-nic-0000:17:00.0 nic-group=dpdk
d8 k label nni worker-02-nic-0000:17:00.1 nic-group=dpdk
```

i You can check the PCI information and SR-IOV support status for each interface:

```
d8 k get nni worker-01-nic-0000:17:00.0 -o json | jq '.status.nic.pci.pf'
```

The `status.nic.pci.pf.sriov.supported` section contains information about SR-IOV support.

Creating UnderlayNetwork in Dedicated mode

In Dedicated mode, each Physical Function is exposed as an exclusive device. This mode is suitable when:

- SR-IOV is not available or not needed.
- Each pod needs exclusive access to a complete PF.

To create an Underlay network in Dedicated mode, follow these steps:

1. Create and apply the UnderlayNetwork resource. In the `spec.mode` field, specify the value `Dedicated`.

   Example configuration:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: UnderlayNetwork
metadata:
  name: dpdk-dedicated-network
spec:
  mode: Dedicated
  autoBonding: false
  memberNodeNetworkInterfaces:
    - labelSelector:
       matchLabels:
         nic-group: dpdk # Label used to mark interfaces during the verification
and configuration of network interfaces.
```

When `autoBonding` is set to `true`, all matched PFs on a node are grouped into a single DRA device, exposing all PFs to the pod as separate interfaces. When `false`, each PF is published as a separate DRA device.

2. Check the status of the created UnderlayNetwork:

   ```
   d8 k get underlaynetwork dpdk-dedicated-network -o yaml
   ```

   Example status of UnderlayNetwork in `Dedicated` mode:

   ```
   apiVersion: network.deckhouse.io/v1alpha1
   kind: UnderlayNetwork
   metadata:
     name: dpdk-dedicated-network
   ...
   status:
     observedGeneration: 1
     conditions:
     - message: All 2 member node network interface selectors have matches
       observedGeneration: 1
       reason: AllInterfacesAvailable
       status: "True"
       type: InterfacesAvailable
   ```

Creating UnderlayNetwork in Shared mode

In `Shared` mode, Virtual Functions (VF) are created from Physical Functions (PF) using SR-IOV, allowing multiple pods to share the same hardware. This mode requires SR-IOV support on the NICs.

To create an Underlay network in `Shared` mode, follow these steps:

1. Create and apply the UnderlayNetwork resource. In the `spec.mode` field, specify the value `Shared`.

   Example configuration:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: UnderlayNetwork
metadata:
  name: dpdk-shared-network
spec:
  mode: Shared
  autoBonding: true
  memberNodeNetworkInterfaces:
    - labelSelector:
       matchLabels:
         nic-group: dpdk
  shared:
    sriov:
      enabled: true
      numVFs: 8
```

In this example:

- `mode: Shared` enables SR-IOV and VF creation.
- `autoBonding: true` groups one VF from each matched PF into a single DRA device.
- `shared.sriov.enabled: true` enables SR-IOV on selected PFs.
- `shared.sriov.numVFs: 8` creates 8 Virtual Functions per Physical Function.

> **i** The `mode` and `autoBonding` fields are immutable once set. Plan your configuration carefully before creating the resource.

2. After creating the UnderlayNetwork, monitor the SR-IOV configuration status:

```
d8 k get underlaynetwork dpdk-shared-network -o yaml
```

Example status of UnderlayNetwork in `Shared` mode:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: UnderlayNetwork
metadata:
  name: dpdk-shared-network
...
status:
  observedGeneration: 1
  sriov:
    supportedNICs: 4
    enabledNICs: 4
  conditions:
  - lastTransitionTime: "2025-01-15T10:30:00Z"
    message: SR-IOV configured on 4 NICs
    reason: SRIOVConfigured
    status: "True"
    type: SRIOVConfigured
  - lastTransitionTime: "2025-01-15T10:30:05Z"
    message: Interfaces are available for allocation
    reason: InterfacesAvailable
    status: "True"
    type: InterfacesAvailable
```

3. Verify that VFs have been created by checking NodeNetworkInterface resources:

```
d8 k get nni -l network.deckhouse.io/nic-pci-type=VF
```

Preparing namespaces for UnderlayNetwork usage

Before users can request UnderlayNetwork devices in their pods, the namespace must be labeled to enable UnderlayNetwork support. This is an administrative task that should be done for namespaces where DPDK applications will run:

```
d8 k label namespace mydpdk direct-nic-access.network.deckhouse.io/enabled=""
```

Configuring and connecting system networks (service networks)

System networks (service networks) are intended for internal traffic at the node level (e.g., for storage, management, etc.) and are not used as additional pod networks.

Additional service networks are created on cluster nodes on top of existing underlay networks. The custom resource SystemNetwork is used for this purpose. System networks obtain IP addresses from the ClusterIPAddressPool during IPAM configuration.

Principles and features of system networks:

- **Working on top of underlay networks**: A system network attaches to an underlay network (UnderlayNetwork). To connect, specify the name of the underlay network to which the system network should be connected in the `spec.underlayNetworkName` parameter of the SystemNetwork resource. The set of node interfaces (PF or VF) used by the system network is defined in the `memberNodeNetworkInterfaces` parameter of the UnderlayNetwork resource.
- **Support for different types of system network connections to the underlay network**: You can create a VLAN sub-interface (`type: VLAN`), use the underlay as-is (`type: Access`), or attach via an SR-IOV Virtual Function (`type: SRIOVVirtualFunction`) with optional tuning (MTU, MAC, spoof checking, etc.).
- **Support for IPAM mechanism**: Optional `spec.ipam` parameter references a ClusterIPAddressPool. The controller and agent then allocate addresses from that pool and assign them to the node interfaces for this system network.
- **Tracking the status of system networks**: The agent reports node addresses (including SystemNetwork IPs) in NodeNetworkStatus resources. Internal SystemNetworkNodeNetworkInterfaceAttachment resources track the binding of each system network to each node’s parent interface.

Prerequisites for creating and using system networks

To enable system networks in a cluster, the following requirements must be met:

1. An underlay network must exist. The system network will attach to it by name via `spec.underlayNetworkName` parameter. The underlay’s `memberNodeNetworkInterfaces` selectors determine which node interfaces are used.
2. **Optional**. To automatically assign IP addresses on interfaces belonging to a system network, create a system network address pool. It must be specified in the `spec.ipam.clusterIPAddressPoolName` parameter of the SystemNetwork resource when the network is created.

Creating a system network

To create a system network, use the SystemNetwork resource. Supported system networks have the following types of connections to the underlay networks on which they will operate:

- `VLAN`: VLAN interfaces are created on interfaces connected to the underlay network (underlay interfaces).
- `Access`: Direct access (without VLAN) to interfaces on nodes connected to the underlay network.
- `SRIOVVirtualFunction`: Connection to a physical interface via SR-IOV.

VLAN type

Creates a VLAN sub-interface on each matched underlay interface. When creating a network, you must specify the VLAN ID (parameter `spec.vlan.id`).

Example of a system network manifest with a `VLAN` connection type to the underlay network:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: SystemNetwork
metadata:
  name: storage-network
spec:
  type: VLAN
  underlayNetworkName: my-underlay
  vlan:
    id: 100
  ipam:
    clusterIPAddressPoolName: storage-pool
```

To check the network status after creation, use the section Checking system network status.

Access type

Uses the underlay interface as-is (no VLAN tag). Useful when the underlay already represents a single L2 segment.

Example of a system network manifest with a `Access` connection type to the underlay network:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: SystemNetwork
metadata:
  name: mgmt-network
spec:
  type: Access
  underlayNetworkName: my-underlay
  ipam:
    clusterIPAddressPoolName: mgmt-pool
```

To check the network status after creation, use the section Checking system network status.

SRIOVVirtualFunction type

Attaches via an SR-IOV Virtual Function. The underlay must be in `Shared` mode so that VFs exist. You can optionally tune VF settings.

Example of a system network manifest with a `SRIOVVirtualFunction` connection type to the underlay network:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: SystemNetwork
metadata:
  name: vf-service-network
spec:
  type: SRIOVVirtualFunction
  underlayNetworkName: dpdk-shared-network
  sriovVirtualFunction:
    vlan: 200
    mtu: 1500
    linkState: Auto
  ipam:
    clusterIPAddressPoolName: vf-pool
```

To check the network status after creation, use the section Checking system network status.

Creating a pool of IP addresses for configuring the IPAM system network

To create an address pool for configuring the system network IPAM, use the ClusterIPAddressPool resource:

```
apiVersion: network.deckhouse.io/v1alpha1
kind: ClusterIPAddressPool
metadata:
  name: storage-pool
spec:
  leaseTTL: 24h
  pools:
    - network: 10.20.30.0/24
      ranges:
        - 10.20.30.10-10.20.30.250
```

When creating a system network, specify this pool in the `spec.ipam.clusterIPAddressPoolName` parameter of the SystemNetwork resource.

Checking system network status

To get a list of system networks, use the command:

```
d8 k get systemnetworks
```

To view the status of a specific system network, use the command:

```
d8 k get systemnetwork storage-network -o yaml
```

In `status` you will see:

- `nodeAttachementsCount`: Total attachments (one per matched node interface).
- `readyNodeAttachementsCount`: Attachments that are configured and ready.
- `conditions` — e.g. `Ready`: When all attachments are ready.

To view internal attachments (one per a “system network + parent interface” pair), use the command:

```
d8 k get systemnetworknodenetworkinterfaceattachments
```

To view IP addresses at the node level (including system network IPs) for all nodes, use the command (one NodeNetworkStatus is assigned to each node):

```
d8 k get nodenetworkstatus
```

To view information about IP addresses at the node level (including system network IPs) for a specific node, use the command:

```
d8 k get nodenetworkstatus -l network.deckhouse.io/node-name=worker-01 -o yaml
```

In `status.addresses` look for entries with `type: SystemNetworkIP` and `systemNetworkName` set to your system network name.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtual machine networking

The `.spec.settings.virtualMachineCIDRs` block lists the subnets in CIDR notation from which Deckhouse Platform (DP) assigns IP addresses to virtual machines, either automatically or on request.

Specify the subnet start address aligned to the mask, for example `192.168.1.192/27`, not an arbitrary address from the range.

Example:

```
spec:
  settings:
    virtualMachineCIDRs:
      - 10.66.10.0/24
      - 10.66.20.0/24
      - 10.77.20.0/16
```

The first and the last address of each subnet are reserved and never assigned to virtual machines. For example, in the `10.66.10.0/24` subnet, the `10.66.10.0` and `10.66.10.255` addresses are unavailable.

You can leave the block unset. The module still starts, but you can no longer work with virtual machine addresses:

- You can't create or use the VirtualMachineIPAddress resource.
- A virtual machine can't request the `Main` network in the `.spec.networks` parameter.
- The `.spec.networks` parameter of a virtual machine can't be empty.

⚠ The subnets in the `.spec.settings.virtualMachineCIDRs` block must not overlap with the cluster node subnets, the service subnet, or the pod subnet (`podCIDR`).

You can't delete a subnet if addresses from it are already assigned to virtual machines. You also can't clear the block once it's set.

Additional resources

- Module `virtualization` parameters
- Module `virtualization` custom resources

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managing static routes and ip rules on cluster nodes

In Deckhouse Platform, static-routing and ip rule management on cluster nodes is implemented using the `static-routing-manager` module.

Configuration examples

Creating a route in main routing table

```
apiVersion: network.deckhouse.io/v1alpha1
kind: RoutingTable
metadata:
  name: myrt-main
spec:
  ipRoutingTableID: 254 # Main routing table ID is 254.
  routes:
  - destination: 10.0.0.0/8
    gateway: 192.168.0.1
  nodeSelector:
    node-role.deckhouse.io: load-balancer
```

Based on this configuration, the route `10.0.0.0/8 via 192.168.0.1` will be created on the nodes

falling under `nodeSelector`:

```
ip -4 route ls
```

Example output:

```
10.0.0.0/8 via 192.168.0.1 dev eth0 realm 216
```

The `realm 216` instruction in the route is used as a marker to identify the route under module control (d8 hex = 216 dec).

Creating a route in additional routing table

```
apiVersion: network.deckhouse.io/v1alpha1
kind: RoutingTable
metadata:
  name: myrt-extra
spec:
  routes:
  - destination: 0.0.0.0/0
    gateway: 192.168.0.1
  nodeSelector:
    node-role.deckhouse.io: load-balancer
status:
  ipRoutingTableID: 10000 # If spec.ipRoutingTableID is not specified, it will be
generated automatically and placed in status.
```

According to this configuration, the route `10.0.0.0.0/8 via 192.168.0.1` will be created on the nodes falling under `nodeSelector` in the table `10000`:

```
ip -4 route ls table 10000
```

Example output:

```
default via 192.168.0.1 dev eth0 realm 216
```

Creating an ip rule

```
apiVersion: network.deckhouse.io/v1alpha1
kind: IPRuleSet
metadata:
  name: myiprule
spec:
  rules:
  - selectors:
     from:
     - 192.168.111.0/24
     - 192.168.222.0/24
     to:
     - 8.8.8.8/32
     - 172.16.8.0/21
     sportRange:
       start: 100
       end: 200
     dportRange:
       start: 300
       end: 400
     ipProto: 6
    actions:
     lookup:
       routingTableName: myrt-extra
    priority: 50
  nodeSelector:
    node-role.deckhouse.io: load-balancer
```

According to this configuration, an ip rule will be created on the nodes falling under `nodeSelector`. To view results, run:

```
ip rule list
```

Example output:

```
...
50: from 192.168.111.0/24 to 172.16.8.0/21 ipproto tcp sport 100-200 dport 300-400
lookup 10000 realms 216
50: from 192.168.222.0/24 to 8.8.8.8 ipproto tcp sport 100-200 dport 300-400 lookup
10000 realms 216
50: from 192.168.222.0/24 to 172.16.8.0/21 ipproto tcp sport 100-200 dport 300-400
lookup 10000 realms 216
50: from 192.168.111.0/24 to 8.8.8.8 ipproto tcp sport 100-200 dport 300-400 lookup
10000 realms 216
...
```

Managing DNS in a Kubernetes cluster

DNS management in a Kubernetes cluster is implemented using the `kube-dns` module.

The module installs CoreDNS components for managing DNS in the Kubernetes cluster.

> The module deletes Deployments, ConfigMaps as well as RBAC for CoreDNS that were previously created using the `kubeadm` tool. When deploying your own CoreDNS, avoid using the names `coredns` or `system:coredns` for any resources (Deployment, Service, ConfigMap, ServiceAccount, ClusterRole, ClusterRoleBinding). Use alternative names like `infra-dns` to prevent automatic removal by Deckhouse Platform.

Configuration example

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: kube-dns
spec:
  version: 1
  enabled: true
  settings:
    upstreamNameservers:
    - 8.8.8.8
    - 8.8.4.4
    hosts:
    - domain: one.example.com
      ip: 192.168.0.1
    - domain: two.another.example.com
      ip: 10.10.0.128
    stubZones:
    - zone: consul.local
      upstreamNameservers:
      - 10.150.0.1
    enableLogs: true
    clusterDomainAliases:
    - foo.bar
    - baz.qux
```

Additional resources

- Module `kube-dns` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Caching DNS requests on cluster nodes

In Deckhouse Platform, you can deploy a local caching DNS server on each cluster node. It exports metrics to Prometheus for visualization in a Grafana dashboard.

This feature is implemented by the `node-local-dns` module. The module consists of the original CoreDNS deployed as a DaemonSet on all cluster nodes, along with a network configuration algorithm and iptables rules.

Detailed information about the problems that caching DNS-server allows to solve and the principle of its work is available in Caching DNS server in a cluster.

Example custom DNS configuration in a Pod

```
apiVersion: v1
kind: Pod
metadata:
  name: dns-example
spec:
  dnsPolicy: "None"
  dnsConfig:
    nameservers:
      - 169.254.20.10
  containers:
    - name: test
      image: nginx
```

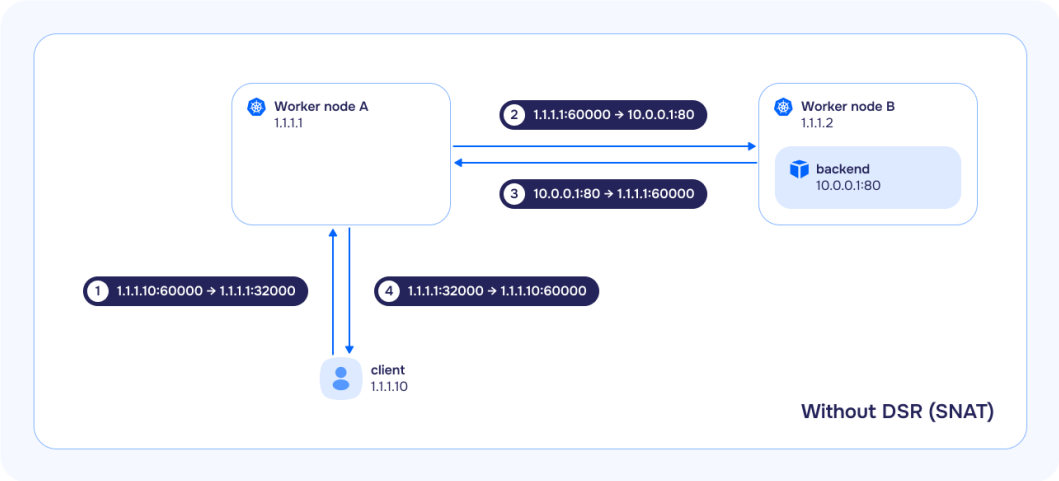
For details on DNS configuration, refer to the Kubernetes documentation.

Additional resources

- Module `node-local-dns` documentation

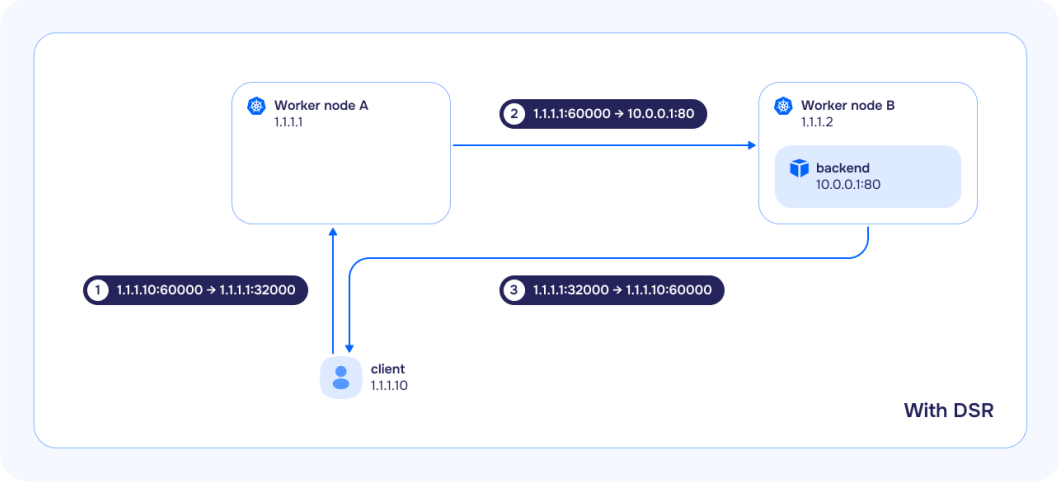
> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

BpfLB operation modes for external traffic processing



You can use the `cni-cilium` module to configure the BPF Load Balancer (bpfLB) mode of operation in Deckhouse Platform.

In Kubernetes, traffic typically comes through a load balancer that distributes incoming requests among servers and processes responses. Thus, the total throughput is limited by the load balancer resources.



To optimize traffic and unload the balancer, the `DSR` mechanism is used, in which incoming packets go through the load balancer, and outgoing ones go directly from the terminating servers. Since responses are usually much larger in size than requests, this approach can significantly increase the overall throughput.

The module allows selecting the mode of operation via the `bpfLBMode` parameter, which affects the behavior of Services of the `NodePort` and `LoadBalancer` types:

- `SNAT` (Source Network Address Translation): A subtype of NAT in which, for each outgoing packet, the source IP address is translated to the IP address of the gateway from the target subnet, and incoming packets passing through the gateway are translated back based on a translation table. In this mode, `bpfLB` fully replicates the logic of `kube-proxy`:
  - If `externalTrafficPolicy: Local` is specified for a Service object, the traffic will be forwarded and balanced only to those target pods running on the same node where the traffic arrived. If the target pod is not running on this node, the traffic will be dropped.
  - If `externalTrafficPolicy: Cluster` is specified for a Service object, the traffic will be forwarded and balanced to all target pods in the cluster. At the same time, if the target pods are located on other nodes, SNAT will be performed when transmitting traffic to them (the source IP address will be replaced with the InternalIP of the node).

- `DSR` (Direct Server Return): A method where all incoming traffic passes through the load balancer, and all outgoing traffic bypasses it. This method is used instead of `SNAT`. Often, responses are much larger than requests, and `DSR` can significantly increase the overall throughput of the scheme:
  - If `externalTrafficPolicy: Local` is specified in the `Service`, its behavior is completely analogous to `kube-proxy` and `bpfLB` in `SNAT` mode.
  - If `externalTrafficPolicy: Cluster` is specified in the `Service`, the traffic will be forwarded and balanced to all target pods in the cluster. Note the following:
    - If the target pods are on other nodes, then the source IP address will be preserved when incoming traffic is sent to them.
    - Outgoing traffic will go directly from the node on which the target pod was launched.
    - The source IP address will be replaced with the external IP address of the node to which the incoming request came originally.

> **i** In case of using `DSR` and `Service` mode with `externalTrafficPolicy: Cluster` additional network environment settings are required.
> Network equipment must be ready for asymmetric traffic flow: IP address anti-spoofing tools (`uRPF`, `sourceGuard`, etc.) must be disabled or configured accordingly.

- `Hybrid`: In this mode, TCP traffic is handled per `DSR` rules, while UDP traffic is handled per `SNAT` rules.

Example of bpfLB operation mode configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cni-cilium
spec:
  settings:
    tunnelMode: VXLAN
    bpfLBMode: SNAT # SNAT mode is selected.
  version: 1
  enabled: true
```

Additional resources

- Module `cni-cilium` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Synchronizing time on nodes

To synchronize time on Deckhouse cluster nodes, DP uses a built-in solution based on chrony. Using the Network Time Protocol (NTP), DP ensures that system clocks on cluster nodes are synchronized with external NTP servers. If required, you can disable this built-in mechanism and configure custom NTP daemons.

Enabling built-in time synchronization

Enable the `chrony` module to activate time synchronization:

```
d8 system module enable chrony
```

By default, the time source is the server `pool.ntp.org`. You can specify a list of NTP servers using the `ntpServers` parameter in the configuration of the `chrony` module.

An example of the module configuration specifying NTP servers:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: chrony
spec:
  enabled: true
  settings:
    ntpServers:
      - ntp.ubuntu.com
      - time.google.com
  version: 1
```

Using custom NTP daemons

To disable the built-in time synchronization mechanism and use your own NTP daemons on the nodes, follow these steps:

1. Disable the `chrony` module:

   ```
   d8 system module disable chrony
   ```

   If the command is successful, you should see the message confirming that the module has been

disabled:

```
Module chrony disabled
```

2. Create a NodeGroupConfiguration resource to enable the NTP daemons on the nodes.

   Example for `systemd-timesyncd`:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: enable-ntp-on-node.sh
spec:
  weight: 100
  nodeGroups: ["*"]
  bundles: ["*"]
  content: |
    systemctl enable systemd-timesyncd
    systemctl start systemd-timesyncd
EOF
```

Additional resources

- Module `chrony` documentation
- Module `node-manager` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Access via OpenVPN

This section describes how to configure access to cluster resources using OpenVPN with certificate-based authentication.

Settings are available through a simple web interface that allows you to:

- Issue certificates;
- Revoke certificates;
- Undo certificate revocation;
- Download a ready-to-use user configuration file.

OpenVPN is integrated with user authentication, enabling access control for the web interface.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuration

External access to OpenVPN

You can configure the publication of the OpenVPN server in several ways:

1. Select one or more external IP addresses for connection.
2. Choose one of the connection methods:
   - via external IP address (`ExternalIP`) — if there are nodes with public IPs;

- using `LoadBalancer` — for all cloud providers and their deployment schemes that support LoadBalancer provisioning;
- `Direct` — manually configure the traffic path from the cluster entry point to the OpenVPN pod.

Example for bare-metal clusters

Apply the following YAML file in your cluster:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: openvpn
spec:
  version: 2
  enabled: true
  settings:
    inlet: ExternalIP
    externalIP: 5.4.54.4 # External IP address.
```

Example for AWS and Google Cloud

Apply the following YAML file in your cluster:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: openvpn
spec:
  version: 2
  enabled: true
  settings:
    inlet: LoadBalancer
```

Example for a public IP address on an external Load Balancer

Apply the following YAML file in your cluster:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: openvpn
spec:
  version: 2
  enabled: true
  settings:
    externalHost: 5.4.54.4
    externalIP: 192.168.0.30 # Internal IP address that will receive traffic from the
external Load Balancer.
    inlet: ExternalIP
    nodeSelector:
      kubernetes.io/hostname: node
```

Authentication

You can configure user authentication to access OpenVPN. Alternatively, you can use the externalAuthentication parameter.
If both options are disabled, basic authentication with a generated password will be enabled.

To view the generated password, run the following command:

```
d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller module values openvpn
-o json | jq '.openvpn.internal.auth.password'
```

To generate a new password, delete the Secret resource:

```
d8 k -n d8-openvpn delete secret/basic-auth
```

> **i** The `auth.password` parameter is no longer supported.

Available cluster resources after connecting to VPN

After connecting to the VPN, the following parameters are pushed to the user's computer:

- The `kube-dns` address is added to the client's DNS servers to allow direct access to Kubernetes services via FQDN;
- A route to the local network;
- A route to the cluster service network;
- A route to the pod network.

Auditing user connections

To monitor user connections, you can enable logging of VPN activity in JSON format. Traffic is grouped by the following fields: `src_ip`, `dst_ip`, `src_port`, `dst_port`, `ip_proto`.
Using log-shipper, you can collect and store container logs for later auditing.

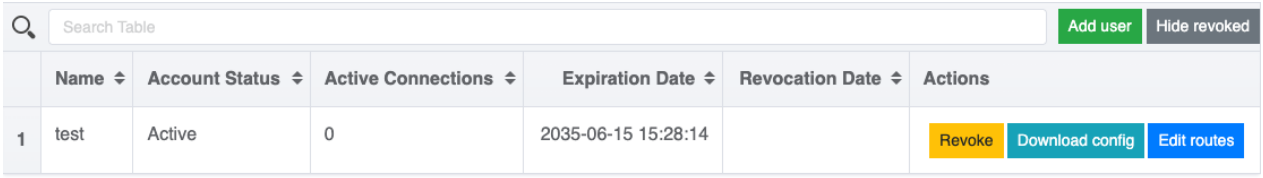
Why automatic DNS configuration doesn't work on macOS and Linux with the OpenVPN client

Due to the architectural specifics of Linux and macOS, automatic DNS server configuration when using the official OpenVPN client is not supported.

These operating systems allow using external scripts that run on VPN connect and disconnect to configure DNS.

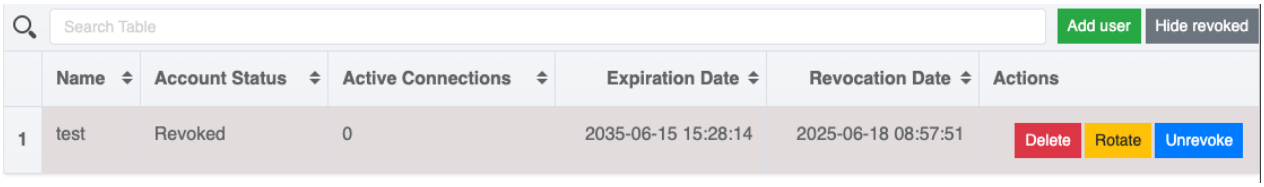
In the client configurations generated by the module, the following blocks are predefined and commented out:

```
# Uncomment the lines below for use with Linux
#script-security 2
# If you use resolved
#up /etc/openvpn/update-resolv-conf
#down /etc/openvpn/update-resolv-conf
# If you use systemd-resolved, first install the openvpn-systemd-resolved package
#up /etc/openvpn/update-systemd-resolved
#down /etc/openvpn/update-systemd-resolved
```



To activate these code blocks, you need to uncomment them (remove the leading `#`) and provide correct paths to the scripts.

You can either write your own scripts or use existing solutions provided by the official OpenVPN Community (for Linux).
For macOS, you can use a third-party script.



> **⚠** The scripts must have execution permissions.

How to revoke, rotate or delete a user certificate

All operations with client certificates are performed via the openvpn-admin web interface. Buttons for managing certificates are available to the right of each user's name:

To rotate (issue a new certificate) or delete a client, you must first revoke their current certificate:

Once revoked, the Renew (rotation) and Delete (removal) actions become available.

How to rotate a server certificate

The server certificate is rotated automatically several days before it expires.

If you need to rotate the certificate manually (e.g., due to certificate corruption or an unscheduled replacement), follow these steps:

1. Delete the secret `openvpn-pki-server` in the namespace `d8-openvpn`:

   ```
   d8 k -n d8-openvpn delete secrets openvpn-pki-server
   ```

2. Restart the OpenVPN pods to trigger the generation of a new certificate:

   ```
   d8 k -n d8-openvpn rollout restart sts openvpn
   ```

A new certificate will be generated automatically when the pods start.

How to rotate a root certificate (CA)

The root certificate (CA) and server certificate are rotated automatically 1 day before expiration. Automatic rotation of clients certificates is not provided. The root certificate (CA) is used to sign all certificates in OpenVPN — both server and client. Therefore, when replacing the CA, you must reissue all dependent certificates.

Steps to rotate the root certificate:

1. Revoke or delete all active client certificates using the openvpn-admin web interface. If you choose to revoke certificates, you can rotate them later (Renew) after the CA is replaced, without recreating the clients.
2. Delete secrets `openvpn-pki-ca` and `openvpn-pki-server` in the namespace `d8-openvpn`:

   ```
   d8 k -n d8-openvpn delete secrets openvpn-pki-ca openvpn-pki-server
   ```

3. Restart OpenVPN pods:

   ```
   d8 k -n d8-openvpn rollout restart sts openvpn
   ```

4. Rotate certificates of revoked users, or create new ones.
5. Delete all revoked certificate secrets:

   ```
   d8 k -n d8-openvpn delete secrets -l revokedForever=true
   ```

Storage

Reliable data storage is one of the key tasks when deploying and operating Kubernetes clusters. In Deckhouse Platform, this is achieved through flexible support for both software-defined and external storage systems, as well as convenient automation and management tools.

In this section, you will learn:

- Which types of storage Deckhouse supports.
- How to set up both local (SDS) and external storage systems.
- Which tools Deckhouse provides to simplify storage configuration and operation.
- How to choose the optimal solution for your scenarios, based on requirements for reliability, performance, and scalability.

For more details on disk layout and recommended sizes, see the “Disk layout and size” guide.

Supported storage types

Deckhouse Platform offers a wide range of solutions, which can be divided into two main groups.

Software-defined storage

- Managing logical volumes on cluster nodes
- Local storage using Local Path Provisioner
- Local storage based on LVM (Logical Volume Manager)
- Replicated storage based on DRBD (Distributed Replicated Block Device)

External storage

- Distributed Ceph storage
- HPE data storage
- Huawei data storage
- NFS data storage
- S3-based object storage
- SCSI-based data storage
- TATLIN.UNIFIED (Yadro) unified storage

Key features

- All storage configurations are performed through Deckhouse and its modules, simplifying integration with all cluster components.
- Ready-to-use solutions for Ceph, NFS, S3, corporate storage systems, and other options, which make connecting storage to the cluster straightforward.
- Thanks to SDS support (including DRBD) and distributed solutions (Ceph, S3), you can scale up as your workload grows.
- Data replication and integration with robust storage systems help protect critical services and applications from data loss.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage configuration

Storage setup involves several steps depending on the selected storage type. The main configuration steps include:

- Enabling and configuring the corresponding modules.
- Creating Volume Groups.
- Preparing and creating StorageClass objects, followed by assigning and using them.

Each storage type may have its own specific requirements and configuration details, which are described in the corresponding guides.

Creating a StorageClass

To create StorageClass objects, you need to connect one or more storage backends that manage PersistentVolume resources. The created StorageClass objects can then be used to provision virtual disks and images. For more information on creating and using StorageClasses, refer to the appropriate documentation sections for each storage type.

Setting a default StorageClass

The default StorageClass is used when a PersistentVolumeClaim is created without explicitly specifying a storage class. This simplifies the process of creating and using storage by eliminating the need to define the class manually each time.

To set the default StorageClass, specify the desired class in the global configuration. Example command:

```
# Replace with the name of your StorageClass object.
DEFAULT_STORAGE_CLASS=replicated-storage-class
d8 k patch mc global --type='json' -p='[{"op": "replace", "path":
"/spec/settings/defaultClusterStorageClass", "value":
"'"$DEFAULT_STORAGE_CLASS"'"}]'
```

Additional resources

- Global parameters

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring volume snapshot creation

Deckhouse Platform supports volume snapshot creation for CSI drivers in a Kubernetes cluster.

Snapshots capture the state of a volume at a specific point in time and can be used for data recovery or volume cloning. The ability to create snapshots depends on the capabilities of the CSI driver in use.

Supported CSI drivers

The following CSI drivers support snapshot creation:

- OpenStack cloud provider
- VMware vSphere cloud provider
- Distributed storage based on Ceph
- Amazon Web Services cloud provider
- Microsoft Azure cloud provider
- Google Cloud Platform cloud provider
- Replicated storage based on DRBD
- NFS-based storage

Creating snapshots

Before creating snapshots, make sure that VolumeSnapshotClass resources are configured in the cluster. You can list available classes with the following command:

```
d8 k get volumesnapshotclasses.snapshot.storage.k8s.io
```

To create a snapshot for a volume, specify the required VolumeSnapshotClass in the manifest:

```
apiVersion: snapshot.storage.k8s.io/v1
kind: VolumeSnapshot
metadata:
  name: example-snapshot
spec:
  volumeSnapshotClassName: <class-name>
  source:
    persistentVolumeClaimName: <pvc-name>
```

Restoring from a snapshot

To restore data from a snapshot, create a PVC that references the existing VolumeSnapshot:

```
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
  name: restored-pvc
spec:
  dataSource:
    name: example-snapshot
    kind: VolumeSnapshot
    apiGroup: snapshot.storage.k8s.io
  storageClassName: <storage-class-name>
  accessModes:
    - ReadWriteOnce
  resources:
    requests:
      storage: 10Gi
```

⚠ Not all CSI drivers support restoring volumes from snapshots. Ensure that your driver provides the required capabilities.

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Local path provisioner storage

Deckhouse Platform provides the ability to configure local storage using Local Path Provisioner. This is a simple solution without support for snapshots or volume size limits, best suited for development, testing, and small clusters. It uses local disk space on Kubernetes nodes to create PersistentVolumes without relying on external storage systems.

How it works

For each LocalPathProvisioner resource, a corresponding `StorageClass` object is created. The list of nodes allowed to use the StorageClass is defined by the `nodeGroups` field and is used when scheduling pods.

When a pod requests a disk, the following occurs:

- A PersistentVolume of type `HostPath` is created;
- A directory is created on the appropriate node, with the `path` generated from the path parameter, the PV name, and the PVC name.

Example path:

```
/opt/local-path-provisioner/pvc-d9bd3878-f710-417b-a4b3-38811aa8aac1_d8-monitoring_prometheus-main-db-prometheus-main-0
```

Limitations

- It is not possible to set a size limit for created volumes.

Example LocalPathProvisioner resources

ReclaimPolicy: Retain (default)

```
apiVersion: deckhouse.io/v1alpha1
kind: LocalPathProvisioner
metadata:
  name: localpath-system
spec:
  nodeGroups:
  - system
  path: "/opt/local-path-provisioner"
```

ReclaimPolicy: Delete

```
apiVersion: deckhouse.io/v1alpha1
kind: LocalPathProvisioner
metadata:
  name: localpath-system
spec:
  nodeGroups:
  - system
  path: "/opt/local-path-provisioner"
  reclaimPolicy: "Delete"
```

Configuring Prometheus to use local storage

1. Apply the LocalPathProvisioner resource:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: LocalPathProvisioner
   metadata:
     name: localpath-system
   spec:
     nodeGroups:
     - system
     path: "/opt/local-path-provisioner"
   ```

2. Ensure that `spec.nodeGroups` matches the NodeGroup where Prometheus will be running.
3. Specify the name of the created StorageClass in the Prometheus configuration:

   ```
   longtermStorageClass: localpath-system
   storageClass: localpath-system
   ```

4. Wait for Prometheus pods to restart.

Additional resources

- Module `local-path-provisioner` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Node configuration for software-defined storage

Deckhouse Platform provides automatic management of logical volumes (Logical Volume Manager, LVM) on cluster nodes using custom Kubernetes resources. This functionality is provided by the `sds-node-configurator` module and includes:

- Detection of block devices on each node and creation of corresponding BlockDevice resources.

  > Manual creation and modification of the BlockDevice resource is prohibited.

- Automatic discovery and management of LVMVolumeGroup resources with the label `storage.deckhouse.io/enabled=true` (including thin pools) on cluster nodes. When Volume Groups (VG) are detected on nodes without corresponding resources, the controller automatically creates the LVMVolumeGroup resource.
- Regular scanning of Physical Volumes (PV) that are part of managed Volume Groups (VG) on nodes. Upon expansion of the underlying block device, the controller performs `pvresize` on the corresponding physical volume and automatically increases the size of all logical volumes in this volume group.

  > Reducing the size of the block device is not supported.

- Synchronization of the LVMVolumeGroup state with the actual state of the node: creation of new volume groups according to LVMVolumeGroup, expansion of existing ones when `desiredCapacity` changes, and deletion of the group when the resource is deleted. For detailed examples of operation, see the section Examples of working with LVMVolumeGroup.

Additional resources

- Module `sds-node-configurator` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Usage

> Functionality is guaranteed only when using stock kernels supplied with supported distributions. When using non-standard kernels or distributions, behavior may be unpredictable.

The controller operates with two types of Kubernetes custom resources:

- BlockDevice: A resource representing a block device.
- LVMVolumeGroup: A resource describing a Logical Volume Manager volume group.

Working with BlockDevice resources

Creating a BlockDevice resource

The controller periodically scans available block devices on each node and automatically creates a BlockDevice resource when it detects a device that matches the rules. As a result, a resource object with a unique name is created, containing detailed information about the device's characteristics.

Criteria for device selection by the controller

- The device is not used as a DRBD volume (Distributed Replicated Block Device).
- The device is not a loop interface (virtual block device).
- The device is a logical volume.
- The file system is absent or has the label `LVM2_MEMBER` (indicating it belongs to an LVM device).
- The device does not contain partitions (no partition table).
- The device's capacity exceeds 1 GiB.
- For virtual disks, a serial number is required.

The created BlockDevice resource serves as a data source for subsequent work with LVMVolumeGroup resources.

Updating a BlockDevice resource

When the state of a block device changes (for example, size change, metadata change, or the device disappears from the system), the controller automatically detects these changes and updates the fields of the BlockDevice resource, ensuring the information is up-to-date. User edits to the BlockDevice resource are prohibited and will be overwritten by the controller.

Deleting a BlockDevice resource

The controller deletes a BlockDevice resource only when the following conditions are met:

- The resource is in the `Consumable` state (available for consumption in the Logical Volume Manager).
- The block device is no longer available in the system (the device has been removed or disconnected).
- The block device is not part of a volume group with the label `storage.deckhouse.io/enabled=true` (such a volume group is managed by LVMVolumeGroup, and the BlockDevice is not deleted).

> **i** A BlockDevice resource is deleted without a help from a user. If the user manually deletes the resource, the controller will recreate it during the next scan if the device still meets the criteria.

Working with LVMVolumeGroup resources

The LVMVolumeGroup resource combines several BlockDevice resources into a single Logical Volume Manager (LVM) volume group on a node and reflects the current state of this group.

> **i** Currently, only the `Local` type (local volume groups) is supported.

Creating an LVMVolumeGroup resource

There are two scenarios for creating an LVMVolumeGroup resource:

- Automatic creation of the resource:
  - The controller scans the list of active LVM volume groups on each node.
  - If a discovered volume group has the label `storage.deckhouse.io/enabled=true` and there is no corresponding LVMVolumeGroup resource, the controller automatically creates the resource.
  - The controller fills out the `spec` section, except for the `thinPools` field. All other parameters (block device names, Volume Group name, etc.) are automatically pulled from the system state.
  - To manage thin pools, the user can manually add information about them to the `spec` section after the resource is created.
- Manual creation of the resource:
  - The user creates a YAML manifest, specifying the minimum set of fields:
    - `metadata.name`: Unique name for the LVMVolumeGroup resource.
    - `spec`: Name of the node where the volume group will exist.
  - After validation, the controller creates the volume group on the node and updates the custom

resource with current information about the state of the created LVM Volume Group.

Example of creating a local Volume Group without a thin pool:

```
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-0-on-node-0"
spec:
  type: Local
  local:
    nodeName: "node-0"
  blockDeviceSelector:
    matchExpressions:
      - key: kubernetes.io/metadata.name
        operator: In
        values:
          - dev-07ad52cef2348996b72db262011f1b5f896bb68f
          - dev-e90e8915902bd6c371e59f89254c0fd644126□7
  actualVGNameOnTheNode: "vg-0"
```

```
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-0-on-node-0"
spec:
  type: Local
  local:
    nodeName: "node-0"
  blockDeviceSelector:
    matchLabels:
      kubernetes.io/hostname: node-0
  actualVGNameOnTheNode: "vg-0"
```

Example of creating a local Volume Group with a thin pool (250 GiB):

```
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-0-on-node-0"
spec:
  type: Local
  local:
    nodeName: "node-0"
  blockDeviceSelector:
    matchExpressions:
      - key: kubernetes.io/metadata.name
        operator: In
        values:
          - dev-07ad52cef2348996b72db262011f1b5f896bb68f
          - dev-e90e8915902bd6c371e59f89254c0fd644126□7
  actualVGNameOnTheNode: "vg-0"
  thinPools:
    - name: thin-1
      size: 250Gi
```

```
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-0-on-node-0"
spec:
  type: Local
  local:
    nodeName: "node-0"
  blockDeviceSelector:
    matchLabels:
      kubernetes.io/hostname: node-0
  actualVGNameOnTheNode: "vg-0"
  thinPools:
    - name: thin-1
      size: 250Gi
```

The user can use any valid selectors (`matchLabels` or `matchExpressions`) to select BlockDevice resources:

- `matchLabels` allows selecting all devices that have the specified label (for example, `kubernetes.io/hostname=node-0`).
- `matchExpressions` allows for more flexible expressions, such as including listed device names.

The `spec.local.nodeName` field must match the name of the node where the Volume Group is created. Otherwise, the resource will not be started. All selected block devices must physically reside on the same node for a resource of type Local.

⚠ After applying the manifest, the controller will automatically create or update the LVM infrastructure on the node, including working with physical volumes (`pvcreate`), creating or modifying the volume group (`vgcreate`/`vgextend`), and setting up the thin pool (`lvcreate`).

Updating an LVMVolumeGroup resource

To change the configuration of the volume group (adding/removing block devices or changing thin pool parameters), it is sufficient to edit the `spec` section of the resource. The controller will validate the new parameters and adjust the state on the node (execute commands like `vgextend`, `lvcreate`, `lvresize`, etc.).

The `status` section of the resource automatically reflects the current information about the state of the Volume Group (list of physical volumes, thin pool data, free/used space, etc.).

⚠
- The controller does not change the `spec` automatically — it only reads the desired state and brings the actual state of the node into compliance. All changes to the desired state must be made by the user in `spec`.
- Avoid modifying `status` manually, as this section is managed by the controller.

Deleting an LVMVolumeGroup resource

The controller automatically deletes the resource if the Volume Group no longer exists on the node (for example, all block devices are disconnected or removed). For manual deletion of the Volume Group and its associated logical volumes, the user can use:

```
d8 k delete lvg <resource-name>
```

After that, the controller will perform a full removal of the physical and logical LVM objects (`lvremove`, `vgremove`, etc.).

⚠ If there are logical volumes (including thin pools) in the Volume Group, the user must first delete or move them (using commands `lvremove` or `pvmove` + `vgreduce`). Otherwise, the controller will not be able to delete the resource. To prevent accidental deletion of the resource, you can set the annotation `storage.deckhouse.io/deletion-protection` — while it is present, the controller will not initiate the deletion of the volume group.

Removing a BlockDevice from an LVMVolumeGroup

1. To exclude a specific BlockDevice from the Volume Group, adjust the `spec.blockDeviceSelector` selector of the LVMVolumeGroup resource or remove the corresponding label from the BlockDevice resource.
2. On the node, manually transfer data (if there are volumes in the Volume Group) using the following command:

   ```
   pvmove <source-device>
   ```

3. Remove the physical volume from the group:

   ```
   vgreduce <VG-name> <excluded-device>
   ```

4. Finally, remove the physical volume metadata:

   ```
   pvremove <excluded-device>
   ```

i If logical volumes remain during the removal process, delete them in advance using the `lvremove` command. To protect against unintentional deletion, you can use the annotation `storage.deckhouse.io/deletion-protection` — until it is removed, the LVMVolumeGroup resource will not be deleted.

Protecting against data leaks between volumes

When files are deleted, the operating system does not erase the data on the disk: the corresponding blocks are merely marked as “free”. If the same physical blocks are used when creating a new volume, they may contain residual data from the previous user.

For example:

- User #1 created a volume from StorageClass #1 on node #1 (regardless of the “Block” or “Filesystem” mode) and wrote files to it.
- User #1 deleted the files and the volume itself.
- The blocks that the volume occupied were marked as free but not overwritten.
- User #2 requested a new volume from StorageClass #1 on the same node #1 in block mode.
- There is a risk that some or all of the previously freed blocks will be allocated to user #2 again.
- As a result, user #2 may gain access to user #1’s data.

Thick volume

To ensure confidentiality, the `volumeCleanup` parameter is used in the `PersistentVolume` configuration. Available modes:

- Parameter not set: When the volume is deleted, no additional operations are performed, the blocks remain uninitialized, and the data may be accessible to the next user.
- `RandomFillSinglePass`: The volume is overwritten once with random data (it is recommended to avoid this on solid-state drives due to wear).
- `RandomFillThreePass`: The volume is overwritten three times with random data (maximum reliability but high load on the device).
- `Discard`: Using TRIM, all block devices are marked as free. Effective on most modern solid-state drives, but depends on the SSD controller’s support for DRAT/RZAT.

Using Discard mode

Most modern solid-state drives support the `discard` (TRIM) command, which marks freed blocks as “zero” and does not return old data on subsequent reads. Therefore, using the `Discard` option is the most reliable way to prevent data leaks on solid-state drives. However, the following nuances should be

considered:

- The `discard` command initiates cell cleaning, but the actual zeroing is performed by the drive's controller in the background. Until this operation is completed, some blocks may still contain old data.
- Not all solid-state drives clean specific physical blocks individually: many devices work at the page level and larger blocks, so individual logical blocks may remain uncleaned until the entire page is fully processed.
- To be sure that after `discard` the blocks are indeed read as zeros, the disk must support DRAT (Deterministic TRIM) — predictable behavior of the `discard` command and RZAT (Deterministic Read Zero after TRIM) — guaranteed reading of "zeros" after `discard`. If the device has not confirmed support for DRAT and RZAT, there is no guarantee that the freed blocks will never return the old data.
- Even with declared support for DRAT/RZAT, manufacturers may not fully comply with the specifications. In the absence of independent tests or certification of solid-state drives, it is recommended to refrain from using the `Discard` mode for critical tasks related to data security.

⚠ If the drive is not confirmed to support DRAT and RZAT (meaning, has not passed verification for deterministic cleaning and reading of zeroed blocks), the use of the `Discard` option is **not recommended**, as there remains a risk of recovering old data.

Thin volume

When a block of a thin volume is released, the `discard` command from the guest OS is passed directly to the storage device. If a mechanical hard drive or a solid-state drive without `discard` support is used, the freed blocks in the thin pool remain with the previous data until they are physically overwritten. However, clients are provided only with thin volumes, not access to the thin pool itself. When a block is next allocated to a thin-LV, LVM guaranteedly fills the corresponding block in the thin pool with zeros (zero-fill), thanks to the `thin_pool_zero=1` parameter. This ensures the absence of residual data between different thin volumes and prevents information leaks between clients.

Additional resources

- Module `sds-node-configurator` custom resources

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuration scenarios

i Functionality is guaranteed only when using stock kernels supplied with supported distributions. When using non-standard kernels or distributions, behavior may be unpredictable.

Cloning virtual machines

When creating virtual machines using cloning methods, replace the UUID of the volume groups (VG) by executing:

```
vgchange -u
```

This command will generate new UUIDs for all VGs on the virtual machine. If necessary, the command can be added to the `cloud-init` script.

⚠ Changing the UUID is only possible if there are no active logical volumes (LV) in the group. They can be deactivated as follows:

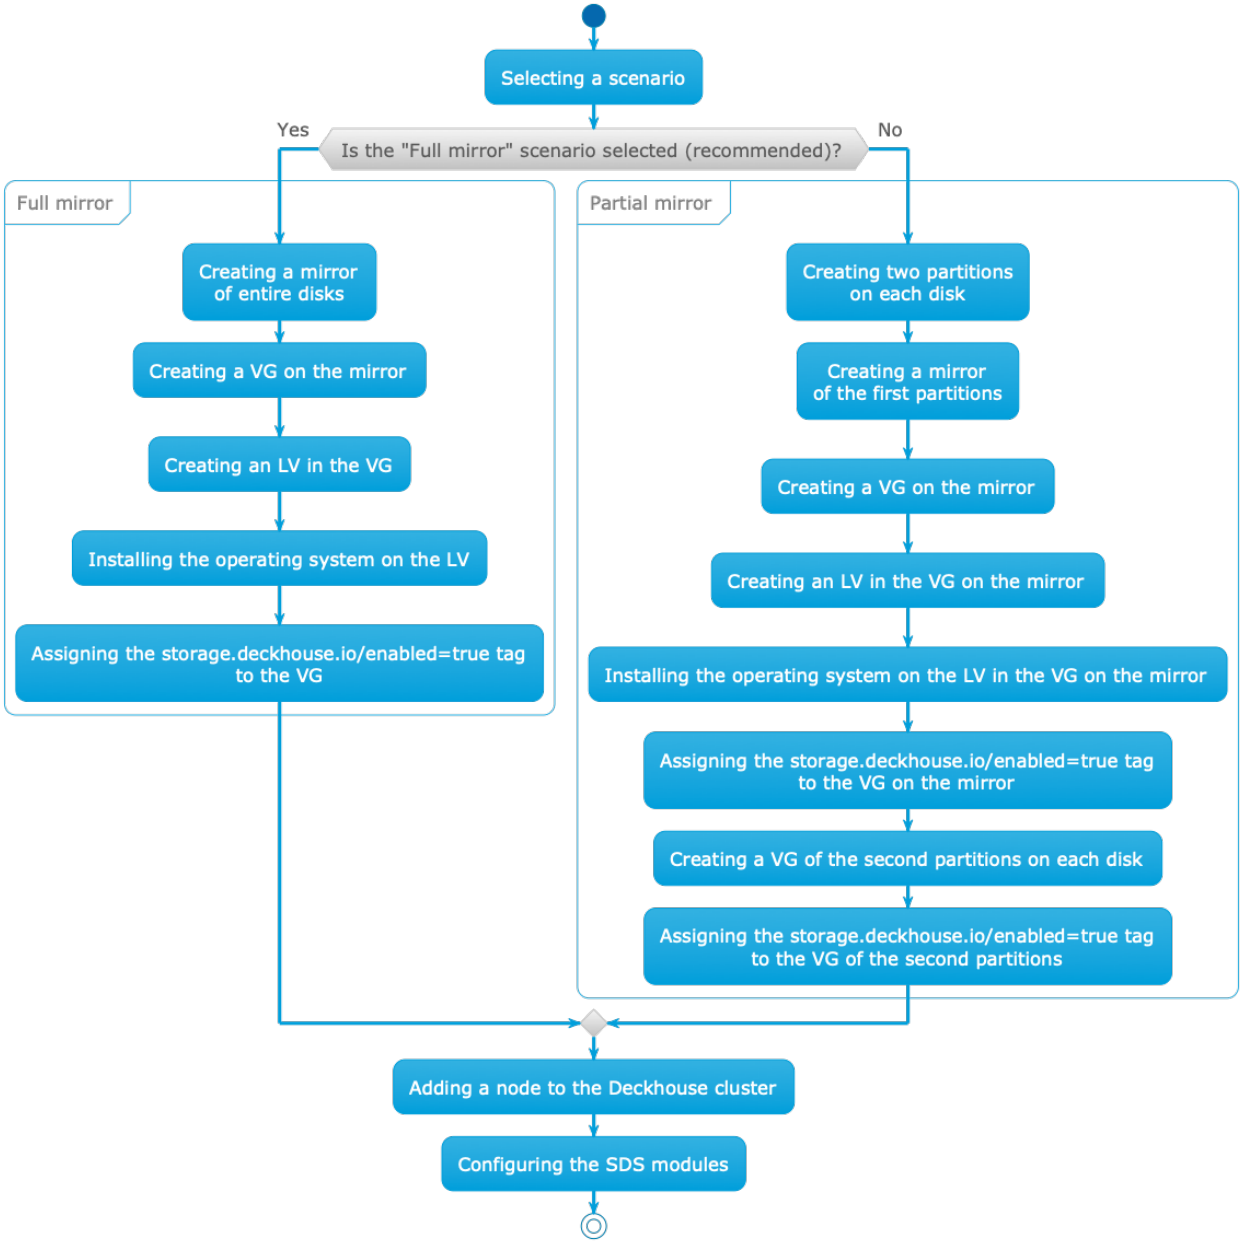
```
lvchange -an <VG_or_LV_NAME>
```

Where `<VG_or_LV_NAME>` is the name of the VG to deactivate all volumes in the group, or the name of the LV to deactivate a specific volume.

Methods and scenarios for configuring the disk subsystem of nodes

The disk subsystem of each node can be organized in two ways, depending on whether the disks installed in the server are identical.

- Storage with identical disks: All disks in the node are of the same type and size.
- Combined storage: The node has disks of different types (for example, SSD + HDD).



For each method of configuring the disk subsystem on nodes, there are two configuration scenarios:

- **Full mirror**: Recommended, reliable, and the simplest.
- **Partial mirror**: More flexible but requires caution.

The features, advantages, and disadvantages of the scenarios are presented in the table:

Configuration scenario	Implementation features	Advantages	Disadvantages
Full mirror	• Disks are not partitioned; a mirror is created from entire disks • Single VG for OS and data	• High reliability • Ease of setup and operation • Flexible resource allocation between SDS	• Excessive disk consumption with SDS replication
Partial mirror	• Disks are divided into 2 partitions • A mirror is created from the first partitions of each disk, on which a VG for the OS is created • A VG for data is created from the second partitions without mirroring	• Reliable storage • Maximum efficiency in space utilization	• Complex setup • Difficulties in reallocating space between safe and unsafe partitions

The differences in the configuration order of the disk subsystem depending on the chosen configuration scenario are illustrated in the diagram:

Storage with identical disks

Full mirror

We recommend using this configuration scenario as it is sufficiently reliable and easy to set up.

To configure a node according to this scenario, follow these steps:

1. Create a mirror from all disks (hardware or software). This mirror will be used simultaneously for the root system and for data.
2. Install the operating system:
   - Create a VG named `main` on the mirror.
   - Create an LV named `root` in the VG `main`.
   - Install the operating system on the LV `root`.
3. Set the tag `storage.deckhouse.io/enabled=true` for the VG `main` using the following command:

   ```
   vgchange main --addtag storage.deckhouse.io/enabled=true
   ```

4. Add the prepared node to the Deckhouse cluster.

   If the node matches the `nodeSelector` specified in `spec.nodeSelector` of the `sds-replicated-volume` or `sds-local-volume` modules, the `sds-node-configurator` agent will detect the VG `main` and create a LVMVolumeGroup resource. This can be used in the `sds-local-volume` and `sds-replicated-volume` modules.

Example of configuring SDS modules (identical disks, “Full mirror”)

In this scenario, three nodes of the Deckhouse cluster are configured in “Full mirror” mode.
After automatic discovery, three CRD resources of type LVMVolumeGroup with automatically generated names will appear in the cluster.

To list the LVMVolumeGroup resources, execute the following command:

```
d8 k get lvmvolumegroups.storage.deckhouse.io
```

The result will be the following list:

```
NAME                                     THINPOOLS   CONFIGURATION APPLIED   PHASE
NODE       SIZE      ALLOCATED SIZE   VG     AGE
vg-08d3730c-9201-428d-966c-45795cba55a6   0/0         True                    Ready
worker-2   25596Mi   0                main   61s
vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d   0/0         True                    Ready
worker-0   25596Mi   0                main   4m17s
vg-c7863e12-c143-42bb-8e33-d578ce50d6c7   0/0         True                    Ready
worker-1   25596Mi   0                main   108s
```

Configuring the sds-local-volume module (identical disks, “Full mirror”)

To configure `sds-local-volume` in “Full Mirror” mode, create a LocalStorageClass resource and specify all discovered LVMVolumeGroup resources in it. This ensures that the VG with the label `main` is available on each node in the module:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LocalStorageClass
metadata:
  name: local-sc
spec:
  lvm:
    lvmVolumeGroups:
      - name: vg-08d3730c-9201-428d-966c-45795cba55a6
      - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
      - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
    type: Thick
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

Configuring the sds-replicated-volume module (identical disks, “Full mirror”)

To configure the `sds-replicated-volume` module according to the “Full mirror” scenario, follow these steps:

1. Create a ReplicatedStoragePool resource and add all LVMVolumeGroup resources to it, so that the VG `main` is used on all nodes in the `sds-replicated-volume` module:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStoragePool
metadata:
  name: data
spec:
  type: LVM
  lvmVolumeGroups:
    - name: vg-08d3730c-9201-428d-966c-45795cba55a6
    - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
    - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
EOF
```

2. Create a ReplicatedStorageClass resource and specify the name of the previously created ReplicatedStoragePool resource in the `storagePool` field:

```
d8 k apply -f -<<EOF
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-r1
spec:
  storagePool: data
  replication: None
  reclaimPolicy: Delete
  topology: Ignored # If this topology is specified, there should be no zones
in the cluster (nodes with labels topology.kubernetes.io/zone).
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-r2
spec:
  storagePool: data
  replication: Availability
  reclaimPolicy: Delete
  topology: Ignored
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-r3
spec:
  storagePool: data
  replication: ConsistencyAndAvailability
  reclaimPolicy: Delete
  topology: Ignored
EOF
```

Partial mirror

⚠

- Do not use partitions with the same `PARTUUID`.
- Changing the `PARTUUID` of a partition on which a VG is already created is not supported.
- It is recommended to use GPT for the partition table — in MBR, `PARTUUID` is pseudo-random and contains the partition number, and there is no support for `PARTLABEL`, which may be useful for identifying partitions in Deckhouse.

In this scenario, two partitions are used on each disk:

- A partition for the root system and storage of SDS data that is not replicated.
- A partition for SDS data that is replicated.

The first partition of each disk is used to create a mirror, and the second is used to create a separate VG without mirroring. This allows for the most efficient use of disk space.

To configure a node according to the “Partial mirror” scenario, follow these steps:

1. During the operating system installation:
   - Create two partitions on each disk.
   - Assemble a mirror from the first partitions on each disk.
   - Create a VG named `main-safe` on the mirror.
   - Create an LV named `root` in the VG `main-safe`.
   - Install the operating system on the LV `root`.
2. Set the tag `storage.deckhouse.io/enabled=true` for the VG `main-safe` using the following command:

   ```
   vgchange main-safe --addtag storage.deckhouse.io/enabled=true
   ```

3. Create a VG named `main-unsafe` from the second partitions of each disk.
4. Set the tag `storage.deckhouse.io/enabled=true` for the VG `main-unsafe` using the following command:

   ```
   vgchange main-unsafe --addtag storage.deckhouse.io/enabled=true
   ```

5. Add the prepared node to the Deckhouse cluster.

   If the node matches the `nodeSelector` specified in `spec.nodeSelector` of the `sds-replicated-volume` or `sds-local-volume` modules, the `sds-node-configurator` agent will run on this node, detect the VGs `main-safe` and `main-unsafe`, and add the corresponding LVMVolumeGroup resources to the Deckhouse cluster. These LVMVolumeGroup resources can then be used to create volumes in the `sds-replicated-volume` or `sds-local-volume` modules.

Example of configuring SDS modules (identical disks, “Partial mirror”)

In this example, it is assumed that you have configured three nodes according to the “Partial mirror” scenario. In the Deckhouse cluster, six LVMVolumeGroup resources with randomly generated names will appear. In the future, it will be possible to specify a name for the LVMVolumeGroup resources created during the automatic VG discovery process using the `LVM` tag with the desired resource name.

To list the LVMVolumeGroup resources, execute the following command:

```
d8 k get lvmvolumegroups.storage.deckhouse.io
```

The result will be the following list:

```
NAME                                   THINPOOLS   CONFIGURATION APPLIED   PHASE
NODE       SIZE      ALLOCATED SIZE   VG            AGE
vg-08d3730c-9201-428d-966c-45795cba55a6   0/0         True                    Ready
worker-2   25596Mi   0                main-safe     61s
vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d   0/0         True                    Ready
worker-0   25596Mi   0                main-safe     4m17s
vg-c7863e12-c143-42bb-8e33-d578ce50d6c7   0/0         True                    Ready
worker-1   25596Mi   0                main-safe     108s
vg-deccf08a-44d4-45f2-aea9-6232c0eeef91   0/0         True                    Ready
worker-2   25596Mi   0                main-unsafe   61s
vg-e0f00cab-03b3-49cf-a2f6-595628a2593c   0/0         True                    Ready
worker-0   25596Mi   0                main-unsafe   4m17s
vg-fe679d22-2bc7-409c-85a9-9f0ee29a6ca2   0/0         True                    Ready
worker-1   25596Mi   0                main-unsafe   108s
```

Configuring the sds-local-volume module (identical disks, “Partial mirror”)

To configure the `sds-local-volume` module according to the “Partial mirror” scenario, create a LocalStorageClass resource and add the LVMVolumeGroup resources to it so that only the VG `main-`

`safe` is used on all nodes in the `sds-local-volume` module:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LocalStorageClass
metadata:
  name: local-sc
spec:
  lvm:
    lvmVolumeGroups:
      - name: vg-08d3730c-9201-428d-966c-45795cba55a6
      - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
      - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
    type: Thick
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

Configuring the sds-replicated-volume module (identical disks, “Partial mirror”)

To configure the `sds-replicated-volume` module according to the “Partial mirror” scenario, follow these steps:

1. Create a ReplicatedStoragePool resource named `data-safe` and add the LVMVolumeGroup resources to it so that only the VG `main-safe` is used on all nodes in the `sds-replicated-volume` module for ReplicatedStorageClass with the parameter `replication: None`:

   ```
   d8 k apply -f -<<EOF
   apiVersion: storage.deckhouse.io/v1alpha1
   kind: ReplicatedStoragePool
   metadata:
     name: data-safe
   spec:
     type: LVM
     lvmVolumeGroups:
       - name: vg-08d3730c-9201-428d-966c-45795cba55a6
       - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
       - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
   EOF
   ```

2. Create a ReplicatedStoragePool resource named `data-unsafe` and add the LVMVolumeGroup resources to it so that only the VG `main-unsafe` is used on all nodes in the `sds-replicated-volume` module for ReplicatedStorageClass with the parameter `replication: Availability` or `replication: ConsistencyAndAvailability`:

   ```
   d8 k apply -f -<<EOF
   apiVersion: storage.deckhouse.io/v1alpha1
   kind: ReplicatedStoragePool
   metadata:
     name: data-unsafe
   spec:
     type: LVM
     lvmVolumeGroups:
       - name: vg-deccf08a-44d4-45f2-aea9-6232c0eeef91
       - name: vg-e0f00cab-03b3-49cf-a2f6-595628a2593c
       - name: vg-fe679d22-2bc7-409c-85a9-9f0ee29a6ca2
   EOF
   ```

3. Create a ReplicatedStorageClass resource and specify the name of the previously created ReplicatedStoragePool resources in the `storagePool` field so that the VGs `main-safe` and `main-unsafe` are used on all nodes:

```
d8 k apply -f -<<EOF
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-r1
spec:
  storagePool: data-safe # Note that due to replication: None, this resource
uses data-safe; therefore, data replication for persistent volumes (PV) created
with this StorageClass will not be performed.
  replication: None
  reclaimPolicy: Delete
  topology: Ignored # If this topology is specified, there should be no zones
in the cluster (nodes with labels topology.kubernetes.io/zone).
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-r2
spec:
  storagePool: data-unsafe # Note that due to replication: Availability, this
resource uses data-unsafe; therefore, data replication for PVs created with
this StorageClass will be performed.
  replication: Availability
  reclaimPolicy: Delete
  topology: Ignored
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-r3
spec:
  storagePool: data-unsafe # Note that due to replication:
ConsistencyAndAvailability, this resource uses data-unsafe; therefore, data
replication for PVs created with this StorageClass will be performed.
  replication: ConsistencyAndAvailability
  reclaimPolicy: Delete
  topology: Ignored
EOF
```

Combined storage

Combined storage involves the simultaneous use of disks of different types on a node.

When combining disks of different types to create storage, we recommend creating a mirror from disks of one type and installing the operating system on it according to the “Full mirror” scenario, but not using it for SDS.

For SDS, use disks of other types (hereinafter referred to as additional disks) that differ from those used for the mirror under the operating system.

Recommendations for using additional disks depending on their type:

Disk type	Recommended use cases
NVMe SSD	Creating volumes that require high performance
SATA SSD	Creating volumes that do not require high performance
HDD	Creating volumes that do not require high performance

Additional disks can be configured according to either the “Full mirror” or “Partial mirror” scenarios.

Below, the process of configuring additional disks will be considered using the following types as

examples:

- NVMe SSD
- SATA SSD
- HDD

Configuring additional disks (Full mirror)

⚠ The following describes the procedure for configuring additional disks for the case of initial deployment and configuration of the cluster when connecting to nodes via SSH. If you already have a running cluster and are adding additional disks to its nodes, it is recommended to create and configure VGs using the LVMVolumeGroup resource instead of executing the commands below on the node.

To configure additional disks on a node according to the “Full mirror” scenario, follow these steps:

1. Assemble a mirror from all additional disks of a certain type entirely (hardware or software).
2. Create a VG named `<vg-name>` on the mirror.
3. Set the tag `storage.deckhouse.io/enabled=true` for the VG `<vg-name>` using the following command:

   ```
   vgchange <vg-name> --addtag storage.deckhouse.io/enabled=true
   ```

i In the example above, replace `<vg-name>` with an informative name depending on the type of additional disks.

Examples of VG names for additional disks of different types:

- `ssd-nvme`: For NVMe SSD disks.
- `ssd-sata`: For SATA SSD disks.
- `hdd`: For HDD disks.

Example of configuring SDS modules (combined storage, “Full mirror”)

In this example, it is assumed that you have configured three nodes according to the “Full Mirror” scenario. In the Deckhouse cluster, three LVMVolumeGroup resources with randomly generated names will appear. In the future, it will be possible to specify a name for the LVMVolumeGroup resources created during the automatic VG discovery process using the `LVM` tag with the desired resource name.

To list the LVMVolumeGroup resources, execute the following command:

```
d8 k get lvmvolumegroups.storage.deckhouse.io
```

The result will be a list like this:

```
NAME                                     THINPOOLS   CONFIGURATION APPLIED   PHASE
NODE       SIZE      ALLOCATED SIZE   VG          AGE
vg-08d3730c-9201-428d-966c-45795cba55a6   0/0         True                    Ready
worker-2   25596Mi   0                <vg-name>   61s
vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d   0/0         True                    Ready
worker-0   25596Mi   0                <vg-name>   4m17s
vg-c7863e12-c143-42bb-8e33-d578ce50d6c7   0/0         True                    Ready
worker-1   25596Mi   0                <vg-name>   108s
```

Where `<vg-name>` is the name assigned to the VG on the mirror in the previous step.

Configuring the sds-local-volume module (combined storage, “Full mirror”)

To configure the `sds-local-volume` module according to the “Full Mirror” scenario, create a LocalStorageClass resource and add all LVMVolumeGroup resources to it so that the VG `<vg-name>` is used on all nodes in the `sds-local-volume` module:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LocalStorageClass
metadata:
  name: <local-storage-class-name>
spec:
  lvm:
    lvmVolumeGroups:
      - name: vg-08d3730c-9201-428d-966c-45795cba55a6
      - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
      - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
    type: Thick
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

i In the example above, replace `<local-storage-class-name>` with an informative name depending on the type of additional disks.

Examples of informative names for the LocalStorageClass resource for additional disks of different types:

- `local-sc-ssd-nvme`: For NVMe SSD disks.
- `local-sc-ssd-sata`: For SATA SSD disks.
- `local-sc-hdd`: For HDD disks.

Configuring the sds-replicated-volume module (combined storage, “Full mirror”)

To configure the `sds-replicated-volume` module according to the “Full Mirror” scenario, follow these steps:

1. Create a ReplicatedStoragePool resource and add all LVMVolumeGroup resources to it so that the VG `<vg-name>` is used on all nodes in the `sds-replicated-volume` module:

   ```
   d8 k apply -f -<<EOF
   apiVersion: storage.deckhouse.io/v1alpha1
   kind: ReplicatedStoragePool
   metadata:
     name: <replicated-storage-pool-name>
   spec:
     type: LVM
     lvmVolumeGroups:
       - name: vg-08d3730c-9201-428d-966c-45795cba55a6
       - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
       - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
   EOF
   ```

   i In the example above, replace `<replicated-storage-pool-name>` with an informative name depending on the type of additional disks.

   Examples of informative names for the ReplicatedStoragePool resource for additional disks of different types:

   - `data-ssd-nvme`: For NVMe SSD disks.
   - `data-ssd-sata`: For SATA SSD disks.
   - `data-hdd`: For HDD disks.

2. Create a ReplicatedStorageClass resource and specify the name of the previously created ReplicatedStoragePool resource in the `storagePool` field:

```
d8 k apply -f -<<EOF
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-ssd-nvme-r1
spec:
  storagePool: <replicated-storage-pool-name>
  replication: None
  reclaimPolicy: Delete
  topology: Ignored # If this topology is specified, there should be no zones
in the cluster (nodes with labels topology.kubernetes.io/zone).
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-ssd-nvme-r2
spec:
  storagePool: <replicated-storage-pool-name>
  replication: Availability
  reclaimPolicy: Delete
  topology: Ignored
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-ssd-nvme-r3
spec:
  storagePool: <replicated-storage-pool-name>
  replication: ConsistencyAndAvailability
  reclaimPolicy: Delete
  topology: Ignored
EOF
```

Configuring additional disks (Partial mirror)

⚠
- Do not use partitions with the same `PARTUUID`.
- Changing the `PARTUUID` of a partition on which a VG is already created is not supported.
- It is recommended to use GPT for the partition table — in MBR, `PARTUUID` is pseudo-random and contains the partition number, and there is no support for `PARTLABEL`, which may be useful for identifying partitions in Deckhouse.

⚠ The following describes the procedure for configuring additional disks for the case of initial deployment and configuration of the cluster when connecting to nodes via SSH. If you already have a running cluster and are adding additional disks to its nodes, it is recommended to create and configure VGs using the LVMVolumeGroup resource instead of executing the commands below on the node.

In this scenario, two partitions are used on each disk: one for storing SDS data that is not replicated and another for SDS data that is replicated. The first partition of each disk is used to create a mirror, and the second is used to create a separate VG without mirroring. This allows for the most efficient use of disk space.

To configure a node with additional disks according to the “Partial mirror” scenario, follow these steps:

1. Create two partitions on each additional disk.
2. Assemble a mirror from the first partitions on each disk.
3. Create a VG named `<vg-name>-safe` on the mirror.
4. Create a VG named `<vg-name>-unsafe` from the second partitions of each disk.
5. Set the tag `storage.deckhouse.io/enabled=true` for the VGs `<vg-name>-safe` and `<vg-name>-unsafe` using the following commands:

```
vgchange <vg-name>-safe --addtag storage.deckhouse.io/enabled=true
vgchange <vg-name>-unsafe --addtag storage.deckhouse.io/enabled=true
```

> **i** In the example above, replace `<vg-name>` with an informative prefix depending on the type of additional disks.
>
> Examples of informative prefixes `<vg-name>` for additional disks of different types:
>
> - `ssd-nvme`: For NVMe SSD disks.
> - `ssd-sata`: For SATA SSD disks.
> - `hdd`: For HDD disks.

Example of configuring SDS modules (Combined storage, “Partial mirror”)

In this example, it is assumed that you have configured three nodes according to the “Partial Mirror” scenario. In the Deckhouse cluster, six LVMVolumeGroup resources with randomly generated names will appear. In the future, it will be possible to specify a name for the LVMVolumeGroup resources created during the automatic VG discovery process using the `LVM` tag with the desired resource name.

To list the LVMVolumeGroup resources, execute the following command:

```
d8 k get lvmvolumegroups.storage.deckhouse.io
```

The result will be a list like this:

```
NAME                                   THINPOOLS   CONFIGURATION APPLIED   PHASE
NODE       SIZE      ALLOCATED SIZE   VG                AGE
vg-08d3730c-9201-428d-966c-45795cba55a6   0/0         True                    Ready
worker-2   25596Mi   0                <vg-name>-safe    61s
vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d   0/0         True                    Ready
worker-0   25596Mi   0                <vg-name>-safe    4m17s
vg-c7863e12-c143-42bb-8e33-d578ce50d6c7   0/0         True                    Ready
worker-1   25596Mi   0                <vg-name>-safe    108s
vg-deccf08a-44d4-45f2-aea9-6232c0eeef91   0/0         True                    Ready
worker-2   25596Mi   0                <vg-name>-unsafe  61s
vg-e0f00cab-03b3-49cf-a2f6-595628a2593c   0/0         True                    Ready
worker-0   25596Mi   0                <vg-name>-unsafe  4m17s
vg-fe679d22-2bc7-409c-85a9-9f0ee29a6ca2   0/0         True                    Ready
worker-1   25596Mi   0                <vg-name>-unsafe  108s
```

Where `<vg-name>` is the prefix of the name assigned to the VGs created in the previous step.

Configuring the sds-local-volume module (combined storage, “Partial mirror”)

To configure the `sds-local-volume` module according to the “Partial Mirror” scenario, create a LocalStorageClass resource and add the LVMVolumeGroup resources to it so that only the VG `<vg-name>-safe` is used on all nodes in the `sds-local-volume` module:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LocalStorageClass
metadata:
  name: <local-storage-class-name>
spec:
  lvm:
    lvmVolumeGroups:
      - name: vg-08d3730c-9201-428d-966c-45795cba55a6
      - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
      - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
    type: Thick
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

i In the example above, replace `<local-storage-class-name>` with an informative name depending on the type of additional disks.

Examples of informative names for the LocalStorageClass resource for additional disks of different types:

- `local-sc-ssd-nvme`: For NVMe SSD disks.
- `local-sc-ssd-sata`: For SATA SSD disks.
- `local-sc-hdd`: For HDD disks.

Configuring the sds-replicated-volume module (combined storage, “Partial mirror”)

To configure the `sds-replicated-volume` module according to the “Partial mirror” scenario, follow these steps:

1. Create a ReplicatedStoragePool resource named `data-<vg-name>-safe` and add the LVMVolumeGroup resources to it so that only the VG `<vg-name>-safe` is used on all nodes in the `sds-replicated-volume` module for ReplicatedStorageClass with the parameter `replication: None`:

   ```
   d8 k apply -f -<<EOF
   apiVersion: storage.deckhouse.io/v1alpha1
   kind: ReplicatedStoragePool
   metadata:
     name: data-<vg-name>-safe
   spec:
     type: LVM
     lvmVolumeGroups:
       - name: vg-08d3730c-9201-428d-966c-45795cba55a6
       - name: vg-b59ff9e1-6ef2-4761-b5d2-6172926d4f4d
       - name: vg-c7863e12-c143-42bb-8e33-d578ce50d6c7
   EOF
   ```

   i In the example above, replace `data-<vg-name>-safe` with an informative name depending on the type of additional disks.

   Examples of informative names for the ReplicatedStoragePool resource for additional disks of different types:

   - `data-ssd-nvme-safe`: For NVMe SSD disks.
   - `data-ssd-sata-safe`: For SATA SSD disks.
   - `data-hdd-safe`: For HDD disks.

2. Create a ReplicatedStoragePool resource named `data-<vg-name>-unsafe` and add the LVMVolumeGroup resources to it so that only the VG `<vg-name>-unsafe` is used on all nodes in the `sds-replicated-volume` module for ReplicatedStorageClass with the parameter `replication: Availability` or `replication: ConsistencyAndAvailability`:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStoragePool
metadata:
  name: data-<vg-name>-unsafe
spec:
  type: LVM
  lvmVolumeGroups:
    - name: vg-deccf08a-44d4-45f2-aea9-6232c0eeef91
    - name: vg-e0f00cab-03b3-49cf-a2f6-595628a2593c
    - name: vg-fe679d22-2bc7-409c-85a9-9f0ee29a6ca2
EOF
```

> **i** In the example above, replace `data-<vg-name>-unsafe` with an informative name depending on the type of additional disks.
>
> Examples of informative names for the ReplicatedStoragePool resource for additional disks of different types:
>
> - `data-ssd-nvme-unsafe`: For NVMe SSD disks.
> - `data-ssd-sata-unsafe`: For SATA SSD disks.
> - `data-hdd-unsafe`: For HDD disks.

3. Create a ReplicatedStorageClass resource and specify the name of the previously created ReplicatedStoragePool resources in the `storagePool` field so that the VGs `<vg-name>-safe` and `<vg-name>-unsafe` are used on all nodes:

```
d8 k apply -f -<<EOF
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-ssd-nvme-r1
spec:
  storagePool: data-<vg-name>-safe # Note that due to replication: None, this
resource uses data-<vg-name>-safe; therefore, data replication for PVs created
with this StorageClass will not be performed.
  replication: None
  reclaimPolicy: Delete
  topology: Ignored # If this topology is specified, there should be no zones
in the cluster (nodes with labels topology.kubernetes.io/zone).
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-ssd-nvme-r2
spec:
  storagePool: data-<vg-name>-unsafe # Note that due to replication:
Availability, this resource uses data-<vg-name>-unsafe; therefore, data
replication for PVs created with this StorageClass will be performed.
  replication: Availability
  reclaimPolicy: Delete
  topology: Ignored
---
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-sc-ssd-nvme-r3
spec:
  storagePool: data-<vg-name>-unsafe # Note that due to replication:
ConsistencyAndAvailability, this resource uses data-<vg-name>-unsafe;
therefore, data replication for PVs created with this StorageClass will be
performed.
  replication: ConsistencyAndAvailability
  reclaimPolicy: Delete
  topology: Ignored
EOF
```

i

In the example above, replace `data-<vg-name>-unsafe` with an informative name depending on the type of additional disks.

Examples of informative names for the ReplicatedStoragePool resource for additional disks of different types:

- `data-ssd-nvme-unsafe`: For NVMe SSD disks.
- `data-ssd-sata-unsafe`: For SATA SSD disks.
- `data-hdd-unsafe`: For HDD disks.

In a similar way, replace `data-<vg-name>-safe`.

Examples of informative names for the ReplicatedStoragePool resource for additional disks of different types:

- `data-ssd-nvme-safe`: For NVMe SSD disks.
- `data-ssd-sata-safe`: For SATA SSD disks.
- `data-hdd-safe`: For HDD disks.

FAQ

> Functionality is guaranteed only when using stock kernels supplied with supported distributions. When using non-standard kernels or distributions, behavior may be unpredictable.

Reasons why BlockDevice resources aren’t created in the cluster

Most often, BlockDevice resources are not created because the available devices do not pass the controller’s filters. Ensure that the devices meet the selection criteria.

Reasons why LVMVolumeGroup resources aren’t created in the cluster

- Absence of BlockDevice: The controller will not create an LVMVolumeGroup if there are no BlockDevice resources in the cluster specified in its specification.
- Absence of a tag: If BlockDevice resources are present but the LVMVolumeGroup is missing, check that the corresponding LVM group on the node has the tag `storage.deckhouse.io/enabled=true`.

Reasons why after deleting the LVMVolumeGroup, the resource and Volume Group remain

This situation is possible in two cases:

1. There are logical volumes in the Volume Group — the controller is not responsible for deleting logical volumes on the node, so if there are any logical volumes in the Volume Group created via the resource, they must be manually deleted. After that, both the LVMVolumeGroup resource and the Volume Group itself (including physical volumes) will be automatically deleted.
2. The resource has the annotation `storage.deckhouse.io/deletion-protection` — this annotation protects the resource from deletion, along with the associated Volume Group. Remove the annotation with the command:

   ```
   d8 k annotate lvg <resource-name> storage.deckhouse.io/deletion-protection-
   ```

   After that, the LVMVolumeGroup resource and the corresponding Volume Group will be automatically deleted.

Reasons for failed attempts to create a Volume Group using the LVMVolumeGroup resource

Most likely, the resource did not pass validation by the controller (unlike the Kubernetes schema). The reason can be found in the `status.message` field of the LVMVolumeGroup resource or in the controller logs. Check that the specified BlockDevice resources meet the conditions:

- The `consumable` field is set to `true`.
- For `spec.type: Local`, all BlockDevice resources belong to the same node.
- Current names of BlockDevice resources are used.

Behavior of the LVMVolumeGroup resource when one of the devices in the Volume Group is disabled

The LVMVolumeGroup resource remains as long as the corresponding LVM group exists. When a device becomes unavailable, the group enters an error state, which is reflected in the `status` field.

After the device is restored, the group returns to the `Healthy` status, and the resource status is

automatically updated.

Transferring management of an existing Volume Group on the node to the controller

Add the tag `storage.deckhouse.io/enabled=true` to the desired Volume Group:

```
vgchange myvg-0 --addtag storage.deckhouse.io/enabled=true
```

The controller will create the corresponding LVMVolumeGroup resource and take over management of the group.

Disabling tracking of the LVM Volume Group by the controller

Remove the tag `storage.deckhouse.io/enabled=true`:

```
vgchange myvg-0 --deltag storage.deckhouse.io/enabled=true
```

The controller will stop tracking and delete the associated LVMVolumeGroup resource.

Reasons for automatic setting of the tag storage.deckhouse.io/enabled=true on the Volume Group

The controller adds the tag when creating the Volume Group through the LVMVolumeGroup resource.

When migrating from the `linstor` module to `sds-node-configurator` and `sds-replicated-volume`, all `linstor-*` tags are replaced with `storage.deckhouse.io/enabled=true` to transfer management to the new logic.

Using the LVMVolumeGroupSet resource to create LVMVolumeGroup

The LVMVolumeGroupSet resource allows template-based creation of LVMVolumeGroup on nodes. Currently, the PerNode strategy is supported — one resource per node that matches the selector.

Example specification of LVMVolumeGroupSet:

```
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroupSet
metadata:
  name: my-lvm-volume-group-set
  labels:
    my-label: my-value
spec:
  strategy: PerNode
  nodeSelector:
    matchLabels:
      node-role.kubernetes.io/worker: ""
  lvmVolumeGroupTemplate:
    metadata:
      labels:
        my-label-for-lvg: my-value-for-lvg
    spec:
      type: Local
      blockDeviceSelector:
        matchLabels:
          status.blockdevice.storage.deckhouse.io/model: <model>
      actualVGNameOnTheNode: <VG-name-on-the-node>
```

Labels added by the controller to BlockDevice resources

- `status.blockdevice.storage.deckhouse.io/type`: LVM type.
- `status.blockdevice.storage.deckhouse.io/fstype`: File system type.
- `status.blockdevice.storage.deckhouse.io/pvuuid`: Physical volume (PV) UUID.

- `status.blockdevice.storage.deckhouse.io/vguuid`: Volume group (VG) UUID.
- `status.blockdevice.storage.deckhouse.io/partuuid`: Partition UUID.
- `status.blockdevice.storage.deckhouse.io/lvmvolumegroupname`: Name of the LVMVolumeGroup resource.
- `status.blockdevice.storage.deckhouse.io/actualvgnameonthenode`: Name of the LVM Volume Group on the node.
- `status.blockdevice.storage.deckhouse.io/wwn`: WWN (World Wide Name) of the device.
- `status.blockdevice.storage.deckhouse.io/serial`: Serial number of the device.
- `status.blockdevice.storage.deckhouse.io/size`: Size of the device.
- `status.blockdevice.storage.deckhouse.io/model`: Model of the device.
- `status.blockdevice.storage.deckhouse.io/rota`: Rotational device flag.
- `status.blockdevice.storage.deckhouse.io/hotplug`: Hotplug capability.
- `status.blockdevice.storage.deckhouse.io/machineid`: Identifier of the machine where the device is installed.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Setting up local storage based on LVM

Local storage reduces network latency and provides higher performance compared to remote storage accessed over a network. This approach is particularly effective in test environments and EDGE clusters. This functionality is provided by the `sds-local-volume` module.

Configuring local storage

To ensure the correct operation of the `sds-local-volume` module, follow these steps:

1. Configure LVMVolumeGroup. Before creating a StorageClass, you must create an LVMVolumeGroup resource for the `sds-node-configurator` module on the cluster nodes.
2. Enable the `sds-node-configurator` module. Ensure that the module is enabled **before** enabling the `sds-local-volume` module.
3. Create the corresponding StorageClasses. Creating a StorageClass for the CSI driver `local.csi.storage.deckhouse.io` by a user is **prohibited**.

The module supports two operating modes: LVM and LVMThin.

Quick start

All commands are executed on a machine with access to the Kubernetes API and administrator privileges.

Enabling modules

Enabling the `sds-node-configurator` module:

1. Create a ModuleConfig resource to enable the module:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: sds-node-configurator
spec:
  enabled: true
  version: 1
EOF
```

2. Wait for the module to reach the `Ready` state. At this stage, it is not necessary to check the pods in the `d8-sds-node-configurator` namespace.

```
d8 k get modules sds-node-configurator -w
```

Enabling the `sds-local-volume` module:

1. Activate the `sds-local-volume` module. The example below starts the module with default settings, which will create service pods for the `sds-local-volume` component on all cluster nodes:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: sds-local-volume
spec:
  enabled: true
  version: 1
EOF
```

2. Wait for the module to reach the `Ready` state.

```
d8 k get modules sds-local-volume -w
```

3. Ensure that all pods in the `d8-sds-local-volume` and `d8-sds-node-configurator` namespaces are in the `Running` or `Completed` state and are running on all nodes where LVM resources are planned to be used.

```
d8 k -n d8-sds-local-volume get pod -owide -w
d8 k -n d8-sds-node-configurator get pod -o wide -w
```

Preparing nodes for storage creation

For storage to function correctly on nodes, the `sds-local-volume-csi-node` pods must be running on the selected nodes.

By default, these pods are launched on all cluster nodes. You can verify their presence using the command:

```
d8 k -n d8-sds-local-volume get pod -owide
```

The placement of `sds-local-volume-csi-node` pods is managed by specific labels (`nodeSelector`). These labels are set in the `spec.settings.dataNodes.nodeSelector` parameter of the module.

Configuring storage on nodes

To configure storage on nodes, you need to create LVM volume groups using LVMVolumeGroup resources. This example creates a Thick storage.

⚠ Before creating an LVMVolumeGroup resource, ensure that the `sds-local-volume-csi-node` pod is running on the respective node. This can be checked with the command:

```
d8 k -n d8-sds-local-volume get pod -owide
```

1. Retrieve all BlockDevice resources available in your cluster:

```
d8 k get bd
```

Example output:

```
NAME                                            NODE       CONSUMABLE   SIZE
PATH
dev-ef4fb06b63d2c05fb6ee83008b55e486aa1161aa   worker-0   false
976762584Ki    /dev/nvme1n1
dev-0cfc0d07f353598e329d34f3821bed992c1ffbcd   worker-0   false
894006140416   /dev/nvme0n1p6
dev-7e4df1ddf2a1b05a79f9481cdf56d29891a9f9d0   worker-1   false
976762584Ki    /dev/nvme1n1
dev-b103062f879a2349a9c5f054e0366594568de68d   worker-1   false
894006140416   /dev/nvme0n1p6
dev-53d904f18b912187ac82de29af06a34d9ae23199   worker-2   false
976762584Ki    /dev/nvme1n1
dev-6c5abbd549100834c6b1668c8f89fb97872ee2b1   worker-2   false
894006140416   /dev/nvme0n1p6
```

2. Create an LVMVolumeGroup resource for the `worker-0` node:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-1-on-worker-0" # The name can be any fully qualified resource name
in Kubernetes. This LVMVolumeGroup resource name will be used to create
LocalStorageClass in the future.
spec:
  type: Local
  local:
    nodeName: "worker-0"
  blockDeviceSelector:
    matchExpressions:
      - key: kubernetes.io/metadata.name
        operator: In
        values:
          - dev-ef4fb06b63d2c05fb6ee83008b55e486aa1161aa
          - dev-0cfc0d07f353598e329d34f3821bed992c1ffbcd
  actualVGNameOnTheNode: "vg-1" # The name of the LVM VG that will be created
from the specified block devices on the node.
EOF
```

3. Wait for the created LVMVolumeGroup resource to transition to the `Ready` state:

```
d8 k get lvg vg-1-on-worker-0 -W
```

   If the resource has transitioned to the `Ready` state, it means that an LVM VG named `vg-1` has been created on the `worker-0` node from the block devices `/dev/nvme1n1` and `/dev/nvme0n1p6`.

4. Create an LVMVolumeGroup resource for the `worker-1` node:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-1-on-worker-1"
spec:
  type: Local
  local:
    nodeName: "worker-1"
  blockDeviceSelector:
    matchExpressions:
      - key: kubernetes.io/metadata.name
        operator: In
        values:
          - dev-7e4df1ddf2a1b05a79f9481cdf56d29891a9f9d0
          - dev-b103062f879a2349a9c5f054e0366594568de68d
  actualVGNameOnTheNode: "vg-1"
EOF
```

5. Wait for the created LVMVolumeGroup resource to transition to the `Ready` state:

   ```
   d8 k get lvg vg-1-on-worker-1 -w
   ```

   If the resource has transitioned to the `Ready` state, it means that an LVM VG named `vg-1` has been created on the `worker-1` node from the block devices `/dev/nvme1n1` and `/dev/nvme0n1p6`.

6. Create an LVMVolumeGroup resource for the `worker-2` node:

   ```
   d8 k apply -f - <<EOF
   apiVersion: storage.deckhouse.io/v1alpha1
   kind: LVMVolumeGroup
   metadata:
     name: "vg-1-on-worker-2"
   spec:
     type: Local
     local:
       nodeName: "worker-2"
     blockDeviceSelector:
       matchExpressions:
         - key: kubernetes.io/metadata.name
           operator: In
           values:
             - dev-53d904f18b912187ac82de29af06a34d9ae23199
             - dev-6c5abbd549100834c6b1668c8f89fb97872ee2b1
     actualVGNameOnTheNode: "vg-1"
   EOF
   ```

7. Wait for the created LVMVolumeGroup resource to transition to the `Ready` state:

   ```
   d8 k get lvg vg-1-on-worker-2 -w
   ```

   If the resource has transitioned to the `Ready` state, it means that an LVM VG named `vg-1` has been created on the `worker-2` node from the block devices `/dev/nvme1n1` and `/dev/nvme0n1p6`.

8. Create a LocalStorageClass resource:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LocalStorageClass
metadata:
  name: local-storage-class
spec:
  lvm:
    lvmVolumeGroups:
      - name: vg-1-on-worker-0
      - name: vg-1-on-worker-1
      - name: vg-1-on-worker-2
    type: Thick
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

For a thin volume:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LocalStorageClass
metadata:
  name: local-storage-class
spec:
  lvm:
    lvmVolumeGroups:
      - name: vg-1-on-worker-0
      - name: vg-1-on-worker-1
      - name: vg-1-on-worker-2
        thin:
          poolName: thin-1
    type: Thin
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

Important. In a LocalStorageClass with `type: Thick`, you cannot use an LVMVolumeGroup that contains at least one thin pool.

9. Wait for the created LocalStorageClass resource to transition to the `Created` state:

```
d8 k get lsc local-storage-class -w
```

10. Verify that the corresponding StorageClass has been created:

```
d8 k get sc local-storage-class
```

If a StorageClass named `local-storage-class` appears, the configuration of the `sds-local-volume` module is complete. Users can now create PVCs by specifying the StorageClass named `local-storage-class`.

Selecting a volume cleanup method after PV deletion

When files are deleted, the operating system does not physically erase the content but only marks the corresponding blocks as “free.” If a new volume receives physical blocks previously used by another volume, those blocks may still contain the previous user’s data.

This is possible, for example, in the following scenario:

- User #1 places files in a volume requested from StorageClass 1 on node 1 (in either “Block” or “Filesystem” mode).
- User #1 deletes the files and the volume.

- The physical blocks that were occupied become “free” but are not wiped.
- User #2 requests a new volume from StorageClass 1 on node 1 in “Block” mode.
- There is a risk that some or all of the blocks previously used by User #1 will be reallocated to User #2.
- In this case, User #2 may be able to recover User #1’s data.

Thick volumes

To prevent data leaks through thick volumes, the `volumeCleanup` parameter is provided. It allows you to select the volume cleanup method before deleting a PV.

Possible values:

- Parameter not set: No additional actions are performed when deleting the volume. Data may remain accessible to the next user.
- `RandomFillSinglePass`: The volume is overwritten with random data once before deletion. This option is not recommended for solid-state drives, as it reduces the drive’s lifespan.
- `RandomFillThreePass`: The volume is overwritten with random data three times before deletion. This option is not recommended for solid-state drives, as it reduces the drive’s lifespan.
- `Discard`: All volume blocks are marked as free using the `discard` system call before deletion. This option is only meaningful for solid-state drives.

  Most modern solid-state drives guarantee that a block marked with `discard` will not return previous data when read. This makes the `Discard` option the most effective way to prevent data leaks when using solid-state drives.

  However, erasing a cell is a relatively slow operation, so it is performed by the device in the background. Additionally, many drives cannot erase individual cells but only groups (pages). As a result, not all drives guarantee the immediate unavailability of freed data. Furthermore, not all drives that claim to guarantee this keep their promise. If a device does not guarantee Deterministic TRIM (DRAT), Deterministic Read Zero after TRIM (RZAT), and is not verified, it is not recommended for use.

Thin volumes

When a block in a thin volume is freed via `discard` by the guest operating system, this command is forwarded to the device. If a hard disk is used or if the solid-state drive does not support `discard`, the data may remain in the thin pool until the block is reused. However, users are only granted access to thin volumes, not the thin pool itself. They can only obtain a volume from the pool, and for thin volumes, the thin pool block is zeroed upon reuse, preventing data leaks between clients. This is ensured by the `thin_pool_zero=1` setting in LVM.

System requirements and recommendations

- Use stock kernels provided with supported distributions.
- Do not use another SDS (Software Defined Storage) to provide disks for SDS Deckhouse.

Additional resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managing local storage based on LVM

Selecting specific nodes for module usage

To restrict the module’s usage to specific cluster nodes, you need to set labels in the `nodeSelector` field in the module settings.

To display and edit the module settings, execute the command:

```
d8 k edit mc sds-local-volume
```

Configuration example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: sds-local-volume
spec:
  enabled: true
  settings:
    dataNodes:
      nodeSelector:
        my-custom-label-key: my-custom-label-value
status:
  message: ""
  version: "1"
```

To view the current labels in the `nodeSelector` field, use the following command:

```
d8 k get mc sds-local-volume -o=jsonpath={.spec.settings.dataNodes.nodeSelector}
```

Example output:

```
nodeSelector:
  my-custom-label-key: my-custom-label-value
```

The module selects only those nodes that have all the labels specified in the `nodeSelector`. By modifying this field, you can control the list of nodes on which the module will run.

> **i** You can specify multiple labels in the `nodeSelector`. However, for the module to work correctly, all these labels must be present on each node where you intend to run `sds-local-volume-csi-node`.

After configuring the labels, ensure that the `sds-local-volume-csi-node` Pods are running on the target nodes. You can check their presence with the command:

```
d8 k -n d8-sds-local-volume get pod -owide
```

Verifying PVC creation on the selected node

Make sure that the `sds-local-volume-csi-node` Pod is running on the selected node. To do this, run the command:

```
d8 k -n d8-sds-local-volume get po -owide
```

If the Pod is absent, verify that all the labels specified in the module settings in the nodeSelector field are present on the node. For available solutions when Pods are missing from the target node, refer to this section.

Removing a node from the module management

To remove a node from module management, you need to delete the labels set in the `nodeSelector` field in the `sds-local-volume` module settings.

To check the current labels, execute the command:

```
d8 k get mc sds-local-volume -o=jsonpath={.spec.settings.dataNodes.nodeSelector}
```

Example output:

```
nodeSelector:
  my-custom-label-key: my-custom-label-value
```

Remove the specified labels from the nodes with the command:

```
d8 k label node %node-name% %label-from-selector%-
```

⚠ After the label key, you must specify a minus sign to remove it.

After this, the `sds-local-volume-csi-node` Pod should be removed from the node. Check its status with the command:

```
d8 k -n d8-sds-local-volume get po -owide
```

If the Pod remains after removing the label, ensure that the labels from the `d8-sds-local-volume-controller-config` config are actually removed. You can verify this using:

```
d8 k get node %node-name% --show-labels
```

If the labels are absent, check that the node does not have any LVMVolumeGroup resources being used by LocalStorageClass resources. More information on this check can be found in this section.

⚠ Note that for LVMVolumeGroup and LocalStorageClass resources that are the reason why the node cannot be removed from module management, the label `storage.deckhouse.io/sds-local-volume-candidate-for-eviction` will be assigned.

On the node itself, the label `storage.deckhouse.io/sds-local-volume-need-manual-eviction` will be present.

Verifying dependent LVMVolumeGroup resources on the node

To check the dependent resources, follow these steps:

1. Display the available LocalStorageClass resources:

   ```
   d8 k get lsc
   ```

2. Check each of them for the list of used LVMVolumeGroup resources.

   If you want to list all LocalStorageClass resources at once, run the command:

   ```
   d8 k get lsc -oyaml
   ```

   Example LocalStorageClass resource:

```
apiVersion: v1
items:
- apiVersion: storage.deckhouse.io/v1alpha1
  kind: LocalStorageClass
  metadata:
    finalizers:
    - localstorageclass.storage.deckhouse.io
    name: test-sc
  spec:
    lvm:
      lvmVolumeGroups:
      - name: test-vg
      type: Thick
    reclaimPolicy: Delete
    volumeBindingMode: WaitForFirstConsumer
  status:
    phase: Created
kind: List
```

Pay attention to the `spec.lvm.lvmVolumeGroups` field. It specifies the used LVMVolumeGroup resources.

3. Display the list of existing LVMVolumeGroup resources.

   ```
   d8 k get lvg
   ```

   Example LVMVolumeGroup output:

   ```
   NAME              HEALTH        NODE            SIZE       ALLOCATED SIZE   VG        AGE
   lvg-on-worker-0   Operational   node-worker-0   40956Mi    0                test-vg   15d
   lvg-on-worker-1   Operational   node-worker-1   61436Mi    0                test-vg   15d
   lvg-on-worker-2   Operational   node-worker-2   122876Mi   0                test-vg   15d
   lvg-on-worker-3   Operational   node-worker-3   307196Mi   0                test-vg   15d
   lvg-on-worker-4   Operational   node-worker-4   307196Mi   0                test-vg   15d
   lvg-on-worker-5   Operational   node-worker-5   204796Mi   0                test-vg   15d
   ```

4. Ensure that the node you intend to remove from the module's control does not have any LVMVolumeGroup resources used in LocalStorageClass resources. To avoid unintentionally losing control over volumes already created using the module, the user needs to manually delete dependent resources by performing necessary operations on the volume.

Remaining sds-local-volume-csi-node Pod after removing labels

If after removing the labels from the node the `sds-local-volume-csi-node` Pod continues to run, this is most likely due to the presence on the node of LVMVolumeGroup resources that are used by one of the LocalStorageClass resources. The verification process is described above.

Absence of component service Pods on the desired node

The issue may be related to incorrectly set labels. The nodes used by the module are determined by the labels specified in the module settings in the `nodeSelector` field. To view the current labels, run:

```
d8 k get mc sds-local-volume -o=jsonpath={.spec.settings.dataNodes.nodeSelector}
```

Example output:

```
nodeSelector:
  my-custom-label-key: my-custom-label-value
```

Additionally, you can check the selectors used by the module in the secret configuration `d8-sds-local-volume-controller-config` in the `d8-sds-local-volume` namespace:

```
d8 k -n d8-sds-local-volume get secret d8-sds-local-volume-controller-config  -o
jsonpath='{.data.config}' | base64 --decode
```

Example output:

```
nodeSelector:
  kubernetes.io/os: linux
  my-custom-label-key: my-custom-label-value
```

This command output should list all the labels from the module settings `data.nodeSelector`, as well as `kubernetes.io/os: linux`.

Check the labels on the desired node:

```
d8 k get node %node-name% --show-labels
```

If necessary, add the missing labels to the desired node:

```
d8 k label node %node-name% my-custom-label-key=my-custom-label-value
```

If the labels are present, check for the presence of the label `storage.deckhouse.io/sds-local-volume-node=` on the node. If this label is missing, ensure that the `sds-local-volume-controller` is running, and review its logs:

```
d8 k -n d8-sds-local-volume get po -l app=sds-local-volume-controller
d8 k -n d8-sds-local-volume logs -l app=sds-local-volume-controller
```

Data migration between PVCs

Copy the following script into a file named `migrate.sh` on any master node:

```
#!/bin/bash

ns=$1
src=$2
dst=$3

if [[ -z $3 ]]; then
  echo "You must give as args: namespace source_pvc_name destination_pvc_name"
  exit 1
fi

echo "Creating job yaml"
cat > migrate-job.yaml << EOF
apiVersion: batch/v1
kind: Job
metadata:
  name: migrate-pv-$src
  namespace: $ns
spec:
  template:
    spec:
      containers:
      - name: migrate
        image: debian
        command: [ "/bin/bash", "-c" ]
        args:
          -
            apt-get update && apt-get install -y rsync &&
            ls -lah /src_vol /dst_vol &&
            df -h &&
            rsync -avPS --delete /src_vol/ /dst_vol/ &&
            ls -lah /dst_vol/ &&
            du -shxc /src_vol/ /dst_vol/
        volumeMounts:
```

```
        - mountPath: /src_vol
          name: src
          readOnly: true
        - mountPath: /dst_vol
          name: dst
      restartPolicy: Never
      volumes:
      - name: src
        persistentVolumeClaim:
          claimName: $src
      - name: dst
        persistentVolumeClaim:
          claimName: $dst
  backoffLimit: 1
EOF

d8 k create -f migrate-job.yaml
d8 k -n $ns get jobs -o wide
kubectl_completed_check=0

echo "Waiting for data migration to be completed"
while [[ $kubectl_completed_check -eq 0 ]]; do
    d8 k -n $ns get pods | grep migrate-pv-$src
   sleep 5
   kubectl_completed_check=`d8 k -n $ns get pods | grep migrate-pv-$src | grep "Completed" |
wc -l`
done
echo "Data migration completed"
```

To use the script, run the following command:

```
migrate.sh NAMESPACE SOURCE_PVC_NAME DESTINATION_PVC_NAME
```

Creating volume snapshots

You can read more about snapshots and associated resources in the Kubernetes documentation.

1. Enable the `snapshot-controller` module:

   ```
   d8 k apply -f -<<EOF
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: snapshot-controller
   spec:
     enabled: true
     version: 1
   EOF
   ```

2. Now you can create volume snapshots. To do this, execute the following command with the necessary parameters:

```
d8 k apply -f -<<EOF
apiVersion: snapshot.storage.k8s.io/v1
kind: VolumeSnapshot
metadata:
  name: my-snapshot
  namespace: <name of the namespace where the PVC is located>
spec:
  volumeSnapshotClassName: sds-local-volume-snapshot-class
  source:
    persistentVolumeClaimName: <name of the PVC to snapshot>
EOF
```

Note that `sds-local-volume-snapshot-class` is created automatically, and its `deletionPolicy` is set to `Delete`, which means that the VolumeSnapshotContent resource will be deleted when the associated VolumeSnapshot resource is deleted.

3. To check the status of the created snapshot, execute the command:

   ```
   d8 k get volumesnapshot
   ```

   This command will display a list of all snapshots and their current status.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Setting up replicated storage based on DRBD

Data replication across multiple nodes ensures fault tolerance and data availability, even if a hardware or software failure occurs on one of the nodes. This guarantees data preservation on other nodes, maintaining continuous access. Such a model is essential for critical data and distributed infrastructures requiring high availability and minimizing data loss during failures.

To create replicated block StorageClass objects based on Distributed Replicated Block Device (DRBD), the `sds-replicated-volume` module is used. It leverages LINSTOR as the backend.

Enabling the module

Discovery of LVM components

Before creating StorageClass objects based on Logical Volume Manager (LVM), it is necessary to detect the block devices and volume groups available on the nodes and obtain current information about their state. To do this, enable the `sds-node-configurator` module:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: sds-node-configurator
spec:
  enabled: true
  version: 1
EOF
```

Wait for the `sds-node-configurator` module to reach the `Ready` status. To check the status, run the following command:

```
d8 k get modules sds-node-configurator -w
```

In the output, you should see information about the `sds-node-configurator` module:

```
NAME                      STAGE   SOURCE     PHASE       ENABLED    READY
sds-node-configurator             Embedded   Available   True       True
```

Connecting DRBD

To enable the `sds-replicated-volume` module with default settings, run the following command:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: sds-replicated-volume
spec:
  enabled: true
  version: 1
EOF
```

This will install the DRBD kernel module on all cluster nodes, register the CSI driver, and launch the `sds-replicated-volume` component Pods.

Wait until the `sds-replicated-volume` module reaches the `Ready` status. To check the module status, run the following command:

```
d8 k get modules sds-replicated-volume -w
```

In the output, you should see information about the `sds-replicated-volume` module:

```
NAME                      STAGE   SOURCE     PHASE       ENABLED    READY
sds-replicated-volume             Embedded   Available   True       True
```

To check that all Pods in the `d8-sds-replicated-volume` and `d8-sds-node-configurator` namespaces are in the `Running` or `Completed` state and have been started on all nodes where DRBD resources are planned to be used, use the following commands:

```
d8 k -n d8-sds-replicated-volume get pod -w
d8 k -n d8-sds-node-configurator get pod -w
```

> **i** Avoid configuring the `LINSTOR` backend manually, as this can can result in errors.

Node pre-configuration

Creating LVM volume groups

Before configuring the creation of StorageClass objects, you need to combine the available block devices on the nodes into LVM volume groups. These volume groups will later be used to place PersistentVolumes. To get the available block devices, you can use the BlockDevice resource, which reflects their current state:

```
d8 k get bd
```

In the output, you should see a list of available block devices:

```
NAME                                             NODE       CONSUMABLE   SIZE
PATH
dev-ef4fb06b63d2c05fb6ee83008b55e486aa1161aa   worker-0   false        976762584Ki
/dev/nvme1n1
dev-0cfc0d07f353598e329d34f3821bed992c1ffbcd   worker-0   false        894006140416
/dev/nvme0n1p6
dev-7e4df1ddf2a1b05a79f9481cdf56d29891a9f9d0   worker-1   false        976762584Ki
/dev/nvme1n1
dev-b103062f879a2349a9c5f054e0366594568de68d   worker-1   false        894006140416
/dev/nvme0n1p6
dev-53d904f18b912187ac82de29af06a34d9ae23199   worker-2   false        976762584Ki
/dev/nvme1n1
dev-6c5abbd549100834c6b1668c8f89fb97872ee2b1   worker-2   false        894006140416
/dev/nvme0n1p6
```

In the example output, there are six block devices available across three nodes.

To combine the block devices on a node, you need to create an LVM volume group using the LVMVolumeGroup resource. To create the LVMVolumeGroup resource on node `worker-0`, apply the following resource, replacing the node and block device names with your own:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: LVMVolumeGroup
metadata:
  name: "vg-on-worker-0"
spec:
  type: Local
  local:
    # Replace with the name of the node where you are creating the volume group.
    nodeName: "worker-0"
  blockDeviceSelector:
    matchExpressions:
      - key: kubernetes.io/metadata.name
        operator: In
        values:
          # Replace with the names of the block devices for the node you are
creating the volume group on.
          - dev-ef4fb06b63d2c05fb6ee83008b55e486aa1161aa
          - dev-0cfc0d07f353598e329d34f3821bed992c1ffbcd
  # The name of the LVM volume group that will be created from the specified block
devices on the selected node.
  actualVGNameOnTheNode: "vg"
  # Uncomment if you want to be able to create thin pools.
  # thinPools:
  #   - name: thin-pool-0
  #     size: 70%
EOF
```

Wait for the created LVMVolumeGroup resource to reach the `Ready` phase. To check the resource phase, run the following command:

```
d8 k get lvg vg-on-worker-0 -w
```

In the output, you should see information about the resource phase:

```
NAME             THINPOOLS   CONFIGURATION APPLIED   PHASE   NODE       SIZE
ALLOCATED SIZE   VG   AGE
vg-on-worker-0   1/1         True                    Ready   worker-0   360484Mi
30064Mi          vg   1h
```

If the resource has transitioned to the `Ready` phase, this means that an LVM volume group named vg has been created on node `worker-0` from the block devices `/dev/nvme1n1` and `/dev/nvme0n1p6`.

Next, you need to repeat the creation of LVMVolumeGroup resources for the remaining nodes (`worker-1` and `worker-2`), changing the resource name, node name, and block device names accordingly.

Ensure that LVM volume groups have been created on all nodes where they are planned to be used by running the following command:

```
d8 k get lvg -W
```

In the output, you should see a list of created volume groups:

```
NAME             THINPOOLS   CONFIGURATION APPLIED   PHASE   NODE       SIZE
ALLOCATED SIZE   VG   AGE
vg-on-worker-0   0/0         True                    Ready   worker-0   360484Mi
30064Mi          vg   1h
vg-on-worker-1   0/0         True                    Ready   worker-1   360484Mi
30064Mi          vg   1h
vg-on-worker-2   0/0         True                    Ready   worker-2   360484Mi
30064Mi          vg   1h
```

Creating replicated thick pools

> **i** To work with thin pool, you need to enable the parameter enableThinProvisioning

Now that the necessary LVM volume groups are created on the nodes, you need to combine them into a single logical space. This can be done by combining them into replicated storage pools in the `LINSTOR` backend through the ReplicatedStoragePool resource interface.

Storage pools can be of two types: LVM (thick) and LVMThin (thin). The thick pool offers high performance, comparable to the performance of the storage device, but it does not allow snapshots. Example of creating a replicated thick pool:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStoragePool
metadata:
  name: thick-pool
spec:
  type: LVM
  lvmVolumeGroups:
    - name: vg-1-on-worker-0
    - name: vg-1-on-worker-1
    - name: vg-1-on-worker-2
EOF
```

Wait for the created ReplicatedStoragePool resource to reach the `Completed` phase. To check the resource phase, run the following command:

```
d8 k get rsp data -W
```

In the output, you should see information about the resource phase:

```
NAME         PHASE       TYPE   AGE
thick-pool   Completed   LVM    87d
```

Creating replicated thin pools

Unlike thick pools, a thin pool allows the use of snapshots but has lower performance.

The previously created LVMVolumeGroup is suitable for creating thick pools. If you need the ability to

create replicated thin pools, update the configuration of the LVMVolumeGroup resources by adding a definition for the thin pool:

```
d8 k patch lvg vg-on-worker-0 --type='json' -p='[
  {
    "op": "add",
    "path": "/spec/thinPools",
    "value": [
      {
        "name": "thin-pool-0",
        "size": "70%"
      }
    ]
  }
]'
```

In the updated version of LVMVolumeGroup, 70% of the available space will be used to create thin pools. The remaining 30% can be used for thick pools.

Repeat the addition of thin pools for the remaining nodes (`worker-1` and `worker-2`). Example of creating a replicated thin pool:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStoragePool
metadata:
  name: thin-pool
spec:
  type: LVMThin
  lvmVolumeGroups:
    - name: vg-1-on-worker-0
      thinPoolName: thin-pool-0
    - name: vg-1-on-worker-1
      thinPoolName: thin-pool-0
    - name: vg-1-on-worker-2
      thinPoolName: thin-pool-0
EOF
```

Wait for the created ReplicatedStoragePool resource to transition to the `Completed` phase. To check the resource phase, run the following command:

```
d8 k get rsp data -w
```

In the output, you should see information about the resource phase:

```
NAME        PHASE       TYPE      AGE
thin-pool   Completed   LVMThin   87d
```

Creating StorageClass objects

StorageClass objects are created through the ReplicatedStorageClass resource, which defines the configuration for the desired StorageClass. Manually creating a StorageClass resource without ReplicatedStorageClass may lead to undesired behavior.

Example of creating a ReplicatedStorageClass resource based on a thick pool, where the PersistentVolumes will be placed on volume groups across three nodes:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: ReplicatedStorageClass
metadata:
  name: replicated-storage-class
spec:
  # Specify the name of one of the storage pools created earlier.
  storagePool: thick-pool
  # Reclaim policy when deleting PVC.
  # Allowed values: "Delete", "Retain".
  # [Learn more...](https://kubernetes.io/docs/concepts/storage/persistent-
volumes/#reclaiming)
  reclaimPolicy: Delete
  # Replicas can be placed on any available node: no more than one replica of a
specific volume on one node.
  # The cluster does not have zones (no nodes with the topology.kubernetes.io/zone
labels).
  topology: Ignored
  # Replication mode where the volume remains available for read and write even if
one replica becomes unavailable.
  # Data is stored in three instances across different nodes.
  replication: ConsistencyAndAvailability
EOF
```

Check that the created ReplicatedStorageClass resource has transitioned to the `Created` phase by running the following command:

```
d8 k get rsc replicated-storage-class -w
```

In the output, you should see information about the created ReplicatedStorageClass resource:

```
NAME                        PHASE     AGE
replicated-storage-class    Created   1h
```

Check that the corresponding StorageClass has been generated by running the following command:

```
d8 k get sc replicated-storage-class
```

In the output, you should see information about the generated StorageClass:

```
NAME                        PROVISIONER                       RECLAIMPOLICY
VOLUMEBINDINGMODE      ALLOWVOLUMEEXPANSION   AGE
replicated-storage-class    local.csi.storage.deckhouse.io    Delete
WaitForFirstConsumer   true                   1h
```

If a StorageClass with the name `replicated-storage-class` appears, it means the configuration of the `sds-replicated-volume` module is complete. Users can now create PersistentVolume objects by specifying the `replicated-storage-class` StorageClass. With the above configuration, a volume with three replicas across different nodes will be created.

Additional resources

- Module `sds-node-configurator` documentation
- Module `sds-replicated-volume` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managing DRBD-based replicated storage

⚠ Functionality is guaranteed only if the system requirements are met. Using it under other conditions is possible, but stable operation is not guaranteed.

System requirements

i Applicable to both single-zone clusters and clusters that use multiple availability zones.

- Use stock kernels shipped with the supported distributions.
- For network connectivity, use infrastructure with bandwidth of 10 Gbps or higher.
- To achieve maximum performance, network latency between nodes should be within 0.5–1 ms.
- Do not use another SDS (Software-defined storage) to provide disks for Deckhouse SDS.

Recommendations

- Do not use RAID. See below for details.
- Use local physical disks. See below.
- For stable cluster operation (with reduced performance), allowable network latency between nodes must not exceed 20 ms.

Retrieving space-usage information

There are two ways to obtain this information:

1. Via the Grafana dashboard:

   Go to “Dashboards” → “Storage” → “LINSTOR/DRBD”. The current cluster space usage level is shown in the upper-right corner.

   i **Warning.** The value reflects the state of all available space. When you create volumes with two replicas, divide the reported figures by two to estimate how many volumes can actually be placed.

2. Via the command line:

   ```
   d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor storage-pool list
   ```

   i **Warning.** The value reflects the state of all available space. When you create volumes with two replicas, divide the reported figures by two to estimate how many volumes can actually be placed.

Assigning the default StorageClass

To designate a StorageClass as the default, set the field `spec.isDefault` to `true` in the ReplicatedStorageClass custom resource.

Adding an existing LVMVolumeGroup

1. Assign the tag `storage.deckhouse.io/enabled=true` to the Volume Group:

   ```
   vgchange myvg-0 --add-tag storage.deckhouse.io/enabled=true
   ```

   After that the Volume Group will be discovered automatically and a corresponding LVMVolumeGroup resource will be created.

2. Reference this resource in ReplicatedStoragePool parameters using `spec.lvmVolumeGroups[].name`.
   If an LVMThin pool is used, additionally specify its name in `spec.lvmVolumeGroups[].thinPoolName`.

Changing DRBD volume limits and cluster ports

The default port range for DRBD resources is TCP `7000`–`7999`. You can override it with the `drbdPortRange` setting by specifying the desired `minPort` and `maxPort` values.

⚠ After changing `drbdPortRange`, restart the LINSTOR controller so that the new settings take effect. Existing DRBD resources will retain their assigned ports.

Correctly rebooting a node with DRBD resources

i To ensure stable module operation, avoid rebooting multiple nodes at the same time.

1. Drain the target node:

   ```
   d8 k drain test-node-1 --ignore-daemonsets --delete-emptydir-data
   ```

2. Make sure there are no faulty DRBD resources or resources in the `SyncTarget` state. To check this, run the following command and analyze the output:

   ```
   d8 k -n d8-sds-replicated-volume exec -t deploy/linstor-controller -- linstor r l --faulty
   ```

   If any resources are in the `SyncTarget` state, wait for the synchronization to complete or take corrective actions.

   Example output:

   ```
   Defaulted container "linstor-controller" out of: linstor-controller, kube-rbac-
   proxy
   +-------------------------------------------------------------------+
   | ResourceName | Node | Port | Usage | Conns | State | CreatedOn |
   |===================================================================|
   +-------------------------------------------------------------------+
   ```

3. Reboot the node and wait for all DRBD resources to resynchronize, then run `uncordon`:

   ```
   d8 k uncordon test-node-1
   node/test-node-1 uncordoned
   ```

If you need to reboot another node, repeat the procedure.

Moving resources to free up space in a Storage Pool

1. List the Storage Pools on the source node to identify which one is running low on free space:

   ```
   d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor storage-pool list -n
   OLD_NODE
   ```

2. Determine which volumes are located in the overloaded Storage Pool to identify potential candidates for migration:

   ```
   d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor volume list -n
   OLD_NODE
   ```

3. Get the list of resources that own these volumes so that you can proceed with moving them:

   ```
   d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor resource list-volumes
   ```

4. Create copies of the selected resources on another node (no more than 1–2 at a time):

```
d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor --yes-i-am-sane-and-i-understand-what-i-am-doing resource create NEW_NODE RESOURCE_NAME
```

5. Wait for the resource synchronization to complete to ensure the data has been replicated properly:

```
d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor resource-definition wait-sync RESOURCE_NAME
```

6. Remove the resource from the source node to free up space in the overloaded Storage Pool:

```
d8 k exec -n d8-sds-replicated-volume deploy/linstor-controller -- linstor --yes-i-am-sane-and-i-understand-what-i-am-doing resource delete OLD_NODE RESOURCE_NAME
```

Automatic management of replicas and monitoring of LINSTOR state

Replica management and state monitoring are automated in the `replicas_manager.sh` script. It checks the availability of the LINSTOR controller, identifies faulty or corrupted resources, creates database backups, and manages disk replicas, including configuring `TieBreaker` for quorum.

To check the existence of the `replicas_manager.sh` script, run the following command on any master node:

```
ls -l /opt/deckhouse/sbin/replicas_manager.sh
```

Upon execution, the script performs the following actions:

- Verifies the availability of the controller and connectivity to satellites.
- Identifies faulty or corrupted resources.
- Creates a backup of the database.
- Manages the number of disk replicas, adding new ones as needed.
- Configures TieBreaker for resources with two replicas.
- Logs all actions to a file named `linstor_replicas_manager_<date_time>.log`.
- Provides recommendations for resolving issues, such as stuck replicas.

Configuration variables for `replicas_manager.sh`:

- `NON_INTERACTIVE`: Enables non-interactive mode.
- `TIMEOUT_SEC`: Timeout between attempts, in seconds (default: 10).
- `EXCLUDED_RESOURCES_FROM_CHECK`: Regular expression to exclude resources from checks.
- `CHUNK_SIZE`: Chunk size for processing resources (default: 10).
- `NODE_FOR_EVICT`: The name of the node excluded from creating replicas.
- `LINSTOR_NAMESPACE`: Kubernetes namespace (default: `d8-sds-replicated-volume`).
- `DISKLESS_STORAGE_POOL`: Pool for diskless replicas (default: `DfltDisklessStorPool`).

Evicting DRBD resources from a node

Eviction of DRBD resources from a node is performed using the `evict.sh` script. It can operate in two modes:

- Node removal: Additional replicas are created for every resource, after which the node is removed from LINSTOR and Kubernetes.
- Resource removal: Replicas are created for the resources, after which the resources themselves are removed from LINSTOR (the node remains in the cluster).

Preparing and running the script

Before eviction:

1. Make sure the script is present on the master node:

```
ls -l /opt/deckhouse/sbin/evict.sh
```

2. Fix faulty resources:

```
d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-controller -- linstor resource list --faulty
```

3. Ensure all Pods in the `d8-sds-replicated-volume` namespace are in the `Running` state:

```
d8 k -n d8-sds-replicated-volume get pods | grep -v Running
```

Example of removing a node from LINSTOR and Kubernetes

Run `evict.sh` on any master node in interactive mode, specifying `--delete-node`:

```
/opt/deckhouse/sbin/evict.sh --delete-node
```

For non-interactive mode, add `--non-interactive` and specify the node name. The script will perform all actions without prompting:

```
/opt/deckhouse/sbin/evict.sh --non-interactive --delete-node --node-name "worker-1"
```

Example of removing resources from a node

Run `evict.sh` on any master node in interactive mode, specifying `--delete-resources-only`:

```
/opt/deckhouse/sbin/evict.sh --delete-resources-only
```

For non-interactive mode, add `--non-interactive` and specify the node name. In this mode, the script runs through all actions without asking for confirmation:

```
/opt/deckhouse/sbin/evict.sh --non-interactive --delete-resources-only --node-name "worker-1"
```

⚠ After the script completes, the node remains in `SchedulingDisabled` status and LINSTOR sets the property `AutoplaceTarget=false`. This blocks automatic creation of new resources on the node.

To allow resource placement again, run:

```
alias linstor='d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-controller -- linstor'
linstor node set-property "worker-1" AutoplaceTarget
d8 k uncordon "worker-1"
```

Check the `AutoplaceTarget` parameter on all nodes (the field will be empty on nodes where LINSTOR resource placement is allowed):

```
alias linstor='d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-controller -- linstor'
linstor node list -s AutoplaceTarget
```

Parameters of the evict.sh script

- `--delete-node`: Remove a node from LINSTOR and Kubernetes after creating additional replicas for all resources on the node.
- `--delete-resources-only`: Remove resources from the node without deleting the node from LINSTOR and Kubernetes, after creating additional replicas.
- `--non-interactive`: Run the script in non-interactive mode.
- `--node-name`: The name of the node to evict resources from. Mandatory when using `--non-interactive`.
- `--skip-db-backup`: Skip creating a LINSTOR DB backup before operations.
- `--ignore-advise`: Perform operations despite `linstor advise resource` warnings. Use if the script was interrupted and the number of replicas for some resources does not match the value

specified in the `ReplicatedStorageClass`.
- `--exclude-resources-from-check`: Exclude resources listed with `|` from checks.

Troubleshooting

Issues can arise at various component layers. The cheat sheet below helps diagnose volume failures in LINSTOR.

Start error of linstor-node while loading the DRBD module

1. Check the `linstor-node` Pods:

   ```
   d8 k get pod -n d8-sds-replicated-volume -l app=linstor-node
   ```

2. If some Pods are stuck in `Init`, check the DRBD version and bashible logs on the node:

   ```
   cat /proc/drbd
   journalctl -fu bashible
   ```

Most likely causes:

- DRBDv8 is loaded instead of the required DRBDv9. Verify the version:

  ```
  cat /proc/drbd
  ```

  If the `/proc/drbd` file is missing, the module is not loaded and the problem lies elsewhere.

- Secure Boot is enabled. Because DRBD is built dynamically (similar to dkms) without a digital signature, the module is not supported when Secure Boot is enabled.

FailedMount error when starting a Pod

Pod stuck in ContainerCreating

If the Pod is stuck in `ContainerCreating` and `d8 k describe pod` shows errors like the one below, the device is mounted on another node:

```
rpc error: code = Internal desc = NodePublishVolume failed for pvc-b3e51b8a-9733-
4d9a-bf34-84e0fee3168d: checking
for exclusive open failed: wrong medium type, check device health
```

Check where the device is in use:

```
alias linstor='d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-controller -
- linstor'
linstor resource list -r pvc-b3e51b8a-9733-4d9a-bf34-84e0fee3168d
```

The `InUse` flag shows on which node the device is used; unmount the disk manually on that node.

Input/output error

Such errors usually occur during filesystem creation (mkfs). Check `dmesg` on the node where the Pod is starting:

```
dmesg | grep 'Remote failed to finish a request within'
```

If the output contains messages like `Remote failed to finish a request within …`, the disk subsystem may be too slow for DRBD to operate correctly.

After the ReplicatedStoragePool resource is deleted, the corresponding Storage Pool remains in the backend

This is expected behavior. The `sds-replicated-volume` module does not handle deletion operations for the ReplicatedStoragePool resource.

Restrictions on changing ReplicatedStorageClass spec

Only the `isDefault` field can be modified. All other parameters are immutable — this is expected behavior.

Deleting a child StorageClass when deleting a ReplicatedStorageClass

If the StorageClass is in the `Created` status, it can be deleted. For other statuses you must restore the resource or delete the StorageClass manually.

Errors when creating a Storage Pool or StorageClass

For temporary external issues (for example, when `kube-apiserver` is unavailable) the module automatically retries the failed operation.

Error “You’re not allowed to change state of linstor cluster manually”

Operations requiring manual intervention are partially or fully automated in the `sds-replicated-volume` module. Therefore, the module restricts the list of allowed LINSTOR commands. For example, creating a Tie-Breaker is automated because LINSTOR sometimes does not create one for two-replica resources. To see the list of allowed commands, run:

```
alias linstor='d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-controller -
- linstor'
linstor --help
```

Restoring the database from a backup

Backend resource backups are stored in Secrets as YAML files split into segments for easier restoration. Backups are created automatically on a schedule.

A correctly formed backup looks like this:

```
linstor-20240425074718-backup-0              Opaque                                1
28s     sds-replicated-volume.deckhouse.io/linstor-db-backup=20240425074718
linstor-20240425074718-backup-1              Opaque                                1
28s     sds-replicated-volume.deckhouse.io/linstor-db-backup=20240425074718
linstor-20240425074718-backup-2              Opaque                                1
28s     sds-replicated-volume.deckhouse.io/linstor-db-backup=20240425074718
linstor-20240425074718-backup-completed      Opaque                                0
28s     <none>
```

The backup is stored in encoded segments in Secrets named `linstor-%date_time%-backup-{0..2}`. The Secret `linstor-%date_time%-backup-completed` contains no data and serves as a marker that the backup process completed successfully.

Backup restoration procedure

1. Set environment variables:

   ```
   NAMESPACE="d8-sds-replicated-volume"
   BACKUP_NAME="linstor_db_backup"
   ```

2. List available backups:

   ```
   d8 k -n $NAMESPACE get secrets --show-labels
   ```

   Example output:

```
linstor-20240425072413-backup-0             Opaque                          1      33m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072413
linstor-20240425072413-backup-1             Opaque                          1      33m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072413
linstor-20240425072413-backup-2             Opaque                          1      33m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072413
linstor-20240425072413-backup-completed     Opaque                          0      33m     <none>
linstor-20240425072510-backup-0             Opaque                          1      32m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072510
linstor-20240425072510-backup-1             Opaque                          1      32m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072510
linstor-20240425072510-backup-2             Opaque                          1      32m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072510
linstor-20240425072510-backup-completed     Opaque                          0      32m     <none>
linstor-20240425072634-backup-0             Opaque                          1      31m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072634
linstor-20240425072634-backup-1             Opaque                          1      31m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072634
linstor-20240425072634-backup-2             Opaque                          1      31m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072634
linstor-20240425072634-backup-completed     Opaque                          0      31m     <none>
linstor-20240425072918-backup-0             Opaque                          1      28m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072918
linstor-20240425072918-backup-1             Opaque                          1      28m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072918
linstor-20240425072918-backup-2             Opaque                          1      28m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425072918
linstor-20240425072918-backup-completed     Opaque                          0      28m     <none>
linstor-20240425074718-backup-0             Opaque                          1      10m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425074718
linstor-20240425074718-backup-1             Opaque                          1      10m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425074718
linstor-20240425074718-backup-2             Opaque                          1      10m     sds-
replicated-volume.deckhouse.io/linstor-db-backup=20240425074718
linstor-20240425074718-backup-completed     Opaque                          0      10m     <none>
```

3. Each backup has its own creation-time label. Choose the desired one and save it to an environment variable. In this example we use the most recent label:

   ```
   LABEL_SELECTOR="sds-replicated-volume.deckhouse.io/linstor-db-
   backup=20240425074718"
   ```

4. Create a temporary directory to store archive parts:

   ```
   TMPDIR=$(mktemp -d)
   echo "Temporary directory: $TMPDIR"
   ```

5. Create an empty archive and combine Secret data into one file:

   ```
   COMBINED="${BACKUP_NAME}_combined.tar"
   > "$COMBINED"
   ```

6. Get the list of Secrets by label, decode the data, and append it to the archive:

   ```
   MOBJECTS=$(d8 k get rsmb -l "$LABEL_SELECTOR" --sort-by=.metadata.name -o jsonpath="
   {.items[*].metadata.name}")

   for MOBJECT in $MOBJECTS; do
     echo "Process: $MOBJECT"
    d8 k get rsmb "$MOBJECT" -o jsonpath="{.data}" | base64 --decode >> "$COMBINED"
   done
   ```

7. Extract the archive to get backup files:

```
mkdir -p "./backup"
tar -xf "$COMBINED" -C "./backup" --strip-components=2
```

8. Check the backup contents:

   ```
   ls ./backup
   TMPDIR=$(mktemp -d)
   echo "Temporary directory: $TMPDIR"
   ```

   Example output:

   ```
   ebsremotes.yaml                     layerdrbdvolumedefinitions.yaml
   layerwritecachevolumes.yaml  propscontainers.yaml      satellitescapacity.yaml
   secidrolemap.yaml         trackingdate.yaml
   files.yaml                          layerdrbdvolumes.yaml
   linstorremotes.yaml            resourceconnections.yaml  schedules.yaml
   secobjectprotection.yaml  volumeconnections.yaml
   keyvaluestore.yaml                  layerluksvolumes.yaml
   linstorversion.yaml            resourcedefinitions.yaml  secaccesstypes.yaml
   secroles.yaml             volumedefinitions.yaml
   layerbcachevolumes.yaml             layeropenflexresourcedefinitions.yaml
   nodeconnections.yaml           resourcegroups.yaml       secaclmap.yaml
   sectyperules.yaml         volumegroups.yaml
   layercachevolumes.yaml              layeropenflexvolumes.yaml
   nodenetinterfaces.yaml         resources.yaml            secconfiguration.yaml
   sectypes.yaml             volumes.yaml
   layerdrbdresourcedefinitions.yaml  layerresourceids.yaml
   nodes.yaml                     rollback.yaml             secdfltroles.yaml
   spacehistory.yaml
   layerdrbdresources.yaml             layerstoragevolumes.yaml
   nodestorpool.yaml              s3remotes.yaml            secidentities.yaml
   storpooldefinitions.yaml
   ```

9. Restore the required entity by applying the corresponding YAML file:

   ```
   d8 k apply -f %something%.yaml
   ```

   Or bulk-apply for a full restore:

   ```
   d8 k apply -f ./backup/
   ```

Missing sds-replicated-volume service Pods on a selected node

The issue is most likely related to node labels.

- Check `dataNodes.nodeSelector` in module settings:

  ```
  d8 k get mc sds-replicated-volume -o=jsonpath={.spec.settings.dataNodes.nodeSelector}
  ```

- Check the selectors used by `sds-replicated-volume-controller`:

  ```
  d8 k -n d8-sds-replicated-volume get secret d8-sds-replicated-volume-controller-config  -o
  jsonpath='{.data.config}' | base64 --decode
  ```

- The secret `d8-sds-replicated-volume-controller-config` must contain the selectors specified in module settings plus `kubernetes.io/os: linux`.
- Verify that the all labels from the `d8-sds-replicated-volume-controller-config` secret are present on the node:

```
d8 k get node worker-0 --show-labels
```

- If the labels are missing, add them via NodeGroup templates or directly to the node.
- If the labels exist, check whether the node has the label `storage.deckhouse.io/sds-replicated-volume-node=`.
  If not, check whether `sds-replicated-volume-controller` is running and inspect its logs:

```
d8 k -n d8-sds-replicated-volume get po -l app=sds-replicated-volume-controller
d8 k -n d8-sds-replicated-volume logs -l app=sds-replicated-volume-controller
```

Additional support

Reasons for failed operations are shown in the `status.reason` field of ReplicatedStoragePool and ReplicatedStorageClass resources. If that information is insufficient, consult the `sds-replicated-volume-controller` logs.

Migration from the linstor module to sds-replicated-volume

During migration the LINSTOR control plane and its CSI are temporarily unavailable, which can affect PV operations (creation, expansion, or deletion).

⚠ User data is not affected because the migration moves to a new namespace and adds components that manage volumes.

Migration procedure

1. Ensure no faulty resources exist in the backend. The command should return an empty list:

   ```
   alias linstor='d8 k -n d8-linstor exec -ti deploy/linstor-controller -- linstor'
   linstor resource list --faulty
   ```

   i **Warning.** All resources must be healthy before migration.

2. Disable the `linstor` module:

   ```
   d8 k patch moduleconfig linstor --type=merge -p '{"spec": {"enabled": false}}'
   ```

3. Wait until the `d8-linstor` namespace is deleted:

   ```
   d8 k get namespace d8-linstor
   ```

4. Create a ModuleConfig for `sds-node-configurator`:

   ```
   d8 k apply -f -<<EOF
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: sds-node-configurator
   spec:
     enabled: true
     version: 1
   EOF
   ```

5. Wait until `sds-node-configurator` reaches `Ready`:

   ```
   d8 k get moduleconfig sds-node-configurator
   ```

6. Create a ModuleConfig for `sds-replicated-volume`:

   > **Warning.** If `settings.dataNodes.nodeSelector` is not specified for `sds-replicated-volume`, its value will be taken from the `linstor` module. If it is absent there as well, it will remain empty and all cluster nodes will be considered data nodes.

   ```
   d8 k apply -f - <<EOF
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: sds-replicated-volume
   spec:
     enabled: true
     version: 1
   EOF
   ```

7. Wait until `sds-replicated-volume` reaches `Ready`:

   ```
   d8 k get moduleconfig sds-replicated-volume
   ```

8. Check the `sds-replicated-volume` settings:

   ```
   d8 k get moduleconfig sds-replicated-volume -oyaml
   ```

9. Wait until all Pods in the `d8-sds-replicated-volume` and `d8-sds-node-configurator` namespaces are `Ready` or `Completed`:

   ```
   d8 k get po -n d8-sds-node-configurator
   d8 k get po -n d8-sds-replicated-volume
   ```

10. Update the `linstor` alias and check resources:

    ```
    alias linstor='d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-controller -- linstor'
    linstor resource list --faulty
    ```

If no faulty resources are found, migration was successful.

Migrating to ReplicatedStorageClass

StorageClasses in this module are managed via the ReplicatedStorageClass resource. StorageClasses must not be created manually.

When migrating from the LINSTOR module, delete old StorageClasses and create new ones via ReplicatedStorageClass according to the table below.

Note that in old StorageClasses you look at the option in the `parameters` section of the StorageClass itself, while when creating a new one you set the corresponding option in ReplicatedStorageClass.

StorageClass parameter	ReplicatedStorageClass	Default	Notes
linstor.csi.linbit.com/placementCount: “1”	replication: “None”		One data replica will be created
linstor.csi.linbit.com/placementCount: “2”	replication: “Availability”		Two data replicas will be created
linstor.csi.linbit.com/placementCount: “3”	replication: “ConsistencyAndAvailability”	Yes	Three data replicas will be created
linstor.csi.linbit.com/storagePool: “name”	storagePool: “name”		Name of the storage pool used for storage

StorageClass parameter	ReplicatedStorageClass	Default	Notes
linstor.csi.linbit.com/allowRemoteVolumeAccess: “false”	volumeAccess: “Local”		Remote Pod access to data volumes is forbidden (local disk access within the node only)

Additional parameters:

- `reclaimPolicy` (Delete, Retain): Corresponds to `reclaimPolicy` of the old StorageClass.
- `zones`: List of zones to place resources in (direct cloud zone names). Note that remote Pod access to the data volume is possible only within one zone.
- `volumeAccess` values: `Local` (access strictly within the node), `EventuallyLocal` (a data replica will synchronize to the node after the Pod starts), `PreferablyLocal` (remote Pod access allowed, `volumeBindingMode: WaitForFirstConsumer`), `Any` (remote Pod access allowed, `volumeBindingMode: Immediate`).
- If you need `volumeBindingMode: Immediate`, set `volumeAccess` in ReplicatedStorageClass to `Any`.

Migrating to ReplicatedStoragePool

The ReplicatedStoragePool resource allows you to create Storage Pools in the backend. It is recommended to create this resource even for existing Storage Pools and reference existing LVMVolumeGroup. The controller will detect that the Storage Pools already exist and leave them unchanged, showing `Created` in `status.phase`.

Migration from the sds-drbd module to sds-replicated-volume

During migration the module control plane and its CSI are unavailable. This prevents creation, expansion, or deletion of PVs and the creation or deletion of Pods that use DRBD PVs for the duration of the migration.

⚠ The migration will not affect user data, as it is performed in a new namespace and volume management will be handled by new components that will replace the functionality of the previous module.

Migration procedure

1. Make sure there are no faulty DRBD resources in the cluster. The command should return an empty list:

   ```
   alias linstor='d8 k -n d8-sds-drbd exec -ti deploy/linstor-controller -- linstor'
   linstor resource list --faulty
   ```

   Warning. All DRBD resources must be healthy before migration.

2. Disable the `sds-drbd` module:

   ```
   d8 k patch moduleconfig sds-drbd --type=merge -p '{"spec": {"enabled": false}}'
   ```

3. Wait until the `d8-sds-drbd` namespace is deleted:

   ```
   d8 k get namespace d8-sds-drbd
   ```

4. Create a ModuleConfig for `sds-replicated-volume`:

   Warning. If `settings.dataNodes.nodeSelector` is not specified for `sds-replicated-volume`, its value will be taken from the `sds-drbd` module. If it is absent there as well, it will remain empty and all cluster nodes will be considered data nodes.

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: sds-replicated-volume
spec:
  enabled: true
  version: 1
EOF
```

5. Wait until `sds-replicated-volume` reaches `Ready`:

```
d8 k get moduleconfig sds-replicated-volume
```

6. Check the `sds-replicated-volume` settings:

```
d8 k get moduleconfig sds-replicated-volume -oyaml
```

7. Wait until all Pods in the `d8-sds-replicated-volume` namespace are `Ready` or `Completed`:

```
d8 k get po -n d8-sds-replicated-volume
```

8. Update the `linstor` alias and check DRBD resources:

```
alias linstor='d8 k -n d8-sds-replicated-volume exec -ti deploy/linstor-
controller -- linstor'
linstor resource list --faulty
```

If no faulty resources are found, migration was successful.

> **Warning.** DRBDStoragePool and DRBDStorageClass resources will be automatically migrated to ReplicatedStoragePool and ReplicatedStorageClass. No user action is required.

The logic of these resources remains unchanged. However, verify that no DRBDStoragePool or DRBDStorageClass resources remain. If they do, contact the Deckhouse technical support.

Reasons to avoid RAID with sds-replicated-volume

Using DRBD with more than one replica already provides network-level RAID functionality. Local RAID can cause the following issues:

- Significantly increases space overhead when using redundant RAID.
  Example: ReplicatedStorageClass with `replication` set to `ConsistencyAndAvailability`. DRBD will store three data replicas (one per node). If those nodes use RAID1, storing 1 GB of data will require 6 GB of disk space. Redundant RAID is reasonable only to simplify server maintenance when storage cost is irrelevant. RAID1 then allows replacing disks without moving data replicas off a “problem” disk.
- With RAID0 the performance gain is negligible because data replication occurs over the network and the bottleneck is likely the network. Additionally, reduced host storage reliability can lead to data unavailability since DRBD failover from a broken replica to a healthy one is not instantaneous.

Recommendations for using local disks

DRBD uses the network for data replication. When using NAS, network load increases dramatically because nodes synchronize data not only with the NAS but also with each other. Latency for reads or writes also increases. NAS typically uses RAID on its side, adding further overhead.

Manual trigger the certificate renewal process

Although the certificate renewal process is automated, manual renewal might still be necessary because it can be performed during a convenient maintenance window when it is acceptable to restart

the module's objects. The automated renewal does not restart any objects.

To manually trigger the certificate renewal process, create a `ConfigMap` named `manualcertrenewal-trigger`:

```
apiVersion: v1
kind: ConfigMap
metadata:
  name: manualcertrenewal-trigger
  namespace: d8-sds-replicated-volume
```

The system will stop all necessary module objects, update the certificates, and then restart them.

You can check the operation status using the following command:

```
d8 k -n d8-sds-replicated-volume get cm manualcertrenewal-trigger -ojsonpath='{.data.step}'
```

Possible statuses:

- `Prepared`: Health checks have passed successfully, and the downtime window has started.
- `TurnedOffAndRenewedCerts`: The system has been stopped and certificates have been renewed.
- `TurnedOn`: The system has been restarted.
- `Done`: The operation is complete and ready to be repeated.

Certificates are issued for a period of one year and are marked as expiring 30 days before their expiration date. The monitoring system alerts about expiring certificates using the `D8LinstorCertificateExpiringIn30d` alert.

To repeat the operation, simply remove the label from the trigger using the following command:

```
d8 k -n d8-sds-replicated-volume label cm manualcertrenewal-trigger storage.deckhouse.io/sds-replicated-volume-manualcertrenewal-completed-
```

Additional resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Distributed Ceph storage

Ceph is a scalable distributed storage system that ensures high availability and fault tolerance of data. Deckhouse Platform (DP) provides Ceph cluster integration using the `csi-ceph` module. This enables dynamic storage management and the use of StorageClass based on RADOS Block Device (RBD) or CephFS.

> The snapshot-controller module is required for working with snapshots.

This page provides instructions on connecting Ceph to Deckhouse, configuring authentication, creating StorageClass objects, and verifying storage functionality.

Migration from `ceph-csi` module

When switching from the `ceph-csi` module to `csi-ceph`, an automatic migration is performed, but its execution requires preliminary preparation:

1. Set the replica count to zero for all operators (redis, clickhouse, kafka, etc.). Exception: the `prometheus` operator will be disabled automatically.

2. Disable the `ceph-csi` module and enable `csi-ceph`.
3. Wait for the operation to complete. The Deckhouse logs should show the message “Finished migration from Ceph CSI module”.
4. Verify functionality. Create test pods and PVCs to test CSI.
5. Restore the operators to their normal replica count.

⚠ If Ceph StorageClass was created without using the `CephCSIDriver` resource, manual migration will be required. Contact technical support.

Connecting to a Ceph cluster

To connect to a Ceph cluster, follow the step-by-step instructions below. Execute all commands on a machine with administrative access to the Kubernetes API.

1. Execute the command to activate the `csi-ceph` module:

   ```
   d8 s module enable csi-ceph
   ```

2. Wait for the module to transition to `Ready` state:

   ```
   d8 k get module csi-ceph -w
   ```

3. Ensure that all pods in the `d8-csi-ceph` namespace are in `Running` or `Completed` state and deployed on all cluster nodes:

   ```
   d8 k -n d8-csi-ceph get pod -owide -w
   ```

4. To configure the connection to the Ceph cluster, apply the CephClusterConnection resource.

   Example command:

   ```
   d8 k apply -f - <<EOF
   apiVersion: storage.deckhouse.io/v1alpha1
   kind: CephClusterConnection
   metadata:
     name: ceph-cluster-1
   spec:
     # FSID/UUID of the Ceph cluster.
     # Get the FSID/UUID of the Ceph cluster using the command `ceph fsid`.
     clusterID: 2bf085fc-5119-404f-bb19-820ca6a1b07e
     # List of IP addresses of ceph-mon in the format 10.0.0.10:6789.
     monitors:
       - 10.0.0.10:6789
     # Username without `client.`.
     # Get the username using the command `ceph auth list`.
     userID: admin
     # Authorization key corresponding to userID.
     # Get the authorization key using the command `ceph auth get-key
   client.admin`.
     userKey: AQDiVXVmBJVRLxAAg65PhODrtwbwSWrjJwssUg==
   EOF
   ```

5. Verify the connection creation with the command (`Phase` should be in `Created` status):

   ```
   d8 k get cephclusterconnection ceph-cluster-1
   ```

6. Create a StorageClass object using the CephStorageClass resource. Manual creation of StorageClass without using CephStorageClass may lead to errors.

   Example of creating StorageClass based on RBD:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: CephStorageClass
metadata:
  name: ceph-rbd-sc
spec:
  clusterConnectionName: ceph-cluster-1
  reclaimPolicy: Delete
  type: RBD
  rbd:
    defaultFSType: ext4
    pool: ceph-rbd-pool
EOF
```

Example of creating StorageClass based on Ceph filesystem:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: CephStorageClass
metadata:
  name: ceph-fs-sc
spec:
  clusterConnectionName: ceph-cluster-1
  reclaimPolicy: Delete
  type: CephFS
  cephFS:
    fsName: cephfs
EOF
```

7. Verify that the created CephStorageClass resources have transitioned to `Created` state:

   ```
   d8 k get cephstorageclass
   ```

   This will output information about the created CephStorageClass resources:

   ```
   NAME          PHASE     AGE
   ceph-rbd-sc   Created   1h
   ceph-fs-sc    Created   1h
   ```

8. Verify the created StorageClass:

   ```
   d8 k get sc
   ```

   This will output information about the created StorageClass:

   ```
   NAME          PROVISIONER        RECLAIMPOLICY   VOLUMEBINDINGMODE
   ALLOWVOLUMEEXPANSION   AGE
   ceph-rbd-sc   rbd.csi.ceph.com   Delete          WaitForFirstConsumer   true
   15s
   ceph-fs-sc    rbd.csi.ceph.com   Delete          WaitForFirstConsumer   true
   15s
   ```

Ceph cluster connection setup is complete. You can use the created StorageClass to create PersistentVolumeClaim in your applications.

Additional information

How to get a list of RBD volumes separated by nodes

For monitoring and diagnostics, it’s useful to know which RBD volumes are connected to each cluster node. The following command provides detailed information about volume mapping:

```
d8 k -n d8-csi-ceph get po -l app=csi-node-rbd -o custom-
columns=NAME:.metadata.name,NODE:.spec.nodeName --no-headers \
  | awk '{print "echo "$2"; kubectl -n d8-csi-ceph exec  "$1" -c node -- rbd
showmapped"}' | bash
```

Which versions of Ceph clusters are supported

The `csi-ceph` module has specific requirements for the Ceph cluster version to ensure compatibility and stable operation. Officially supported versions are >= 16.2.0. In practice, the current version works with clusters running versions >= 14.2.0, but it’s recommended to update Ceph to the latest version.

Which volume access modes are supported

Different types of Ceph storage support different volume access modes, which is important to consider when planning application architecture.

- **RBD**: Supports only ReadWriteOnce (RWO) — access to volume from only one cluster node.
- **CephFS**: Supports ReadWriteOnce (RWO) and ReadWriteMany (RWX) — simultaneous access to volume from multiple cluster nodes.

Examples of permissions (caps) for Ceph users

To ensure proper operation of the `csi-ceph` module, Ceph users must have appropriate permissions (caps) configured. The required permissions depend on the storage type being used (RBD, CephFS, or both). Below are examples of correct permission configurations for different scenarios.

RBD

For a single pool named `rbd`, the following permissions are required:

```
[client.name]
        key = key
        caps mgr = "profile rbd pool=rbd"
        caps mon = "profile rbd"
        caps osd = "profile rbd pool=rbd"
```

CephFS

Before configuring CephFS permissions, ensure that a subvolumegroup `csi` (or another one specified in `Custom resources`) is created in CephFS.

You can create a new subvolumegroup using the following command on the Ceph management node:

```
ceph fs subvolumegroup create <fs_name> <group_name>
```

For example, to create a subvolumegroup `csi` for filesystem `myfs`:

```
ceph fs subvolumegroup create myfs csi
```

Required permissions for CephFS named `myfs`:

```
[client.name]
        key = key
        caps mds = "allow rwps fsname=myfs"
        caps mgr = "allow rw"
        caps mon = "allow r fsname=myfs"
        caps osd = "allow rw tag cephfs data=myfs, allow rw tag cephfs
metadata=myfs"
```

CephFS + RBD

For a user that needs access to both CephFS `myfs` and RBD pool `rbd`, combine the permissions as follows:

```
[client.name]
        key = key
        caps mds = "allow rwps fsname=myfs"
        caps mgr = "allow rw,profile rbd pool=rbd"
        caps mon = "allow r fsname=myfs,profile rbd"
        caps osd = "allow rw tag cephfs metadata=myfs, allow rw tag cephfs
data=myfs,profile rbd pool=rbd"
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

HPE data storage

Deckhouse includes support for HPE 3PAR storage systems, enabling volume management in Kubernetes using a CSI driver. This integration provides reliable, scalable, and high-performance storage suitable for mission-critical workloads. The `csi-hpe` module is used to work with HPE 3PAR systems, allowing StorageClass creation in Kubernetes through the HPEStorageClass resource.

> ⚠ User-created StorageClass for the `csi.hpe.com` CSI driver is not allowed.
> Only HPE 3PAR storage systems are supported. For other HPE storage systems, contact the Deckhouse technical support.

This page provides instructions on connecting HPE 3PAR to Deckhouse, configuring the connection, creating StorageClass, and verifying storage functionality.

System requirements

- A deployed and configured HPE storage system.
- Unique IQNs in `/etc/iscsi/initiatorname.iscsi` on each Kubernetes node.

Configuration

Note that all commands must be run on a machine that has administrator access to the Kubernetes API.

Enabling the module

Enable the `csi-hpe` module. This will result in the following actions across all cluster nodes:

- Registration of the CSI driver.
- Launch of service Pods for the `csi-hpe` components.

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: csi-hpe
spec:
  enabled: true
  version: 1
EOF
```

Wait until the module transitions to the `Ready` state. Check the module's status with the following command:

```
d8 k get module csi-hpe -w
```

Creating a StorageClass

To create a StorageClass, you need to use the HPEStorageClass and HPEStorageConnection resource. Here is an example command to create such a resource:

- Creating a HPEStorageConnection resource:

  ```
  d8 k apply -f -<<EOF
  apiVersion: storage.deckhouse.io/v1alpha1
  kind: HPEStorageConnection
  metadata:
    name: hpe
  spec:
    controlPlane:
      backendAddress: "172.17.1.55" # Storage system address (mutable).
      username: "3paradm" # API username (mutable).
      password: "3pardata" # API password (mutable).
      serviceName: "primera3par-csp-svc"
      servicePort: "8080"
  EOF
  ```

  Verify the creation of the object using the following command (`Phase` should be `Created`):

  ```
  d8 k get hpestorageconnections.storage.deckhouse.io <hpestorageconnection-name>
  ```

- Creating a HPEStorageClass resource:

  ```
  d8 k apply -f -<<EOF
  apiVersion: storage.deckhouse.io/v1alpha1
  kind: HPEStorageClass
  metadata:
    name: hpe
  spec:
    pool: "test-cpg"
    accessProtocol: "iscsi" # fc or iscsi (iscsi by default), immutable.
    fsType: "xfs" # xfs, ext3, ext4, btrfs (ext4 by default), mutable.
    storageConnectionName: "hpe" # Immutable.
    reclaimPolicy: Delete # Delete or Retain.
    cpg: "test-cpg"
  EOF
  ```

  Verify the creation of the object using the following command (`Phase` should be `Created`):

  ```
  d8 k get hpestorageclasses.storage.deckhouse.io <hpestorageclass-name>
  ```

Module health verification

To verify module health, ensure that all Pods in the `d8-csi-hpe` namespace are in the `Running` or `Completed` state and are running on every node in the cluster:

```
d8 k -n d8-csi-hpe get pod -owide -w
```

Additional resources

- Module `csi-hpe` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Huawei data storage

Deckhouse provides support for Huawei Dorado storage systems, enabling volume management in Kubernetes using a CSI driver through the creation of custom resources like HuaweiStorageClass. This solution ensures high-performance and fault-tolerant storage, making it an optimal choice for mission-critical workloads.

> ⚠ User-created StorageClass for the `csi.huawei.com` CSI driver is not allowed.
> Only Huawei Dorado storage systems are supported. For other Huawei storage systems, contact the Deckhouse technical support.

This page provides instructions on connecting Huawei Dorado to Deckhouse, configuring the connection, creating StorageClass, and verifying storage functionality.

System requirements

- Presence of a deployed and configured Huawei storage system.
- Unique IQNs in `/etc/iscsi/initiatorname.iscsi` on each Kubernetes node.

Configuration

Note that all commands must be run on a machine that has administrator access to the Kubernetes API.

Enabling the module

To support Huawei Dorado storage systems, enable the `csi-huawei` module. This will ensure that all cluster nodes have:

- Registration of the CSI driver.
- Launch of service pods for the `csi-huawei` components.

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: csi-huawei
spec:
  enabled: true
  version: 1
EOF
```

Wait until the module transitions to the `Ready` state. Check the module's status with the following command:

```
d8 k get module csi-huawei -w
```

Creating a StorageClass

To create a StorageClass, you need to use the HuaweiStorageClass and HuaweiStorageConnection resource. Here is an example command to create such a resource:

- Creating a HuaweiStorageConnection resource:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: HuaweiStorageConnection
metadata:
  name: huaweistorageconn
spec:
  storageType: OceanStorSAN
  pools:
    - test
  urls:
    - https://192.168.128.101:8088
  login: "admin"
  password: "dh-test-secret-0123456789abcdef"
  protocol: ISCSI
  portals:
    - 10.240.0.101
    - 10.250.0.101
  maxClientThreads: 30

EOF
```

Verify the creation of the object using the following command (`Phase` should be `Created`):

```
d8 k get huaweistorageconnections.storage.deckhouse.io <huaweistorageconnection name>
```

- Creating a HuaweiStorageClass resource:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: HuaweiStorageClass
metadata:
  name: huaweisc
spec:
  fsType: ext4
  pool: test
  reclaimPolicy: Delete
  storageConnectionName: huaweistorageconn
  volumeBindingMode: WaitForFirstConsumer
EOF
```

Verify the creation of the object using the following command (`Phase` should be `Created`):

```
d8 k get huaweistorageclasses.storage.deckhouse.io <huaweistorageclass name>
```

Module health verification

To verify module health, ensure that all pods in the `d8-csi-huawei` namespace are in the `Running` or `Completed` state and are running on every node in the cluster:

```
d8 k -n d8-csi-huawei get pod -owide -w
```

Additional resources

- Module `csi-huawei` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

NetApp data storage

Deckhouse Platform (DP) implements support for NetApp data storage systems for volume management in Kubernetes using CSI driver. This integration provides reliable, scalable, and high-performance storage suitable for critical workloads. For working with NetApp storage systems, the `csi-netapp` module is used, which allows creating StorageClass in Kubernetes through creating a NetappStorageClass resource.

> ⚠ Creating StorageClass for `csi.netapp.com` CSI driver by users is prohibited. Currently, the module supports storage systems compatible with NetApp Trident CSI. For support of other NetApp storage systems, please contact Deckhouse technical support.

This page provides instructions for connecting NetApp to DP, configuring the connection, and creating StorageClass.

System Requirements

Before configuring work with the NetApp storage system, make sure that the following requirements are met:

- Availability of deployed and configured NetApp storage system.
- Unique IQNs in `/etc/iscsi/initiatorname.iscsi` on each Kubernetes node.

Configuring cluster integration with the NetApp storage system

To start working with the NetApp storage system, follow the step-by-step instructions below. Run all commands on a machine with administrative access to the Kubernetes API.

> To work with snapshots, the snapshot-controller module must be connected.

1. Execute the command to activate the `csi-netapp` module.

   ```
   d8 system module enable csi-netapp
   ```

   After activation, the following will be deployed on all cluster nodes:

   - CSI driver will be registered.
   - Service pods of `csi-netapp` components will be deployed.

2. Wait for the module to transition to the `Ready` state:

   ```
   d8 k get module csi-netapp -w
   ```

3. Ensure that all pods in the `d8-csi-netapp` namespace are in the `Running` or `Completed` state and deployed on all cluster nodes:

   ```
   d8 k -n d8-csi-netapp get pod -owide -w
   ```

4. Create a NetappStorageConnection resource:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: NetappStorageConnection
metadata:
  name: netapp
spec:
  controlPlane:
    address: "172.17.1.55"
    username: "admin"
    password: "password"
    svm: "svm1"
EOF
```

5. Verify object creation with the following command (`Phase` should be `Created`):

```
d8 k get netappstorageconnections.storage.deckhouse.io <netappstorageconnection name>
```

6. Create a NetappStorageClass resource:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: NetappStorageClass
metadata:
  name: netapp
spec:
  pool: "test-cpg"
  accessProtocol: "iscsi" # fc or iscsi (default iscsi), immutable parameter.
  fsType: "xfs" # xfs, ext3, ext4 (default ext4), configurable parameter.
  storageConnectionName: "netapp" # Immutable parameter.
  reclaimPolicy: Delete # Delete or Retain.
  cpg: "test-cpg"
EOF
```

7. Verify object creation with the following command (`Phase` should be `Created`):

```
d8 k get netappstorageclasses.storage.deckhouse.io <netappstorageclass name>
```

The NetApp storage system is now ready for use. You can use the created StorageClass to create PersistentVolumeClaims in your applications.

Additional resources

- Module `csi-netapp` documentation
- Module `snapshot-controller` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

NFS storage

Deckhouse Platform (DP) supports integration with Network File System (NFS), providing the ability to use network file storage as Kubernetes volumes. The `csi-nfs` module provides a CSI driver for connecting to NFS servers and creating PersistentVolumes based on them.

This page provides instructions for configuring NFS storage in DP, including connecting to an NFS server, creating StorageClass, configuring RPC-with-TLS security, and verifying system functionality.

System Requirements

Minimum Requirements

The following conditions must be met for the `csi-nfs` module to work:

- Supported Linux distributions with appropriate kernels.
- Configured and accessible NFS server.
- For RPC-with-TLS support: Linux kernel with enabled `CONFIG_TLS` and `CONFIG_NET_HANDSHAKE` options.

Configuration Recommendations

For optimal module operation, it is recommended to:

- For automatic pod restarts when TLS parameters change, enable the `pod-reloader` module (enabled by default).
- Use stable versions of NFS servers with support for required protocols.

⚠ For NFS to work as virtual disk storage in Deckhouse Virtualization Platform, configure the NFS server with the `no_root_squash` option.

Limitations

General Limitations

The following limitations apply when working with the `csi-nfs` module:

- Manual creation of StorageClass for CSI driver `nfs.csi.k8s.io` is prohibited — use the NFSStorageClass resource.
- PersistentVolumes are created only through NFSStorageClass resources.
- Changing NFS server parameters in already created PVs is impossible.

Volume Snapshot Limitations

i A connected `snapshot-controller` module is required for working with snapshots.

Creating NFS volume snapshots has significant limitations related to the NFS architecture and the way they are implemented in `csi-nfs`. Avoid using snapshots in module whenever possible.

Snapshot Operation Principle:

- The CSI driver creates a snapshot at the NFS server level.
- The `tar` utility is used for archiving, which imposes certain limitations.
- The archive is saved in the root folder of the NFS server specified in the `spec.connection.share` parameter.

⚠
- Before creating a snapshot, **mandatory** stop the workload (pods) using the NFS volume.
- NFS does not ensure atomicity of operations at the file system level when creating snapshots.

RPC-with-TLS Mode Limitations

Functional Limitations

The following limitations apply when using RPC-with-TLS:

- Only one client certificate is supported for the `mtls` security policy.
- One NFS server cannot simultaneously work in different security modes: `tls`, `mtls` and standard mode (without TLS).
- The `tlshd` daemon should not be running on cluster nodes, otherwise it will conflict with the module daemon. To prevent conflicts when enabling TLS on nodes, third-party `tlshd` is automatically stopped and its autostart is disabled.

System Requirements

The following system requirements must be met for RPC-with-TLS operation:

- Linux kernel must be compiled with enabled `CONFIG_TLS` and `CONFIG_NET_HANDSHAKE` parameters.
- `nfs-utils` package (in Debian-based distributions — `nfs-common`) version >= 2.6.3.

Configuration

> **i** All commands must be executed on a machine with administrative rights in the Kubernetes API.

The following steps are required to configure NFS storage:

- Module enabling.
- Creating NFSStorageClass.

Enabling the Module

To support working with NFS storage, enable the `csi-nfs` module, which allows creating StorageClass in Kubernetes using custom NFSStorageClass resources. After enabling the module, the following will happen on cluster nodes:

- CSI driver registration.
- Launch of `csi-nfs` service pods and creation of necessary components.

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: csi-nfs
spec:
  enabled: true
  version: 1
EOF
```

Wait for the module to transition to the `Ready` state:

```
d8 k get module csi-nfs -w
```

Check the status of pods in the `d8-csi-nfs` namespace. All pods should be in `Running` or `Completed` state and running on all nodes:

```
d8 k -n d8-csi-nfs get pod -owide -w
```

Creating StorageClass

To create a StorageClass, you must use the NFSStorageClass resource. Example of creating a resource:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: NFSStorageClass
metadata:
  name: nfs-storage-class
spec:
  connection:
    host: 10.223.187.3
    share: /
    nfsVersion: "4.1"
  reclaimPolicy: Delete
  volumeBindingMode: WaitForFirstConsumer
EOF
```

For each PV, a directory `<share directory>/<PV name>` will be created.

Volume Cleanup Configuration

When deleting a PersistentVolume, files with user data may remain on the volume. To ensure data security, you can configure the volume cleanup method before deletion using the `volumeCleanup` parameter.

⚠ Important notes on volume cleanup:

- The cleanup option does not affect files already deleted by the client application.
- Cleanup is performed only through the NFS protocol and depends on:
  - NFS server service.
  - File system.
  - Block device level and their virtualization (e.g., LVM).
  - Physical devices.
- Ensure NFS server trustworthiness before sending sensitive data.

Parameter `RandomFillSinglePass`

File contents are overwritten with a random sequence before deletion. The random sequence is transmitted over the network.

Parameter `RandomFillThreePass`

File contents are overwritten three times with random sequences before deletion. Three random sequences are transmitted over the network.

i Using this method makes sense only if the server stores data on a hard disk, and there is a risk of physical access by an attacker to the device.

Parameter `Discard`

An optimized cleanup method that uses file system capabilities for working with solid-state drives. File contents are marked as free through the `falloc` system call with the `FALLOC_FL_PUNCH_HOLE` flag. The file system will free blocks fully used by the file through the `blkdiscard` call, and the remaining space will be overwritten with zeros.

Advantages of the `Discard` method:

- Traffic volume does not depend on file size, only on their quantity.
- Can ensure inaccessibility of old data in some server configurations.
- Works for both hard drives and solid-state drives.
- Allows increasing solid-state drive lifespan.

Changing NFS Server Parameters for Created PersistentVolumes

Changing NFS server parameters for created PersistentVolumes is impossible, as connection data to the NFS server is stored directly in the PersistentVolume manifest and cannot be changed. Changing NFSStorageClass will also not affect connection settings in existing PVs.

Creating Volume Snapshots

In `csi-nfs`, snapshots are created by archiving the volume folder. The archive is saved in the root of the NFS server folder specified in the `spec.connection.share` parameter. When creating volume snapshots, it’s important to consider the requirements and limitations listed above.

To create a snapshot, perform the following steps:

1. Enable the `snapshot-controller` module:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: snapshot-controller
spec:
  enabled: true
  version: 1
EOF
```

2. Create a volume snapshot, specifying the required parameters:

```
d8 k apply -f - <<EOF
apiVersion: snapshot.storage.k8s.io/v1
kind: VolumeSnapshot
metadata:
  name: my-snapshot
  namespace: <namespace name where the PVC is located>
spec:
  volumeSnapshotClassName: csi-nfs-snapshot-class
  source:
    persistentVolumeClaimName: <PVC name for which the snapshot needs to be
created>
EOF
```

3. Check the status of the created snapshot:

```
d8 k get volumesnapshot
```

Issues with Deleting PVs with RPC-with-TLS Support

If the NFSStorageClass resource was configured with RPC-with-TLS support, a situation may arise where the PersistentVolume cannot be deleted. This happens due to secret deletion (e.g., after deleting NFSStorageClass) that stores mounting parameters. As a result, the controller cannot mount the NFS folder to delete the `<PV name>` folder.

Adding Multiple CAs to the `tlsParameters.ca` Parameter

To add multiple CA certificates to the `tlsParameters.ca` parameter, use the following commands:

For two CAs:

```
cat CA1.crt CA2.crt | base64 -w0
```

For three CAs:

```
cat CA1.crt CA2.crt CA3.crt | base64 -w0
```

For more CAs:

```
cat CA1.crt CA2.crt CA3.crt ... CAN.crt | base64 -w0
```

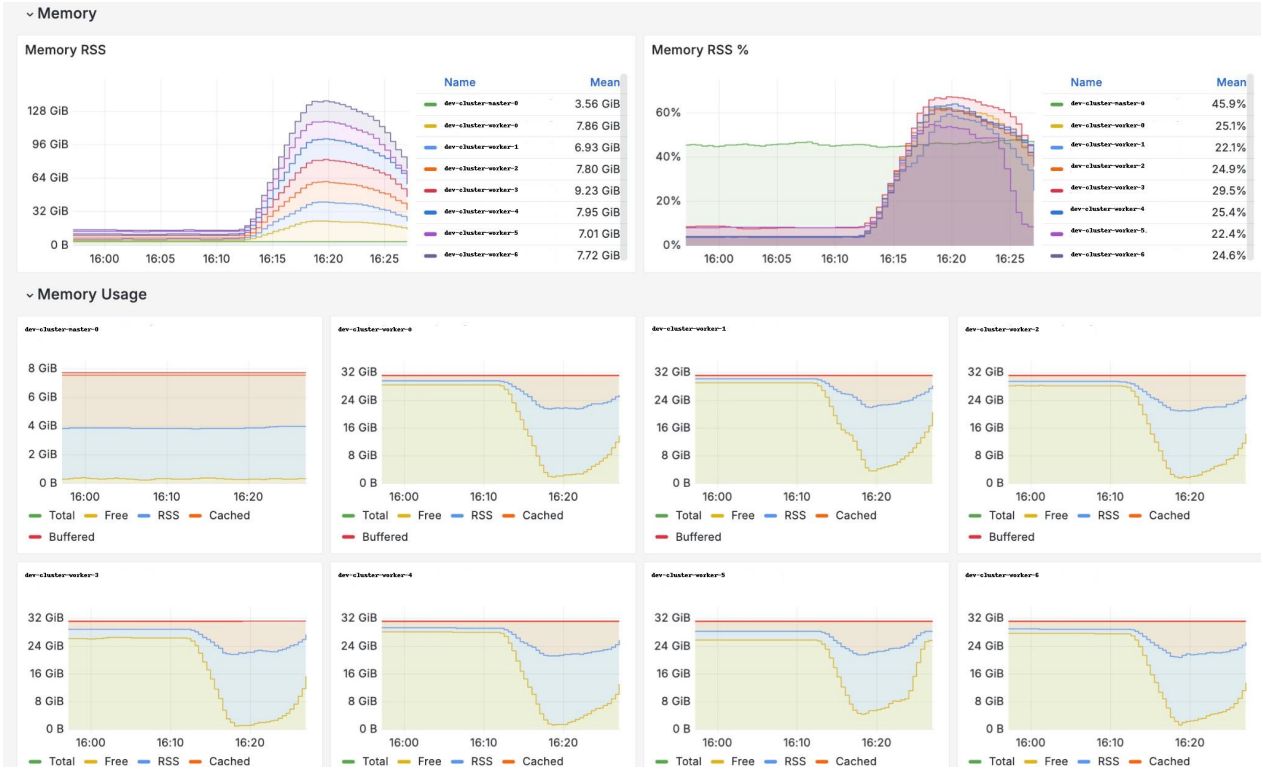
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.



S3 object storage

Deckhouse supports working with S3-based object storage, enabling its use in Kubernetes for storing data as volumes. The GeeseFS file system is used, running via FUSE on top of S3, allowing S3 storage to be mounted as standard file systems.

This page provides instructions for setting up S3 storage in Deckhouse, including connection, creating a StorageClass, and verifying system functionality.

System requirements

- Kubernetes version 1.17+ with support for privileged containers.
- A configured S3 storage with available access keys.
- Sufficient memory on nodes. `GeeseFS` uses caching for working with files retrieved from S3. The cache size is set using the `maxCacheSize` parameter in S3StorageClass.
  Stress test results: 7 nodes, 600 Pods and PVCs, `maxCacheSize` = 500 MB, each Pod writes 300 MB, reads it, and then terminates.

Configuration

Note that all commands must be executed on a machine with administrative privileges in the Kubernetes API.

Required steps:

- Enable the module.
- Create S3StorageClass.

Enabling the module

To support working with S3 storage, enable the `csi-s3` module, which allows the creation of StorageClass and Secret in Kubernetes using custom resources like S3StorageClass.
After enabling the module, the following will occur on cluster nodes:

- CSI driver registration.

- Launch of `csi-s3` service Pods and creation of necessary components.

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: csi-s3
spec:
  enabled: true
  version: 1
EOF
```

Wait for the module to transition to the `Ready` state.

```
d8 k get module csi-s3 -w
```

Creating a StorageClass

The module is configured via the S3StorageClass manifest. Below is an example configuration:

```
apiVersion: storage.deckhouse.io/v1alpha1
kind: S3StorageClass
metadata:
  name: example-s3
spec:
  bucketName: example-bucket
  endpoint: https://s3.example.com
  region: us-east-1
  accessKey: <your-access-key>
  secretKey: <your-secret-key>
  maxCacheSize: 500
  insecure: false
```

If `bucketName` is empty then bucket in S3 will be created for each PV. If `bucketName` is not empty then folder inside the bucket will be created for each PV. If the specifies bucket does not exist it will be created.

Module health check

To verify the health of the module, ensure that all Pods in the `d8-csi-s3` namespace are in the `Running` or `Completed` state and are running on every node in the cluster:

```
d8 k -n d8-csi-s3 get pod -owide -w
```

Limitations

S3 is not a traditional file system, so it comes with several limitations. POSIX compatibility depends on the mounting module used and the specific S3 provider. Some storage backends may not guarantee data consistency (more details here).

Pay attention to the POSIX compatibility matrix.

Key limitations:

- File permissions, symbolic links, user-defined `mtimes`, and special files (block/character devices, named pipes, UNIX sockets) are not supported.
- Special file support is enabled by default for `Yandex S3` but disabled for other providers.
- File permissions are disabled by default.
- User-defined modification times are also disabled: `ctime`, `atime`, and `mtime` are always the same.
- The file modification time cannot be set manually (e.g., using `cp --preserve`, `rsync -a`, or `utimes(2)`).
- Hard links are not supported.
- File locking is not supported.
- “Invisible” deleted files are not retained. If an application keeps an open file descriptor after

deleting a file, it will receive `ENOENT` errors when trying to access it.
- The default file size limit is 1.03 TB, achieved through chunking: 1000 parts of 5 MB, 1000 parts of 25 MB, and 8000 parts of 125 MB. The chunk size can be adjusted, but AWS enforces a maximum file size of 5 TB.

Known bugs

- The requested PVC volume size does not affect the created S3 bucket.
- `df -h` always reports the mounted storage size as 1 PB, and `used` does not change during usage.
- The CSI driver does not validate storage access credentials. Even with incorrect keys, the Pod will remain in `Running` status, and PersistentVolume and PersistentVolumeClaim will be `Bound`. Any attempt to access the mounted directory within the Pod will result in the Pod restarting.

Changing connection parameters for existing PVs

Connection parameters for storage cannot be changed. Changing the StorageClass does not update connection settings in existing PVs.

Displaying the mounted directory size

The `df -h` command shows the mounted volume size as 1 PB, and the `Used` value remains unchanged during operation. This is a peculiarity of the `GeeseFS` mounting module.

Handling exceeded bucket or user quotas

Exceeding the quota is an abnormal situation that should be avoided. The behavior in this case depends on the backend:

- Files can be copied and edited in Pods, but changes will not be reflected in the storage.
- The Pod may fail and restart.

Obtaining information about used space

To get information about the used space, use the storage web interface or a command-line utility.

Using multiple S3 storages in a single module

To do this, create an additional S3StorageClass and a corresponding PVC, then mount them in a Pod as follows:

```
d8 k apply -f - <<EOF
apiVersion: v1
kind: Pod
metadata:
  name: csi-s3-test-nginx
  namespace: default
spec:
  containers:
    - name: csi-s3-test-nginx
      image: nginx
      volumeMounts:
        - mountPath: /usr/share/nginx/html/s3
          name: webroot
        - mountPath: /opt/homedir
          name: homedir
  volumes:
    - name: webroot
      persistentVolumeClaim:
        claimName: csi-s3-pvc # PVC name
        readOnly: false
    - name: homedir
      persistentVolumeClaim:
        claimName: csi-s3-pvc2 # PVC-2 name
        readOnly: false
  EOF
```

Using a single bucket for multiple Pods

When the `bucketName` parameter is specified in S3StorageClass, separate directories are created for each PV in the same bucket, allowing one bucket to be used for multiple Pods.

Troubleshooting

Issues creating a PVC

If you encounter problems when creating a PVC, check the `provisioner` logs:

```
d8 k -n d8-csi-s3 logs -l app=csi-provisioner-s3 -c csi-s3
```

Issues starting containers

Make sure that MountPropagation is not set to `false`, and check the S3 driver logs:

```
d8 k -n d8-csi-s3 logs -l app=csi-s3 -c csi-s3
```

Additional resources

- Module `csi-s3` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

SCSI-based data storage

Deckhouse Platform (DP) supports managing storage connected via iSCSI or Fibre Channel, enabling working with volumes at the block device level. This allows for the integration of storage systems with Kubernetes and management through a CSI driver.

This page provides instructions for connecting SCSI devices in DP, creating SCSITarget, StorageClass, and verifying system functionality.

Supported features

DP supports:

- Detecting Logical Unit Numbers (LUN) via iSCSI or Fibre Channel.
- Creating PersistentVolume (PV) from pre-provisioned LUN.
- Deleting PersistentVolume and wiping data on LUN.
- Attaching LUN to nodes via iSCSI or Fibre Channel.
- Creating multipath devices and mounting them in pods.
- Detaching LUN from nodes.

Limitations

DP doesn’t support:

- Creating LUN on storage systems.
- Resizing LUN.
- Creating snapshots.

System requirements

The following requirements are applicable to the infrastructure and cluster nodes:

- A deployed and configured storage system providing access to LUN via iSCSI or Fibre Channel.
- For iSCSI connections:
  - A unique iSCSI Qualified Name (IQN) must be configured on each cluster node in the

    - `/etc/iscsi/initiatorname.iscsi` file.
    - The `multipath-tools` package must be installed on nodes.
- For Fibre Channel connections:
    - Fibre Channel Host Bus Adapters (FC HBA) must be installed and available on cluster nodes (`/sys/class/fc_host/host*`).
    - In the Storage Area Network (SAN), LUN zoning and masking must be configured, providing node initiators with access to the storage target ports.
    - Necessary LUNs must be pre-provisioned on the storage system. DP does not create LUNs.
    - The `multipath-tools` package must be installed on nodes.

Quick start

All commands should be executed on a machine with access to the Kubernetes API and administrator rights.

Enabling the csi-scsi-generic module

Enable the `csi-scsi-generic` module using the command below. This will ensure that the following happens on all cluster nodes:

- The CSI driver is registered.
- Auxiliary pods for the `csi-scsi-generic` components are running.

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: csi-scsi-generic
spec:
  enabled: true
  version: 1
EOF
```

Wait for the module to transition to the `Ready` state.

```
d8 k get module csi-scsi-generic -w
```

Creating an SCSITarget

The SCSITarget resource describes connection to a single SCSI target. When creating a resource in `spec`, specify one of the connection types: `iSCSI` or `fibreChannel`.

iSCSI

The following is a configuration example for connecting via iSCSI. In this example, two SCSITarget resources are created.

You can create multiple resources for either the same or different storage systems. This lets you use multipath to improve failover and performance.

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: SCSITarget
metadata:
  name: hpe-3par-1
spec:
  deviceTemplate:
    metadata:
      labels:
        my-key: some-label-value
  iSCSI:
    auth:
      login: ""
      password: ""
    iqn: iqn.2000-05.com.3pardata:xxxx1
    portals:
    - 192.168.1.1

---
apiVersion: storage.deckhouse.io/v1alpha1
kind: SCSITarget
metadata:
  name: hpe-3par-2
spec:
  deviceTemplate:
    metadata:
      labels:
        my-key: some-label-value
  iSCSI:
    auth:
      login: ""
      password: ""
    iqn: iqn.2000-05.com.3pardata:xxxx2
    portals:
    - 192.168.1.2
EOF
```

To verify that the object has been created, run:

```
d8 k get scsitargets.storage.deckhouse.io <name-of-scsitarget>
```

An object is considered to be created successfully if it says `Created` in the corresponding `Phase` column in the output.

Fibre Channel

To configure a connection based on Fibre Channel, do the following:

1. Before creating the SCSITarget resource, configure zoning and LUN masking on the SAN so that cluster nodes can access the necessary LUNs.
2. Create the SCSITarget resource. In the `spec.fibreChannel.WWNs` field, define a World Wide Port Name (WWPN) of the target storage ports, which expose the necessary LUNs. DP discovers devices by matching the defined WWPNs against paths under `/dev/disk/by-path/`.

   Define the WWPNs in one of the following formats:

   - 16 hexadecimal characters (`2001c89f1acd6117`)
   - With colons (`20:01:c8:9f:1a:cd:61:17`)
   - With the `0x` prefix (`0x2001c89f1acd6117`)

   DP triggers an FC host scan during discovery and volume attach. It does not configure the commutators or log in to targets.

Configuration example with two target storage system ports for multipath:

```shell kubectl apply -f -«EOF apiVersion: storage.deckhouse.io/v1alpha1 kind: SCSITarget metadata: name: hpe-3par-fc-1 spec: deviceTemplate: metadata: labels: my-key: some-label-value fibreChannel: WWNs: - 2001c89f1acd6117

---

apiVersion: storage.deckhouse.io/v1alpha1 kind: SCSITarget metadata: name: hpe-3par-fc-2 spec: deviceTemplate: metadata: labels: my-key: some-label-value fibreChannel: WWNs: - 2001c89f1acd6118 EOF

```
1. Before applying the resource verify that FC HBA are available on the node and that LUN paths are visible after SAN zoning:

   ```shell
   # FC hosts present.
   ls /sys/class/fc_host/

   # Target WWPNs and LUNs available after zoning.
   ls -l /dev/disk/by-path/ | grep -E 'fc-|/fc-'
```

Possible results:

- If the `/sys/class/fc_host/` directory is empty, the node has no FC HBA or the corresponding driver is not loaded.
- If there are no `fc-*` entries in the `/dev/disk/by-path/` directory, check zoning and LUN masking settings on the storage system.
- If the FC paths are displayed, the node is ready to detect LUN provided via Fibre Channel.

1. After the SCSITarget is created, the controller discovers available LUNs and creates SCSIDevice objects. Use the same SCSIStorageClass resource and `scsiDeviceSelector` workflow as for iSCSI.

2. To verify that the object has been created, run the following command:

   ```
   d8 k get scsitargets.storage.deckhouse.io <name-of-scsitarget>
   ```

   An object is considered to be created successfully if it says `Created` in the corresponding `Phase` column in the output.

Creating a StorageClass

To create a StorageClass, use the SCSIStorageClass resource. A command example to create such a resource:

```
d8 k apply -f -<<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: SCSIStorageClass
metadata:
  name: scsi-all
spec:
  scsiDeviceSelector:
    matchLabels:
      my-key: some-label-value
  reclaimPolicy: Delete
EOF
```

The `scsiDeviceSelector` field is used to select the SCSITarget for PV creation based on labels. In the example above, all SCSITargets with the label `my-key: some-label-value` are selected. This label will be applied to all devices detected within the specified SCSITarget.

To verify that the object has been created, run:

```
d8 k get scsistorageclasses.storage.deckhouse.io <name-of-scsistorageclass>
```

An object is considered to be created successfully if it says `Created` in the corresponding `Phase` column in the output.

Csi-scsi-generic module health check

Check the status of pods in the `d8-csi-scsi-generic` namespace using the command below. All pods should be in the `Running` or `Completed` state and deployed on all nodes.

```
d8 k -n d8-csi-scsi-generic get pod -owide -w
```

Additional resources

- Module `csi-scsi-generic` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

TATLIN.UNIFIED (Yadro) unified storage

Deckhouse supports integration with the TATLIN.UNIFIED (Yadro) storage system, enabling volume management in Kubernetes. This allows the use of centralized storage for containerized workloads, ensuring high performance and fault tolerance.

This page provides instructions on connecting TATLIN.UNIFIED (Yadro) to Deckhouse, configuring the connection, creating a StorageClass, and verifying system functionality.

Enabling the module

To manage volumes based on the TATLIN.UNIFIED (Yadro) storage system in Deckhouse, the `csi-yadro-tatlin-unified` module is used. It allows the creation of StorageClass resources through custom resources like YadroTatlinUnifiedStorageClass. To enable the module, run the following command:

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: csi-yadro-tatlin-unified
spec:
  enabled: true
  version: 1
EOF
```

Wait until `csi-yadro-tatlin-unified` is in the `Ready` status. To check the status, run the following command:

```
d8 k get module csi-yadro-tatlin-unified -w
```

In the output, you should see information about the module:

```
NAME                        STAGE   SOURCE    PHASE       ENABLED    READY
si-yadro-tatlin-unified             Embedded  Available   True       True
```

Connecting to the TATLIN.UNIFIED storage system

To connect to the `TATLIN.UNIFIED` storage system and enable configuring of StorageClass objects, apply the following YadroTatlinUnifiedStorageConnection resource:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: YadroTatlinUnifiedStorageConnection
metadata:
  name: yad1
spec:
  controlPlane:
    address: "172.19.28.184"
    username: "admin"
    password: "cGFzc3dvcmQ=" # Must be encoded in Base64.
    ca: "base64encoded"
    skipCertificateValidation: true
  dataPlane:
    protocol: "iscsi"
    iscsi:
      volumeExportPort: "p50,p51,p60,p61"
EOF
```

Creating a StorageClass

To create a StorageClass, use the YadroTatlinUnifiedStorageClass resource. Creating a StorageClass resource manually without using YadroTatlinUnifiedStorageClass can lead to errors.

Example command to create a StorageClass based on the `TATLIN.UNIFIED` storage system:

```
d8 k apply -f - <<EOF
apiVersion: storage.deckhouse.io/v1alpha1
kind: YadroTatlinUnifiedStorageClass
metadata:
  name: yad1
spec:
  fsType: "xfs"
  pool: "pool-hdd"
  storageConnectionName: "yad1"
  reclaimPolicy: Delete
EOF
```

Ensuring the module works

To make sure the `csi-yadro-tatlin-unified` module is working properly, check the pod status in the `d8-csi-yadro-tatlin-unified` namespace. All pods must have the `Running` or `Completed` status. The `csi-yadro-tatlin-unified` pods must be running on all nodes.

To check that the module works, run the following command:

```
d8 k -n d8-csi-yadro-tatlin-unified get pod -owide -w
```

Additional resources

- Module `csi-yadro-tatlin-unified` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtualization

Deckhouse Platform (DP) runs virtual machines (VMs) in the same cluster as container workloads and

manages them declaratively, through Kubernetes resources. Machines run on the same nodes, networks, and storage as the other workloads, so an administrator configures them with the usual DP tools.

DP lets you do the following:

- Prepare cluster nodes for running virtual machines.
- Store cluster-wide images and provide projects with storage for disks.
- Define the machine parameters that project owners can use.
- Pass node devices through to machines.

Installation and configuration

Virtualization has its own node requirements: hardware virtualization support, the same kernel version everywhere, storage for disks and images, and dedicated subnets for machines. They are listed in Requirements for running virtual machines, while enabling virtualization and placing its components across nodes is covered in Installing virtualization.

The parameters set in the ModuleConfig resource are covered in the module settings reference, and the specifics of updating the components are covered in Updating virtualization.

As guest systems, DP supports operating systems running on the `x86` and `x86-64` architectures. For paravirtualization mode, install the `VirtIO` drivers in the guest system. Linux machines are easier to prepare from images with cloud-init support, and Windows machines with an autounattend answer file.

Storing images and disks

Machine images and disks take up space in the cluster, and an administrator configures how they are stored.

DP keeps uploaded images in its own DVCR storage. Its size, storage class, and the schedule for cleaning up stale data are covered in Virtual machine image storage. The storage classes that projects create disks and images from are listed in Storage for virtual machine disks and images.

Cluster-wide images are prepared by an administrator: project owners create disks from them without uploading the same data again. How to create such images and in what form to store them is covered in Cluster images of virtual machines.

Virtual machine classes

A class defines which processor the guest system sees, which nodes a machine runs on, and which combinations of cores and memory are available to it. A project owner picks a class out of the ones prepared by an administrator, so classes are how DP limits machine parameters in the cluster.

The VirtualMachineClass resource and the purpose of the default class are covered in Virtual machine classes. Each group of settings then has a section of its own: Virtual processor of virtual machines, Placement of virtual machines across nodes, and Virtual machine sizing policy. CPU oversubscription for virtual machines, the share of a physical core that a machine gets guaranteed, is covered separately.

Device passthrough

A machine can be given a node device: a USB device, a GPU, or a PCI device. Each type has its own node requirements and its own preparation order, so each has a section of its own.

Operating a cluster with virtual machines

Running machines also affect other areas of DP configuration:

- Virtual machine networking: Subnets that machines get addresses from.
- Maintenance of nodes running virtual machines: Taking a node out for maintenance without losing machines.
- Virtual machine fault tolerance and balancing: Rebalancing and ColdStandby.
- Virtualization event audit: The log of actions on virtualization resources.

For how virtualization works internally, refer to the Virtualization subsystem section; for the full list of resources and their parameters, refer to the reference. The Virtual machines section is addressed to a project owner.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtual machine image storage

Deckhouse Platform (DP) stores virtual machine images in an internal container image storage (DVCR) that resides on a persistent volume of the cluster. Images travel from there to virtual machine disks, so the size of the volume determines how many images fit into the cluster.

Size and storage class

Set the volume size and the storage class in the `.spec.settings.dvcr.storage` block. To expand the storage, increase the volume size.

> ⚠ After the volume is created, you can’t reduce its size or change its storage class.

Cleaning up image storage

When images and disks are deleted from the cluster, their data remains in DVCR for some time. To keep the storage from filling up with stale data, DP runs garbage collection on a schedule. By default, it runs daily at 02:00. To set your own schedule, use the `.spec.settings.dvcr.gc.schedule` parameter in the `virtualization` ModuleConfig.

While garbage collection is running, the storage works in read-only mode, so creating images and disks is postponed until it completes.

- Using the CLI
- Using the web interface

Example configuration with a custom schedule:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: virtualization
spec:
  # ...
  settings:
    dvcr:
      gc:
        schedule: "0 20 * * *"
  # ...
```

To see how much space is occupied and which data will be removed during the next collection, run:

```
d8 k -n d8-virtualization exec deploy/dvcr -- dvcr-cleaner gc check
```

Example output:

```
Found 2 cvi, 5 vi, 1 vd manifests in registry
Found 1 cvi, 5 vi, 11 vd resources in cluster
  Total     Used    Avail     Use%
36.3GiB  13.1GiB  22.4GiB      39%
Images eligible for cleanup:
KIND                   NAMESPACE            NAME
ClusterVirtualImage                         debian-12
VirtualDisk            default              debian-10-root
VirtualImage           default              ubuntu-2404
```

1. Go to the **System** tab, then to **Deckhouse → Modules**.
2. Select the `virtualization` module from the list.
3. In the window that opens, on the **Configuration** tab, enable the **Advanced settings** toggle.
4. In the **Disk and ISO image storage** block, set the schedule in the **Cleanup schedule in Cron format** field.
5. Click **Save**.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage for virtual machine disks and images

The project owner chooses the storage class for an image or a disk. You can limit that choice and set a default class. The `.spec.settings.virtualImages` block covers images, and the `.spec.settings.virtualDisks` block covers disks.

Example:

```
spec:
  settings:
    virtualImages:
      allowedStorageClassSelector:
        matchNames:
          - sc-1
          - sc-2
      defaultStorageClassName: sc-1
    virtualDisks:
      allowedStorageClassSelector:
        matchNames:
          - sc-3
      defaultStorageClassName: sc-3
```

Both blocks work the same way and both are optional. The `allowedStorageClassSelector.matchNames` parameter lists the classes allowed in the VirtualImage and VirtualDisk specification, and `defaultStorageClassName` sets the class for resources where the `.spec.persistentVolumeClaim.storageClassName` parameter isn't set.

Additional resources

Cluster images of virtual machines

An image holds the contents of a disk that project owners use to create virtual machine disks. A cluster image, ClusterVirtualImage, is available in every namespace and project of the cluster, so an image uploaded once serves all projects at once.

An image appears in the cluster in three steps:

1. The administrator creates a ClusterVirtualImage resource and specifies a data source in it.
2. Deckhouse Platform (DP) downloads the image from that source to the internal storage (DVCR).
3. The downloaded image becomes available for creating disks.

The image source can be an HTTP server hosting the image file, a container image registry, or a file on your computer that you upload from the command line. You can also create an image from another image, from a virtual machine disk, or from a disk snapshot.

The `PHASE` column in the `d8 k get cvi` output shows the progress of image creation; for its values, see the `.status.phase` field. To follow the creation in real time, add the `-w` flag. If an image stays not ready for a long time, check the `.status.conditions` block and the `d8 k describe cvi` output for the reason.

Until an image reaches the `Ready` phase, you can change its `.spec` block, and the download restarts after each change. For a ready image, the `.spec` block can no longer be changed. For all image parameters, see ClusterVirtualImage.

Image types and formats

There are two types of images:

- **ISO image**: An installation image used for the initial installation of an operating system (OS). OS vendors publish such images and use them to install the OS on physical and virtual servers.
- **Disk image with a preinstalled system**: Contains an OS that is already installed and configured, and is ready to work as soon as the virtual machine (VM) is created. Distribution vendors publish such images, or you can build them yourself.

Distribution vendors publish ready-made images with a preinstalled system. The following table lists their download pages and the users configured in those images by default:

Distribution	Default user
AlmaLinux	`almalinux`
AlpineLinux	`alpine`
AltLinux	`altlinux`
AstraLinux	`astra`
CentOS	`cloud-user`
Debian	`debian`
Rocky	`rocky`
Ubuntu	`ubuntu`

DP accepts image files in the following formats:

- `qcow2`
- `raw`
- `vmdk`
- `vdi`
- `vhd`
- `vhdx`

You can provide an image compressed with `gz`, `xz`, or `zst`. DP unpacks it during the upload.

DP detects the image type and size on its own and records them in the resource status. There are two sizes, and both appear in the `d8 k get cvi -o wide` output:

- `STOREDSIZE`: The space the image occupies in the storage. For an image uploaded in a compressed form, it's smaller than the unpacked size. Use this column to estimate how much space the images take in DVCR.
- `UNPACKEDSIZE`: The size of the image after unpacking. It defines the minimum size of a disk that can be created from this image.

> **i** When creating a disk from an image, specify a size no smaller than the `UNPACKEDSIZE` value. If you don't specify a size, the disk is created with exactly the unpacked size of the image.

Creating a cluster image from an HTTP server

The simplest way to create an image is to provide a link to a file hosted on an HTTP server.

- Using the CLI
- Using the web interface

1. Create a ClusterVirtualImage resource:

```
d8 k apply -f - <<EOF
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: ClusterVirtualImage
metadata:
  name: ubuntu-24-04
spec:
  # Source for the image.
  dataSource:
    type: HTTP
    http:
      url: https://cloud-images.ubuntu.com/noble/current/noble-server-cloudimg-
amd64.img
EOF
```

2. Verify that the image is created:

```
d8 k get clustervirtualimage ubuntu-24-04

# Short form of the command.
d8 k get cvi ubuntu-24-04
```

   Example output:

```
NAME           PHASE   CDROM   PROGRESS   AGE
ubuntu-24-04   Ready   false   100%       23h
```

To make DP verify the downloaded file against a checksum, add the `checksum` block to the source. If the file doesn't match any of the specified checksums, the image moves to the `Failed` phase.

1. Go to the **System** tab, then to **Virtualization → Cluster images**.
2. Click **Create**, then select **By link** in the **Source** block.
3. In the **Image name** field, enter the image name.
4. In the **URL** field, specify the link to the image.
5. Click **Create**.
6. Wait until the image reaches the **Ready** state.

Creating a cluster image from a container image registry

DP can pull an image from an external container image registry, but the disk file must be located in the container image under the `/disk` path. The following steps show how to prepare such a container image and create a cluster image from it.

- Using the CLI
- Using the web interface

1. Download the image file to your local machine:

   ```
   curl -L https://cloud-images.ubuntu.com/minimal/releases/noble/release/ubuntu-24.04-minimal-cloudimg-amd64.img -o ubuntu2404.img
   ```

2. Create a `Dockerfile` with the following contents:

   ```
   FROM scratch
   COPY ubuntu2404.img /disk/ubuntu2404.img
   ```

3. Build the container image. The example uses the docker.com registry, which requires an account and a configured environment:

   ```
   docker build -t docker.io/<USERNAME>/ubuntu2404:latest
   ```

   Where `<USERNAME>` is the username you specified when registering in the registry.

4. Push the built container image to the registry:

   ```
   docker push docker.io/<USERNAME>/ubuntu2404:latest
   ```

5. Create a ClusterVirtualImage resource that points to the container image:

   ```
   d8 k apply -f - <<EOF
   apiVersion: virtualization.deckhouse.io/v1alpha2
   kind: ClusterVirtualImage
   metadata:
     name: ubuntu-2404
   spec:
     dataSource:
       type: ContainerImage
       containerImage:
         image: docker.io/<USERNAME>/ubuntu2404:latest
   EOF
   ```

DP works only with registries that have TLS enabled. If the registry uses its own certificate authority, provide the certificate chain in the `caBundle` parameter, and take the credentials for a private registry from the secret specified in the `imagePullSecret` parameter.

1. Go to the **System** tab, then to **Virtualization** → **Cluster images**.
2. Click **Create**, then select **From registry** in the **Source** block.
3. In the **Image name** field, enter the image name.
4. In the **Image in container registry** field, specify the link to the image.
5. Click **Create**.
6. Wait until the image reaches the **Ready** state.

Uploading a cluster image from the command line

If the image file is on your computer, upload it directly. DP creates a temporary upload endpoint for this and waits for the data.

- Using the CLI
- Using the web interface

1. Create a ClusterVirtualImage resource with the `Upload` source:

```
d8 k apply -f - <<EOF
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: ClusterVirtualImage
metadata:
  name: some-image
spec:
  # Image source settings.
  dataSource:
    type: Upload
EOF
```

The resource moves to the `WaitForUserUpload` phase and is ready to accept the file. Start the upload within 10 minutes, otherwise the resource moves to the `Failed` phase and you have to create it again.

2. Get the addresses that accept the file:

   ```
   d8 k get cvi some-image -o jsonpath="{.status.imageUploadURLs}" | jq
   ```

   Example output:

   ```
   {
     "external":"https://virtualization.example.com/upload/<SECRET_URL>",
     "inCluster":"http://10.222.165.239/upload"
   }
   ```

   Use the `inCluster` address if you upload the file from one of the cluster nodes, and `external` in all other cases.

3. Upload the file to the selected address. The example first downloads the Cirros image and then sends it to the cluster:

   ```
   curl -L http://download.cirros-cloud.net/0.5.1/cirros-0.5.1-x86_64-disk.img -o cirros.img
   curl https://virtualization.example.com/upload/<SECRET_URL> --progress-bar -T cirros.img | cat
   ```

   Where `<SECRET_URL>` is the last part of the address from the previous step.

4. Verify that the image has reached the `Ready` phase:

   ```
   d8 k get cvi some-image
   ```

   Example output:

   ```
   NAME         PHASE   CDROM   PROGRESS   AGE
   some-image   Ready   false   100%       1m
   ```

You can also verify the uploaded file against a checksum. To do this, specify the `checksum` block in the data source.

1. Go to the **System** tab, then to **Virtualization → Cluster images**.
2. Click **Create**, then select **Upload** in the **Source** block.
3. In the **Image name** field, enter the image name.
4. In the **Upload file** block, drag the file to the highlighted area or click **select on your computer**.
5. Select the file in the file manager that opens.
6. Click **Create**.
7. Wait until the image reaches the **Ready** state.

Additional resources

- Module `virtualization` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtual machine classes

A virtual machine (VM) class defines what the project owner doesn't configure: the virtual CPU model, the allowed combinations of cores and memory, and the nodes where a VM can run. These rules are described by the VirtualMachineClass resource, which you use to control how project workloads are distributed across cluster nodes.

On the initial installation, the module creates the `generic` class with the Nehalem CPU model. This model is old but supported by any modern CPU, so VMs of this class start on any cluster node and migrate between nodes without restrictions.

> The `generic` class matches a CPU with the smallest instruction set, so it isn't suitable for production workloads.
>
> Once all nodes are added to the cluster and configured, create at least one class with the `Discovery` CPU type. Deckhouse Platform (DP) selects an instruction set available on all nodes at once, so virtual machines can make fuller use of the CPUs while still being able to migrate between nodes. The instruction set is fixed when the resource is created and doesn't change as nodes are added or removed.
>
> For an example of such a class, see vCPU Discovery configuration example.

Classes exist at the cluster level. To list them, run the following command:

```
d8 k get virtualmachineclass
```

Example output:

```
NAME      PHASE   ISDEFAULT   AGE
generic   Ready               6d1h
```

In any class, you can change everything except the `.spec.cpu` block, because the CPU model is fixed when the resource is created. You can both modify and delete the `generic` class, but it won't be created again, because the module adds it only on the initial installation.

The project owner specifies the class in the `.spec.virtualMachineClassName` parameter of a virtual machine:

```
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachine
metadata:
  name: linux-vm
spec:
  virtualMachineClassName: generic # Name of the VirtualMachineClass resource.
  # ...
```

Default VirtualMachineClass

You can designate one of the classes as the default. DP inserts its name into the `.spec.virtualMachineClassName` parameter if the project owner doesn't specify a class.

The default class is marked with the `virtualmachineclass.virtualization.deckhouse.io/is-default-class` annotation set to `true`. A cluster can have only one such class, so to designate a new one, first remove the annotation from the current one.

Don't add the annotation to the `generic` class, because a module update can remove it. Create your own class and designate it as the default instead.

1. Check which classes exist in the cluster:

   ```
   d8 k get vmclass
   ```

   Example output with no default class:

   ```
   NAME                      PHASE   ISDEFAULT   AGE
   generic                   Ready               1d
   host-passthrough-custom   Ready               1d
   ```

2. Designate the default class:

   ```
   d8 k annotate vmclass host-passthrough-custom virtualmachineclass.virtualization.deckhouse.io/is-default-class=true
   ```

3. Verify that the annotation is set:

   ```
   d8 k get vmclass
   ```

   Example output:

   ```
   NAME                      PHASE   ISDEFAULT   AGE
   generic                   Ready               1d
   host-passthrough-custom   Ready   true        1d
   ```

From now on, virtual machines created without a class get the `host-passthrough-custom` class.

VirtualMachineClass settings

A class consists of three blocks, each responsible for its own group of settings:

- Using the CLI
- Using the web interface

Describe the class in a VirtualMachineClass resource:

```
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachineClass
metadata:
  name: <VMCLASS_NAME>
  # The annotation designates the class as the default one. It's optional.
  # annotations:
  #   virtualmachineclass.virtualization.deckhouse.io/is-default-class: "true"
spec:
  # Virtual CPU parameters. The block is required and can't be changed after the
resource is created.
  cpu: ...

  # Rules for placing virtual machines on nodes. The block is optional.
  # Changes apply to all VMs of this class.
  nodeSelector: ...

  # Resource allocation policy for virtual machines. The block is optional.
  # Changes apply to all VMs of this class.
  sizingPolicies: ...
```

Where `<VMCLASS_NAME>` is the name of the class you're creating.

1. Go to the **System** tab, then to **Virtualization** → **VM classes**.
2. Click **Create**.
3. In the form that opens, enter the VM class name in the **Name** field.

The blocks are described separately in the following sections.

Additional resources

- Module `virtualization` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

Virtual processor of virtual machines

A virtual machine (VM) class defines which processor and which instruction set the guest system sees.

Virtual processor

The `.spec.cpu` block defines the CPU that the guest OS sees. It also determines which nodes a VM can migrate between.

> ⚠ The `.spec.cpu` block can't be changed after the resource is created. To use a different CPU, create a new class.

The following examples cover each CPU type.

- A set of CPU instructions required for a VM. Set with the `Features` type:

  ```
  spec:
    cpu:
      features:
        - vmx
      type: Features
  ```

  To configure the vCPU in the web interface, in the VM class creation form:

  1. In the **CPU settings** block, select `Features` in the **Type** field.
  2. In the **Required set of supported instructions** field, select the instructions you need.
  3. Click **Create**.

- A universal CPU for a given set of nodes. Set with the `Discovery` type:

  ```
  spec:
    cpu:
      discovery:
        nodeSelector:
          matchExpressions:
            - key: node-role.kubernetes.io/control-plane
              operator: DoesNotExist
      type: Discovery
  ```

  To do the same in the web interface, in the VM class creation form:

  1. In the **CPU settings** block, select `Discovery` in the **Type** field.
  2. Click **Add** in the **Conditions for creating a universal CPU → Labels and expressions** block.
  3. Set **Key**, **Operator**, and **Value**. They correspond to the `.spec.cpu.discovery.nodeSelector` parameter.
  4. Press **Enter** to confirm the key parameters.
  5. Click **Create**.

- A CPU close to the node CPU. Set with the `Host` type. The guest OS gets almost the full instruction set of the node, so performance is higher than with a fixed model. A VM of this class migrates only between nodes with similar CPUs. For example, migration between nodes with Intel and AMD CPUs isn't possible, and neither is migration between CPU generations with different instruction sets.

```
spec:
  cpu:
    type: Host
```

To do the same in the web interface, in the VM class creation form:

1. In the **CPU settings** block, select `Host` in the **Type** field.
2. Click **Create**.

- The node CPU without changes. Set with the `HostPassthrough` type. A VM of this class migrates only to a node whose CPU exactly matches the CPU of the source node.

```
spec:
  cpu:
    type: HostPassthrough
```

To do the same in the web interface, in the VM class creation form:

1. In the **CPU settings** block, select `HostPassthrough` in the **Type** field.
2. Click **Create**.

- A specific CPU model with a known instruction set. Set with the `Model` type. First, check which models the target node supports:

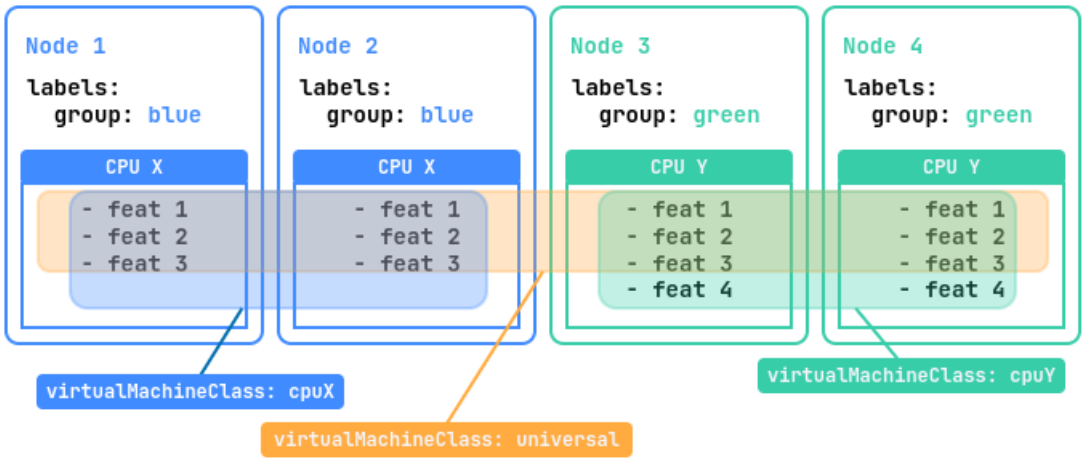
```
d8 k get nodes <NODE_NAME> -o json | jq '.metadata.labels | to_entries[] | select(.key
| test("cpu-model.node.virtualization.deckhouse.io")) | .key | split("/")[1]' -r
```

Where `<NODE_NAME>` is the name of a cluster node.

Example output:

```
Broadwell-noTSX
Broadwell-noTSX-IBRS
Haswell-noTSX
Haswell-noTSX-IBRS
IvyBridge
IvyBridge-IBRS
Nehalem
Nehalem-IBRS
Penryn
SandyBridge
SandyBridge-IBRS
Skylake-Client-noTSX-IBRS
Westmere
Westmere-IBRS
```

Then specify the selected model in the class specification:



```
spec:
  cpu:
    model: IvyBridge
    type: Model
```

To do the same in the web interface, in the VM class creation form:

1. In the **CPU settings** block, select `Model` in the **Type** field.
2. In the **Model** field, select the CPU model.
3. Click **Create**.

vCPU Discovery configuration example

The following example shows how to choose the processor types in a cluster with heterogeneous nodes.

The example below uses a cluster of four nodes. Two nodes labeled `group=blue` are equipped with the “CPU X” processor with three instruction sets, and the other two labeled `group=green` have the newer “CPU Y” processor with four sets.

> **i** A CPU instruction set is every command the processor can execute, from addition to memory operations. The set determines which programs run and how fast, and it differs between CPU generations.

Three classes suit such a cluster:

- `universal`: VMs start on any node and migrate between all four. Deckhouse Platform (DP) takes the instruction set common to both processors, so compatibility is maximal, while some capabilities of “CPU Y” stay unused.
- `cpuX`: VMs start only on nodes with “CPU X” and migrate between them, using all instructions of that processor.
- `cpuY`: The same for nodes with “CPU Y”.

The classes for such a cluster look as follows:

```
---
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachineClass
metadata:
  name: universal
spec:
  cpu:
    # An empty discovery means that all cluster nodes are taken into account.
    discovery: {}
    type: Discovery
---
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachineClass
metadata:
  name: cpuX
spec:
  cpu:
    discovery:
      nodeSelector:
        matchExpressions:
          - key: group
            operator: In
            values: ["blue"]
    type: Discovery
---
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachineClass
metadata:
  name: cpuY
spec:
  cpu:
    discovery:
      nodeSelector:
        matchExpressions:
          - key: group
            operator: In
            values: ["green"]
    type: Discovery
```

Additional resources

- Module `virtualization` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Placement of virtual machines across nodes

The optional `.spec.nodeSelector` block limits the set of nodes where virtual machines (VMs) of this class run. Nodes are selected by labels:

```
spec:
  nodeSelector:
    matchExpressions:
      - key: node.deckhouse.io/group
        operator: In
        values:
          - green
```

⚠ A change to the `.spec.nodeSelector` block affects all virtual machines of the class at once. Those running on nodes that no longer match the new conditions have to be moved:

- In commercial editions, Deckhouse Platform (DP) migrates such VMs to suitable nodes.
- In DP Open, the VMs are restarted, and the restart time depends on the `.spec.disruptions.restartApprovalMode` parameter of the virtual machine, which defaults to `Manual` and requires the project owner's approval.

To do the same in the web interface, in the VM class creation form:

1. Click **Add** in the **Conditions for scheduling VMs on nodes → Labels and expressions** block.
2. Set **Key**, **Operator**, and **Value**. They correspond to the `.spec.nodeSelector` parameter.
3. Press **Enter** to confirm the key parameters.
4. Click **Create**.

Virtual machine sizing policy

The `.spec.sizingPolicies` block defines which combinations of cores, core fraction, and memory are allowed for virtual machines (VMs) of this class.

⚠ Changes to the `.spec.sizingPolicies` block affect existing virtual machines. For virtual machines that no longer meet the new requirements, the `SizingPolicyMatched` condition in the `.status.conditions` block gets the `False` status.

When defining policies, take the CPU topology of virtual machines into account.

A policy consists of a list of rules, each applying to its own range of cores. The range is set in the required `cores` block, and ranges of different rules must not overlap, otherwise Deckhouse Platform (DP) rejects the class.

A valid structure, where the ranges follow one another without overlapping:

```
- cores:
    min: 1
    max: 4
  # ...
- cores:
    min: 5 # The next range starts one above the previous max.
    max: 8
```

An invalid structure, where the value `4` falls into two ranges at once:

```
- cores:
   min: 1
   max: 4
  # ...
- cores:
   min: 4
   max: 8
```

DP doesn’t forbid gaps between ranges, but a virtual machine whose number of cores falls outside every range is left without a policy. For this reason, start each range with the value that follows the `max` of the previous one.

Within a range, you set the requirements for memory and for the core fraction:

- `memory`: The minimum and maximum amount of memory. Set either for the whole range or per core, in the nested `memory.perCore` block.
- `coreFractions`: The list of allowed core fractions, for example `[25, 50, 100]` for 25%, 50%, and 100%. If the project owner sets the `coreFraction` parameter of a virtual machine explicitly, the value must come from this list.
- `defaultCoreFraction`: The core fraction that a virtual machine gets if `coreFraction` isn’t set in it. The value must be in the `coreFractions` list. If the parameter isn’t specified, 100% applies.

A rule with neither `memory` nor `coreFractions` doesn’t limit anything, so set at least one of them.

In commercial DP editions, you can set the `defaultCoreFraction` parameter to `Auto`. In that case, the core fraction for VMs without an explicit `coreFraction` is chosen by vertical autoscaling. `Auto` is a mode, not a share of a core, so it must not appear in the `coreFractions` list.

```
spec:
  sizingPolicies:
    - cores:
       min: 1
       max: 8
      coreFractions: [10, 25, 50, 100]
      defaultCoreFraction: Auto
```

The `Auto` value is accepted only when both capabilities are available:

- Vertical autoscaling of virtual machines, which is enabled automatically in commercial DP editions when the `vertical-pod-autoscaler` module is enabled.
- Changing the number of cores and the amount of memory without a restart, which is enabled by the `HotplugCPUAndMemoryWithInPlaceResize` feature in the `.spec.settings.featureGates` parameter.

If at least one of them is unavailable, DP rejects the creation of such a class.

A new default applies only to the virtual machines created after the change. An existing machine already carries the previous value in its specification, and the value stays there until the project owner sets another one.

The following examples show how the amount of memory depends on the number of cores:

- The `memory` parameter sets the same limits for the whole range of cores:

  ```
  - cores:
     min: 1
     max: 4
    memory:
     min: 2Gi
     max: 8Gi
  ```

  A virtual machine with any number of cores from 1 to 4 gets from 2 to 8 GiB of memory, and the number of cores doesn’t affect these limits.

- The `memory.perCore` parameter sets the limits per core, and the resulting limits are the product of that value and the number of cores:

```
- cores:
    min: 1
    max: 4
  memory:
    perCore:
      min: 1Gi
      max: 2Gi
```

With such a policy, the allowed amount of memory grows with the number of cores:

- 1 core: From 1 to 2 GiB.
- 2 cores: From 2 to 4 GiB.
- 3 cores: From 3 to 6 GiB.
- 4 cores: From 4 to 8 GiB.

- The `memory.step` parameter limits the allowed memory values to a grid, so that the project owner can’t choose arbitrary amounts.

  Together with `memory.min` and `memory.max`, the step is counted from the minimum:

  ```
  - cores:
      min: 1
      max: 4
    memory:
      min: 2Gi
      max: 8Gi
      step: 1Gi
  ```

  Only the values 2, 3, 4, 5, 6, 7, and 8 GiB are allowed; 2.5 or 7.5 GiB can’t be set.

  Together with `memory.perCore`, the step is counted from the memory per core, and the resulting value is then multiplied by the number of cores:

  ```
  - cores:
      min: 1
      max: 4
    memory:
      perCore:
        min: 1Gi
        max: 2Gi
      step: 512Mi
  ```

  Per core, 1, 1.5, and 2 GiB are allowed, so the resulting amount depends on the number of cores:

  - 1 core: 1, 1.5, or 2 GiB.
  - 2 cores: 2, 3, or 4 GiB.
  - 3 cores: 3, 4.5, or 6 GiB.
  - 4 cores: 4, 6, or 8 GiB.

An example of a policy that covers ranges from 1 to 248 cores:

```
spec:
  sizingPolicies:
    # For 1-4 cores, from 1 to 8 GiB of memory is available with a 512 MiB step,
    # that is, 1 GiB, 1.5 GiB, 2 GiB, 2.5 GiB, and so on.
    # All core fractions are available.
    - cores:
        min: 1
        max: 4
      memory:
        min: 1Gi
        max: 8Gi
        step: 512Mi
      coreFractions: [5, 10, 20, 50, 100]
      defaultCoreFraction: 50 # Default core fraction for the 1-4 core range.
    # For 5-8 cores, from 5 to 16 GiB of memory is available with a 1 GiB step,
    # that is, 5 GiB, 6 GiB, 7 GiB, and so on.
    # Core fractions are limited to three values.
    - cores:
        min: 5
        max: 8
      memory:
        min: 5Gi
        max: 16Gi
        step: 1Gi
      coreFractions: [20, 50, 100]
      defaultCoreFraction: 100 # Default core fraction for the 5-8 core range.
    # For 9-16 cores, from 9 to 32 GiB of memory is available with a 1 GiB step.
    # Core fractions are limited to two values.
    - cores:
        min: 9
        max: 16
      memory:
        min: 9Gi
        max: 32Gi
        step: 1Gi
      coreFractions: [50, 100]
    # For 17-248 cores, from 1 to 2 GiB of memory is available per core.
    # The core fraction is 100% only.
    - cores:
        min: 17
        max: 248
      memory:
        perCore:
          min: 1Gi
          max: 2Gi
      coreFractions: [100]
```

To configure sizing policies in the web interface, in the VM class creation form:

1. Click **Add** in the **Resource allocation rules for virtual machines** block.
2. In the **CPU** block, enter `1` in the **Min** field and `4` in the **Max** field.
3. In the **CPU** block, in the **Allow setting core fractions** field, select the values `5%`, `10%`, `20%`, `50%`, `100%` in order.
4. In the **Memory** block, set the toggle to **Amount per 1 core**.
5. In the **Memory** block, enter `1` in the **Min** field and `8` in the **Max** field.
6. In the **Memory** block, enter `1` in the **Discretization step** field.
7. Add other ranges with the **Add** button, if required.
8. Click **Create**.

CPU oversubscription for virtual machines

Oversubscription lets you give the virtual machines (VMs) on a node more virtual cores than the node physically has. This makes sense because VMs rarely load the CPU at the same time and at full capacity.

The degree of oversubscription is controlled by the `coreFraction` parameter of a virtual machine, and you define its allowed values in the sizing policy of the class. The parameter defines the share of a core's capacity guaranteed to a VM. For example, with `coreFraction: 20%`, a VM always gets a fifth of a core, and it can take a whole core when the node has spare resources.

> If the `coreFractions` list isn't set in the class or contains several values, the project owner chooses the degree of oversubscription by specifying `coreFraction` when creating a VM.

When placing a VM on a node, Deckhouse Platform (DP) sums the guaranteed shares of all VMs on that node using the `Σ(cores × coreFraction / 100)` formula. If the sum exceeds the number of physical cores, the VM doesn't start on that node.

Consider a node with 4 physical cores and 5 VMs, each with 2 cores and `coreFraction: 20%`. The guaranteed load is `5 × 2 × 0.2 = 2` cores, with 10 virtual cores on 4 physical ones, which is an oversubscription of 2.5 to 1. All five VMs fit on the node, because 2 cores is less than the available 4.

Fixed oversubscription

A list with a single value leaves the project owner no choice, and you define the degree of oversubscription for all VMs of the class:

```
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachineClass
metadata:
  name: oversubscribed
spec:
  sizingPolicies:
    - cores:
        min: 1
        max: 8
      memory:
        perCore:
          min: 1Gi
          max: 8Gi
      coreFractions: [20] # The only allowed value.
      defaultCoreFraction: 20
```

All VMs of this class get 20% of a core each, which gives an oversubscription of 5 to 1.

Oversubscription chosen by the project owner

A list with several values leaves the choice to the project owner:

```
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachineClass
metadata:
  name: standard
spec:
  sizingPolicies:
    - cores:
        min: 1
        max: 4
      memory:
        perCore:
          min: 1Gi
          max: 8Gi
      coreFractions: [5, 10, 20, 50, 100]
      defaultCoreFraction: 20
```

The project owner selects `coreFraction` from the list, and if they don’t, the VM gets 20%.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

USB devices in virtual machines

USB device passthrough to virtual machines (VMs) is handled by the `virtualization-dra` system component, which needs three kernel modules on the node:

- `usbip_core`
- `usbip_host`
- `vhci_hcd`

DP loads them on the nodes itself. A node where all three modules are available gets the `virtualization.deckhouse.io/usbip=true` label, and the `virtualization-dra` component runs only on such nodes. If the kernel modules stop being available, the label is removed and the component is deleted from the node.

To see which nodes are ready for USB device passthrough, run the following command:

```
d8 k get nodes -l virtualization.deckhouse.io/usbip=true
```

Example output:

```
NAME     STATUS   ROLES    AGE   VERSION
node-1   Ready    worker   10d   v1.34.1
```

To verify that the component is actually running on these nodes, run the following command:

```
d8 k -n d8-virtualization get pods -l app=virtualization-dra -o wide
```

A node missing from the output failed to load the kernel modules, and USB devices on that node aren’t detected. Install the kernel modules yourself from your operating system package, or build them for the kernel in use. DP detects them on its own and assigns the label to the node within a few minutes.

Path of a USB device from a node to a VM

A USB device travels from the node to a virtual machine in four steps:

1. The DRA driver detects USB devices on the nodes and publishes information about them to the Kubernetes API as a ResourceSlice. DP creates NodeUSBDevice resources from this data.
2. The administrator assigns a namespace to the NodeUSBDevice resource by setting the

`.spec.assignedNamespace` parameter. This makes the device available in that namespace.

3. Once the namespace is assigned, DP creates a USBDevice resource in it.
4. The project owner attaches the USBDevice device to a virtual machine by adding it to the `.spec.usbDevices` parameter of the VirtualMachine resource.

Discovered devices (NodeUSBDevice)

The NodeUSBDevice resource describes a physical USB device detected on a node. The resource exists at the cluster level, so you see all detected devices in a single list:

```
d8 k get nodeusbdevice
```

Example output:

```
NAME              NODE     READY   ASSIGNED   ATTACHED   NAMESPACE    AGE
usb-flash-drive   node-1   True    False      False                   10m
logitech-webcam   node-2   True    True       True       my-project   15m
```

The conditions in the `.status.conditions` block reflect the readiness of the device and its state. The `Ready` and `Attached` conditions match the USBDevice conditions, and the `Assigned` condition shows whether a namespace is assigned to the device:

- `Available`: No namespace is assigned.
- `InProgress`: A namespace is assigned and the USBDevice resource is being created.
- `Assigned`: The USBDevice resource is created and the device is available in the namespace.

Assigning a namespace to a USB device

Until a namespace is assigned to a device, the project owner doesn’t see it. To make the device available in a project, follow these steps.

1. Connect the USB device to a node that is ready for passthrough and wait for a NodeUSBDevice resource to appear.
2. Assign the namespace with the `.spec.assignedNamespace` parameter:

   ```
   d8 k apply -f - <<EOF
   apiVersion: virtualization.deckhouse.io/v1alpha2
   kind: NodeUSBDevice
   metadata:
     name: logitech-webcam
   spec:
     assignedNamespace: my-project
   EOF
   ```

3. Verify that a USBDevice resource appears in the namespace:

   ```
   d8 k get usbdevice -n my-project
   ```

After that, the project owner attaches the device to a virtual machine.

Viewing USB device details

Full details about a device and its current state are available in the resource status.

> **i** When a device is physically disconnected from the node, the `Attached` condition gets the `False` value, and the `Ready` condition gets the `NotFound` reason. The same is reflected in the status of the USBDevice resource in the project namespace.

- Using the CLI
- Using the web interface

The device identifiers, its location, and the current conditions are stored in the resource status:

```
d8 k get nodeusbdevice <DEVICE_NAME> -o yaml
```

Where `<DEVICE_NAME>` is the name of the NodeUSBDevice resource.

To get only the device attributes, query the fields you need directly:

```
d8 k get nodeusbdevice <DEVICE_NAME> \
  -o jsonpath='{.status.attributes.manufacturer}{" "}{.status.attributes.product}{"
("}{.status.attributes.vendorID}{":"}{.status.attributes.productID}{")\n"}'
```

Example output:

```
Logitech Webcam C920 (046d:082d)
```

1. Go to the **System** tab, then to **Virtualization → Node USB devices**.
2. Review the list, which shows the device status, manufacturer, product, serial number, node, bus, device number, and assigned namespace.

The project owner sees the devices assigned to their project in the **Virtualization → USB devices** section of that project.

Requirements and limitations

When planning USB device passthrough, consider the following requirements and limitations:

- A node where USB devices must be detected has to carry the `virtualization.deckhouse.io/usbip=true` label and run containerd version 2, otherwise the `virtualization-dra` component doesn't start there.
- A device is passed to a virtual machine over the network using USBIP, so the VM can run on a node other than the one the device is physically connected to.
- Only a device that reports the USB 2.0 speed (480 Mbps) or a USB 3.x speed (5 Gbps and higher) can be passed through. DP doesn't let you attach a slower device to a VM, for example a mouse or a keyboard at 1.5 or 12 Mbps.
- A node connects no more than 16 devices, 8 per USB 2.0 hub and 8 per USB 3.0 hub.
- The hub is selected by the device speed and can't be changed manually. A USB 2.0 device doesn't connect to a USB 3.0 hub, and vice versa.
- A device can be attached to a running VM and detached from it without stopping the VM.

Additional resources

- Module `virtualization` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

GPU devices in virtual machines

DP attaches physical GPU devices to virtual machines using DRA (Dynamic Resource Allocation). A project owner requests a device by a reference to a `GPUClass` in the `.spec.gpus` block of their machine, and you prepare the cluster for this.

To make passthrough work, provide the following:

- Kubernetes 1.34 or later with the DRA feature gates required by your cluster configuration.
- The `GPU` feature gate in the module settings.
- The enabled `gpu` module in the DRA mode, which is set by the `dra.enabled` parameter.
- A `GPUClass` resource that selects devices of the model you need. The `gpu` module creates a DeviceClass resource with the same name from it, and the device is allocated to a machine through that class.

To enable the feature gate, add it to the module settings:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: virtualization
spec:
  settings:
    featureGates:
      - GPU
```

After that, tell the project owners the names of the available `GPUClass` resources. A single machine takes no more than 16 devices, and a change to the `.spec.gpus` block applies only after the machine restarts.

Additional resources

- Module `gpu` documentation
- Module `virtualization` custom resources

PCI devices in virtual machines

PCI device passthrough lets you attach a physical device of a node to a virtual machine (VM), for example an industrial controller, a hardware security module, a capture card, an FPGA, or an entire network card. In the guest operating system, such a device works under its own driver, so a VM can use the hardware DP doesn’t support directly.

A device reaches a machine in two steps. First you assign it to a project namespace, and then the project owner lists the device in the specification of their machine. The device is granted for exclusive use, so it’s available in one namespace and to one machine only.

DP switches the device drivers itself, and you don’t need to configure them on the node manually. When a machine starts, DP unbinds the device from the regular kernel driver and binds it to the `vfio-pci` driver, and once the machine is stopped, it returns the device to the regular driver. While the machine is running, the node doesn’t use the device.

Node requirements

PCI device passthrough is handled by the `virtualization-dra-pci` system component. It runs only on nodes with containerd version 2 and hardware I/O virtualization enabled. DP checks the nodes itself and assigns the `virtualization.deckhouse.io/vfio=true` label to the suitable ones.

To enable hardware I/O virtualization, turn on `VT-d` on Intel or `AMD-Vi` on AMD in the node BIOS and add the `intel_iommu=on` or `amd_iommu=on` kernel parameter.

To see which nodes are ready for PCI device passthrough, run the following command:

```
d8 k get nodes -l virtualization.deckhouse.io/vfio=true,virtualization.deckhouse.io/containerd-version=v2
```

Example output:

```
NAME     STATUS   ROLES    AGE   VERSION
node-1   Ready    worker   10d   v1.34.1
```

A node missing from the output has not been assigned the label. Check the `/sys/kernel/iommu_groups` directory on it. An empty directory means that hardware I/O virtualization is disabled. Enable it and reboot the node, and the label is assigned automatically within a few minutes.

To verify that the component is actually running on these nodes, run the following command:

```
d8 k -n d8-virtualization get pods -l app=virtualization-dra-pci -o wide
```

Assigning a namespace to a PCI device

DP detects the devices on the suitable nodes and creates a NodePCIDevice resource for each of them. The component scans the PCI bus at startup and then every five minutes, so a newly installed device appears in the list within a few minutes.

To make a device available to a project, follow these steps.

1. Find the device among the detected ones:

   ```
   d8 k get nodepcidevice
   ```

   Example output:

   ```
   NAME                                              NODE     ADDRESS        READY
   ASSIGNED   ATTACHED   NAMESPACE    AGE
   pci-4f2c0b1e8d9a3c5b7e1f0a2d4c6b8e0f1a3c5d7e    node-1   0000:3b:00.0   True
   False      False                  10m
   pci-9a1b3c5d7e9f0a2b4c6d8e0f1a3b5c7d9e1f0a2b    node-2   0000:65:00.0   True
   True       False      my-project   15m
   ```

   The resource name is a hash of the device parameters and the node name, so look up the device you need by the `NODE` and `ADDRESS` columns. To verify the choice, use the `.status.attributes` block, which holds the PCI bus address and the vendor and model identifiers. They let you find the same device in the `lspci -nn` output on the node.

2. Assign a namespace with the `.spec.assignedNamespace` parameter:

   ```
   d8 k apply -f - <<EOF
   apiVersion: virtualization.deckhouse.io/v1alpha2
   kind: NodePCIDevice
   metadata:
     name: pci-4f2c0b1e8d9a3c5b7e1f0a2d4c6b8e0f1a3c5d7e
   spec:
     assignedNamespace: my-project
   EOF
   ```

3. Make sure that a PCIDevice resource has appeared in the namespace:

   ```
   d8 k get pcidevice -n my-project
   ```

After that, the project owner attaches the device to their machine by specifying the PCIDevice resource name in the `.spec.pciDevices` parameter of the VirtualMachine resource.

To make the device unavailable to the project, clear the `.spec.assignedNamespace` parameter or set a different namespace. The PCIDevice resource in the previous namespace is deleted.

While the device is listed in a machine specification, the PCIDevice resource isn't deleted and the machine keeps running. Ask the project owner to remove the device from the specification. If you set a different namespace instead of clearing the parameter, the resource appears in it right away, but the machine of the new project stays in the `Pending` phase while the device is occupied by the previous machine.

Requirements and limitations for PCI devices

When planning PCI device passthrough, consider the following requirements and limitations:

- Passthrough works in a cluster with Kubernetes 1.34 or higher and containerd version 2 on the nodes, and the `DRAResourceClaimDeviceStatus`, `DRADeviceBindingConditions`, and `DRAConsumableCapacity` feature gates have to be enabled in kube-apiserver.
- DP doesn't detect every device of a node, because the hardware the node itself depends on stays at its disposal. The following devices never appear in the list:
  - Display adapters, which are handled by the `gpu` module.
  - Devices integrated into the chipset, bridges, memory controllers, and system peripherals.

    - Network controllers with active interfaces.
    - Storage controllers whose disks are used by the node.
    - Devices that share an IOMMU group with any of the above, because a group goes to the VM as a whole.
- A VM starts only on the node that holds the device attached to it, so all its PCI devices have to be on the same node, otherwise the specification is rejected.
- A VM with a PCI device can't be moved by live migration, and the `Migratable` condition gets the `VirtualMachineHostDevicesNotMigratable` reason, so such machines have to be stopped before the node is put into maintenance.
- Devices are attached when the VM starts, so a change to the `.spec.pciDevices` parameter requires its restart.
- A single device is attached to one VM only, and a VM takes no more than eight devices.
- A network card that's passed through works around the cluster network subsystem. It doesn't appear in the `.spec.networks` parameter, and DP neither assigns nor tracks its IP and MAC addresses.

Additional resources

- Module `virtualization` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Security

The "Security" section provides information about the protection mechanisms implemented in Deckhouse Platform.

It contains recommendations, instructions, and configuration examples for built-in protection mechanisms, as well as integration with external systems.

In this section, you will find information on:

- Security event audit:
    - How to enable and configure Kubernetes API event audit.
    - How to collect security events at the kernel and Kubernetes API levels using the platform's built-in capabilities (Falco).
    - How to configure audit rules and receive alerts on suspicious activity.
- Virtualization event audit:
    - How to enable the log of actions on virtual machines.
    - Which events it records and how to view them.
- Security policies:
    - Support for Pod Security Standards.
    - Configuring operational and advanced security policies using Gatekeeper.
    - Verifying container image signatures.
    - Working with custom policies and exceptions.
- Image vulnerability scanning:
    - How to set up regular scanning of container images.
    - How to view scan results and manually trigger rescans.
- Certificate management:
    - Issuing, renewing, and managing TLS certificates using the `cert-manager` module.
    - Examples of using Let's Encrypt, HashiCorp Vault, self-signed, and external CAs.
    - Support for `HTTP-01` and `DNS-01` validation types.
- Integration with external monitoring and security systems:
    - Sending logs to Kaspersky Unified Monitoring and Analysis Platform (KUMA).
    - Configuring exclusions for antivirus solutions, using Kaspersky Endpoint Security for Linux (KESL) as an example.

Additional resources

- Module `cert-manager` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Security events

Deckhouse Platform (DP) provides tools for declarative collection, processing, normalization, and delivery of security events extracted from logs of applications and Kubernetes infrastructure components.

A security event is a structured record of an action or fact that is significant from an information security perspective.

DP lets you:

- Collect security events from various sources (pod logs, node files, Kubernetes API audit).
- Bring events to a unified format with a mandatory minimum set of attributes.
- Enrich events with contextual data.
- Filter events by sources and severity level.
- Deliver events to storage and analytics systems (Loki, Elasticsearch, Kafka, Splunk, Vector, and others).

The `security-events-manager` module is responsible for collecting, processing, and delivering security events. The auxiliary `log-shipper` module is used for log collection.

Dependencies and requirements

The `security-events-manager` module requires the following DP modules:

- `log-shipper`: Collects logs from pod sources and node files, performs preliminary record selection.
- `loki`: Provides in-cluster storage for security events (used by default as a destination).

For details about the security events architecture, refer to “Security events architecture”.

Data sources for security events

The `security-events-manager` module collects data from two types of sources:

- **Container sources**: Application logs in Kubernetes pods. Collection is performed via the `log-shipper` module, which selects records by pod labels and namespaces.
- **Cluster sources**: Node files and system service logs not bound to a specific namespace. For example:
  - `/var/log/kube-audit/audit.log`: Kubernetes API audit log.
  - `/var/log/auth.log`: Node system authentication event log.

Collection is made in two steps:

1. The `log-shipper` module performs preliminary selection of log records using simple comparison operators (`In`, `NotIn`, `Regex`, `NotRegex`, `Exists`, `DoesNotExist`) and forwards them to the `security-events-manager` gateway.
2. The `security-events-manager` gateway parses the records, transforms them to a unified model, and delivers to a configured destination.

Since log parsing is resource-intensive, it is performed only for records pre-selected as potentially containing security events.

Enabling security events

To enable security events, follow these steps:

1. Enable the required modules if they are not yet enabled:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: log-shipper
spec:
  enabled: true
---
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: loki
spec:
  enabled: true
```

2. Enable the `security-events-manager` module:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: security-events-manager
spec:
  enabled: true
```

All available `security-events-manager` parameters are listed in the module documentation.

Configuring event sources

Log collection and processing are configured through the following custom resources:

- PodSecurityEventShipper: For container sources (pod logs in a specific namespace).
- ClusterSecurityEventShipper: For cluster sources (node files, system service logs).

These resources configure:

- Log source (`source` and `input` fields)
- Preliminary record selection rules (`produces` field)
- Parsing rules (`parser` or `parserRef` field with a reference to SecurityEventLoggingTransformationRules or ClusterSecurityEventLoggingTransformationRules)
- Transformation and enrichment rules (`transform` and `enrich` fields)

PodSecurityEventShipper configuration example defining a container source:

```
apiVersion: security.deckhouse.io/v1alpha1
kind: PodSecurityEventShipper
metadata:
  name: runtime-audit-engine
  namespace: d8-runtime-audit-engine
spec:
  - source: runtime-audit-engine
    input:
      type: KubernetesPods
      kubernetesPods:
        labelSelector:
          matchLabels:
            app: runtime-audit-engine
    produces:
      - eventCode: K8S_POD_CREATED
        extract:
          field: message
          operator: Regex
          values:
            - ".*K8s Pod Created.*"
```

ClusterSecurityEventShipper configuration example defining a cluster source:

```
apiVersion: security.deckhouse.io/v1alpha1
kind: ClusterSecurityEventShipper
metadata:
  name: kube-audit
spec:
  - source: kube-audit
    input:
      type: File
      files:
        - /var/log/kube-audit/audit.log
    produces:
      - eventCode: UNAUTHORIZED_ACCESS
        extract:
          field: message
          operator: Regex
          values:
            - ".*\"code\":401.*"
```

Configuring event delivery

After events are formed, you should define the destinations they will be delivered to. For this, you need to:

1. Configure security event destinations.
2. Configure event delivery rules to destinations.

Configuring a destination

Destinations are configured via the ClusterSecurityEventDestination resource.

The `security-events-manager` module supports all destination types available in the `log-shipper` ecosystem (Loki, Elasticsearch, Kafka, Splunk, Vector, File, and others). For in-cluster security event storage, automatic Loki destination configuration is available when the corresponding module option is enabled.

ClusterSecurityEventDestination configuration example defining the Loki destination:

```
apiVersion: security.deckhouse.io/v1alpha1
kind: ClusterSecurityEventDestination
metadata:
  name: cluster-loki
spec:
  type: Loki
  loki:
    auth:
      strategy: Bearer
      token: <EXAMPLE>
    endpoint: https://loki.d8-monitoring:3100
    tls:
      verifyCertificate: true
      verifyHostname: true
      ca: LS0tLS1CRUdJTiBDRVJUSUZJQ0FURS0tLS0t...
```

Configuring event delivery rules

When configuring security event delivery rules, you need to define:

- Sources that will be sending the events
- Minimum severity level for sending
- Target destinations

For this, use the ClusterSecurityEventConfig resource. It defines sources (in the format of exact names or masks), minimum severity level, and an array of destinations (resources of type ClusterSecurityEventDestination) that will receive the selected events.

ClusterSecurityEventConfig configuration example for sending events from the `kube-audit`, `runtime-audit-engine` and `user-authn` sources to the `cluster-loki` destination:

```
apiVersion: security.deckhouse.io/v1alpha1
kind: ClusterSecurityEventConfig
metadata:
  name: default
spec:
  defaultSeverityThreshold: Low
  enabledSources:
    - clusterSecurityEventShipper/kube-audit/kube-audit
    - podSecurityEventShipper/d8-runtime-audit-engine/runtime-audit-engine/falco
    - podSecurityEventShipper/d8-user-authn/user-authn/dex
  # Alternatively, use masks.
  # enabledSourcesMasks:
  #   - clusterSecurityEventShipper/kube-audit/*
  #   - podSecurityEventShipper/*

  destinations:
    - cluster-loki
```

Default module settings

If the module settings are not explicitly specified, the following objects are created in the cluster:

- ClusterSecurityEventConfig: Configures security event delivery to destinations. By default, an object with the following configuration is created:

  ```
  apiVersion: security.deckhouse.io/v1alpha1
  kind: ClusterSecurityEventConfig
  metadata:
    name: default
  spec:
    defaultSeverityThreshold: Medium
    destinations:
      - cluster-loki
    enabledSourcesMasks:
      - podSecurityEventShipper/*
      - clusterSecurityEventShipper/*
  ```

  This object configuration is controlled by the module parameter `securityEventConfig`.

- ClusterSecurityEventDestination: Configures security event destination. By default, the following object is generated that allows sending events to the in-cluster Loki service:

  ```
  apiVersion: security.deckhouse.io/v1alpha1
  kind: ClusterSecurityEventDestination
  metadata:
    name: cluster-loki
  spec:
    type: Loki
    loki:
      auth:
        strategy: Bearer
        token: <token> # Filled automatically.
      endpoint: https://loki.d8-monitoring:3100
  ```

  You can disable generation of the default destination via the dedicated parameter `clusterSecurityEventDestination.clusterLoki`.

Supported security events

The `security-events-manager` module ships with a built-in set of security event detection rules

covering authentication, configuration, RBAC, runtime, and other categories. For the up-to-date list of implemented security events, their codes, severity levels, and descriptions, refer to the module documentation.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Kubernetes API event audit

The Kubernetes auditing feature allows you to track requests to the API server and analyze events occurring in the cluster. Auditing can be useful for troubleshooting unexpected behavior and for meeting security requirements.

Kubernetes supports audit configuration via the Audit policy mechanism, which allows you to define logging rules for target operations. By default, audit results are written to the `/var/log/kube-audit/audit.log` file.

Built-in audit policies

Deckhouse Platform (DP) configures a basic audit policy by default, which can be supplemented with custom rules.

This policy implements the following rules:

- Do not log health probes (`/readyz`, `/livez`, `/healthz`). This rule does not apply to requests that fail authentication.
- Do not log frequent updates for `Endpoints`, `EndpointSlices`, and `Events`.
- Do not log leader election operations on `Lease` resources.
- Do not log cert-manager leader election ConfigMaps.
- Do not log VerticalPodAutoscalerCheckpoints resources.
- Do not log PATCH operations on `VerticalPodAutoscaler` from recommender.
- Do not log UpmeterHookProbes resources.
- Do not log any operations in `d8-upmeter` namespace.
- Do not log ingress-nginx leader election updates in ConfigMaps.
- Do not log dex health-check create/delete operations on `AuthRequest` resources.
- Log create and delete operations for Node resources with request/response payload.
- Log kubectl logs requests (pods/log) at Metadata level.
- Log create/update/patch/delete operations from system service accounts (`kube-system`, `d8-*`).
- Log create/update/patch/delete operations for Pod resources.
- Log Pod status updates from kubelet (pods/status) with the request body to capture container terminations and their reasons.
- Log create/update/patch/delete operations in system namespaces (`kube-system`, `d8-*`).
- Log all LIST operations in all namespaces.
- Log create and delete operations for ServiceAccount resources.
- Log create/update/delete/patch operations for Role and ClusterRole resources.
- Log create/update/delete operations for ClusterRoleBinding resources.
- Log exec, attach and ephemeral container related pod subresource operations.
- Log creation of VirtualMachineOperation resources with request/response payload.
- Log create/update/patch/delete operations for virtualization.deckhouse.io resources.
- Log update/patch operations for internal virtualization subresources.
- Log GET operations for subresources.virtualization.deckhouse.io API group.
- Log create/update/patch/delete operations for `Pod` resources.
- Log create/update/patch/delete operations in `d8-virtualization` namespace.
- Log create/update/patch/delete operations for ModuleConfig resources.
- Do not log requests from authenticated users.
- Log all remaining (unauthenticated) requests at Metadata level.

Detailed information about the rules and an example of the final policy are available in the control-plane-manager module documentation

These policies are enabled by default. These rules from the basic policy are enabled by default. To disable them, set the `basicAuditPolicyEnabled` parameter to `false`.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  settings:
    apiserver:
      auditPolicyEnabled: true
      basicAuditPolicyEnabled: false
```

Configuring a custom audit policy

To create an advanced Kubernetes API audit policy, follow these steps:

1. Enable the `auditPolicyEnabled` parameter in the `control-plane-manager` module configuration:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: control-plane-manager
   spec:
     version: 3
     settings:
       apiserver:
         auditPolicyEnabled: true
   ```

2. Create the `kube-system/audit-policy` Secret containing the policy YAML file encoded in Base64:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: audit-policy
     namespace: kube-system
   data:
     audit-policy.yaml: <Base64>
   ```

   Example `audit-policy.yaml` content with a minimal working configuration:

   ```
   apiVersion: audit.k8s.io/v1
   kind: Policy
   rules:
   - level: Metadata
     omitStages:
     - RequestReceived
   ```

   For more information on possible contents of `audit-policy.yaml`, refer to the following sources:

   - Kubernetes official documentation
   - GCE helper script code snippet

How to generate the contents of the `audit-policy.yaml` file

Kubernetes Documentation Policy Resource Field Structure

A Kubernetes audit policy is defined in a YAML file and consists of a set of rules that determine which events and at what level of detail will be logged. The file has the following structure:

```
apiVersion: audit.k8s.io/v1  # API version used for the audit policy
kind: Policy                # Resource type — constant Policy
rules:                       # Set of rules for auditing
  - level:                   # Log detail level. Required field
    users:                   # List of users whose actions are logged
    userGroups:               # User groups (e.g., system:serviceaccounts)
    verbs:                   # Actions/operations that are logged (create, update,
delete, etc.)
    resources:                # Kubernetes resources for which the rule applies
    namespaces:               # Namespaces that the rule covers
```

The `rules` array describes the audit rules. Each rule contains the following fields:

- `level` — The detail level of the logged event.

  Possible values (from most to least detailed):

  - `None`: Do not log at all.
  - `Metadata`: Only request metadata (who, when, what, where; without object contents).
  - `Request`: Also stores the request body (for update requests only).
  - `RequestResponse`: Stores both the request body and the response content.

- `users`: A list of `usernames` the rule applies to (e.g., `["admin"]`). For service accounts, the name typically looks like `system:serviceaccount:<namespace>:<serviceaccount-name>`. For regular users, the name depends on the authentication system settings. For `deckhouse.io/v1` `Users` objects, `email` is used as the name.

- `userGroups`: `userGroups` (e.g., `["system:authenticated"]`). After authentication, kube-apiserver assigns a list of groups to each user (e.g., all authenticated users are part of `system:authenticated`, service accounts are in additional groups). If a request comes from a user who is a member of at least one of the groups specified in `userGroups`, the rule is applied to that request.

  Kubernetes built-in groups:

  - `system:authenticated`: Everyone who has been authenticated.
  - `system:unauthenticated`: Requests from anonymous users.
  - `system:serviceaccounts`: All service accounts from all namespaces.
  - `system:serviceaccounts:<namespace>`: Service accounts in a specific namespace.

- `verbs`: List of API operations (get, list, create, delete, etc.).

- `resources`: Array of target resources:
  - `group`: API group (e.g., `"apps"`, `"batch"`, `""` for core).
  - `resources`: Resource types (e.g., `["pods", "deployments"]`). A full list of resources and their groups can be obtained using the `kubectl api-resources` command

- `namespaces`: Array of namespaces where the rule applies.

- `nonResourceURLs`: A set of URL paths to audit. The * character is allowed, but only as a full, final step of the path. Examples:
  - `/metrics` — log requests to apiserver metrics
  - `/healthz*` — log all health requests

Examples

Log all requests from all authenticated users

```
apiVersion: audit.k8s.io/v1
kind: Policy
rules:
  - level: Metadata
    userGroups: ["system:authenticated"]
```

⚠ **Warning!** Not recommended for production environments. A high event flow may result in increased load on the control-plane disk subsystem of cluster nodes.

Example log entry:

```
{
  "stage": "ResponseComplete",
  "requestURI": "/healthz",
  "verb": "get",
  "user": {
    "username": "kube-apiserver-kubelet-client",
    "groups": [
      "kubeadm:cluster-admins",
      "system:authenticated"    //  <- everyone who has been authenticated
    ]
  },
  ...
}
```

Logging all requests not from service accounts

```
apiVersion: audit.k8s.io/v1
kind: Policy
rules:
  - level: Metadata
    userGroups: ["system:authenticated"]
    users: []
    omitStages: []
    # Exclude service accounts via a deny rule
  - level: None
    userGroups: ["system:serviceaccounts"]
```

Example log entry:

```
{
  "user": {
    "username": "user@example.com",
    "groups": ["admins","system:authenticated"]
  },
  ...
}
```

Logging all operations with standard resources

```
apiVersion: audit.k8s.io/v1
kind: Policy
rules:
  - level: Metadata
    resources:
      - group: "apps"
        resources: ["deployments", "daemonsets", "statefulsets", "replicasets"]
      - group: "batch"
        resources: ["jobs", "cronjobs"]
      - group: ""
        resources: ["*"]
```

Working with the audit log file

On DP master nodes, it is assumed that a log collection tool (`log-shipper`, `promtail`, or `filebeat`) is installed to monitor the `/var/log/kube-audit/audit.log` file.

The log rotation settings for this file are predefined and cannot be changed:

- Maximum file size: 1000 MB.

- Maximum retention period: 30 days.

Depending on the policy configuration and the volume of requests to the API server, the number of log entries can be very large. In such cases, the retention period may be reduced to less than 30 minutes.

⚠ Unsupported options or typos in the configuration file may cause the API server to fail to start.

If the API server fails to start, take the following steps:

1. Manually remove the `--audit-log-*` parameters from the `/etc/kubernetes/manifests/kube-apiserver.yaml` manifest.
2. Restart the API server with the following command:

```
docker stop $(docker ps | grep kube-apiserver- | awk '{print $1}')

# Alternative option (depending on the CRI in use).
crictl stopp $(crictl pods --name=kube-apiserver -q)
```

3. After restarting, fix the Secret or delete it with the following command:

```
d8 k -n kube-system delete secret audit-policy
```

Redirecting the audit log file to stdout

By default, the audit log is saved to the `/var/log/kube-audit/audit.log` file on master nodes. If necessary, you can redirect its output to the `kube-apiserver` process stdout instead of a file by setting the `apiserver.auditLog.output` parameter in the `control-plane-manager` module to `Stdout`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  settings:
    apiserver:
      auditPolicyEnabled: true
      auditLog:
        output: Stdout
```

In this case, the log will be available in the `kube-apiserver` container stdout.

Then, using the built-in DP logging mechanism , you can configure log collection and forwarding to your own security system.

- Module `control-plane-manager` documentation

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Runtime audit

Deckhouse Platform (DP) provides built-in tools for detecting security threats by analyzing Linux kernel events and auditing Kubernetes API events. With DP, you can:

- Detect threats in environments by analyzing applications and containers.
- Identify attempts to exploit vulnerabilities from the CVE database and signs of cryptocurrency miner activity.
- Detect Kubernetes-specific threats, including:
  - Command-line shells launched in containers or pods.
  - Containers running in privileged mode.
  - Mounting insecure paths into containers (for example, `/proc`).
  - Attempts to read sensitive data (for example, from `/etc/shadow`).

Data sources for runtime audit

DP uses two main sources of events:

- Linux kernel events — via the eBPF driver for the Falco threat detection system.
- Kubernetes API audit events — via integration with Kubernetes auditing and a webhook interface.

For details about the runtime audit architecture, refer to “Runtime audit architecture”.

Minimum requirements

To capture kernel events, you need:

- Linux kernel version 5.8 or higher.
- Support for eBPF. You can check for support in one of the following ways:
  - Make sure the `/sys/kernel/btf/vmlinux` file exists:

    ```
    ls -lah /sys/kernel/btf/vmlinux
    ```

  - Make sure the `CONFIG_DEBUG_INFO_BTF` option is enabled:

    ```
    grep -E "CONFIG_DEBUG_INFO_BTF=(y|m)" /boot/config-*
    ```

Falco agents run on each cluster node and consume resources depending on the number of rules applied and events collected.

> **i** On some systems, eBPF probes may not work.

Enabling runtime audit

To enable the runtime audit, follow these steps:

1. Make sure the nodes meet the minimum requirements.
2. Enable the `runtime-audit-engine` module using the following configuration:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: runtime-audit-engine
   spec:
     enabled: true
   ```

3. (**Optional**) If the cluster control plane is not managed by DP with `control-plane-manager`, configure the Kubernetes API audit webhook manually.

All available runtime audit parameters are listed in the `runtime-audit-engine` module documentation.

Manually configuring the Kubernetes API audit webhook

> **i** Webhook configuration is not required if the `control-plane-manager` module is enabled. In this case, when the `runtime-audit-engine` module is enabled, the settings for collecting Kubernetes API audit events will be applied automatically.

To configure the webhook for receiving audit events from `kube-apiserver`:

1. Create a `kubeconfig` file for the webhook with the address `https://127.0.0.1:9765/k8s-audit` and certificate data (`ca.crt`) from the `d8-runtime-audit-engine/runtime-audit-engine-webhook-tls` Secret.

   Example:

   ```
   apiVersion: v1
   kind: Config
   clusters:
     - name: webhook
       cluster:
         certificate-authority-data: BASE64_CA
         server: "https://127.0.0.1:9765/k8s-audit"
   users:
     - name: webhook
   contexts:
     - context:
         cluster: webhook
         user: webhook
       name: webhook
   current-context: webhook
   ```

2. Specify the path to the configuration file with the `--audit-webhook-config-file` flag in the `kube-apiserver` manifest.
3. (**Optional**) To collect Kubernetes API audit events from not only system but also user namespaces, configure audit policies.

Working with audit rules

Runtime audit event analysis is based on rules that define suspicious behavior criteria. DP includes:

- **Built-in rules**, including:
  - Kubernetes audit rules (located in the `falco` container at `/etc/falco/k8s_audit_rules.yaml`).

  To configure the list of built-in rules, use the `settings.builtInRulesList` parameter of the `runtime-audit-engine` module.

- **Custom rules**, defined via the FalcoAuditRules custom resource.

For more information on how runtime audit rules work, refer to “Runtime audit architecture”.

Adding a custom rule

To add a rule, create a FalcoAuditRules resource with the required conditions. Use the Falco condition syntax. Falco agents will automatically apply the created rule.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: FalcoAuditRules
metadata:
  name: ownership-permissions
spec:
  rules:
    - macro:
        name: spawned_process
        condition: (evt.type in (execve, execveat) and evt.dir=<)
    - rule:
        name: Detect Ownership Change
        desc: detect file permission/ownership change
        condition: >
          spawned_process and proc.name in (chmod, chown) and proc.args contains
"/tmp/"
        output: >
          The file or directory below has had its permissions or ownership changed
(user=%user.name
          command=%proc.cmdline file=%fd.name parent=%proc.pname
pcmdline=%proc.pcmdline gparent=%proc.aname[2])
        priority: Warning
        tags: [filesystem]
```

For more rule examples, see:

- Falco rules official repository
- Falco rules on Artifact Hub

Applying a third-party rule

Since Falco rule structure differs from DP custom resource format, third-party rules from the internet must be converted to a FalcoAuditRules resource before applying them.

Use the following script to convert:

```
git clone github.com/deckhouse/deckhouse
cd deckhouse/ee/modules/runtime-audit-engine/hack/far-converter
go run main.go -input /path/to/falco/rule_example.yaml > ./my-rules-cr.yaml
```

Example conversion result:

- Original rule:

  ```
  # /path/to/falco/rule_example.yaml
  - macro: spawned_process
     condition: (evt.type in (execve, execveat) and evt.dir=<)

  - rule: Linux Cgroup Container Escape Vulnerability (CVE-2022-0492)
     desc: "This rule detects an attempt to exploit a container escape
  vulnerability in the Linux Kernel."
     condition: container.id != "" and proc.name = "unshare" and spawned_process
  and evt.args contains "mount" and evt.args contains "-o rdma" and evt.args
  contains "/release_agent"
     output: "Detect Linux Cgroup Container Escape Vulnerability (CVE-2022-0492)
  (user=%user.loginname uid=%user.loginuid command=%proc.cmdline
  args=%proc.args)"
     priority: CRITICAL
     tags: [process, mitre_privilege_escalation]
  ```

- Converted resource:

```
# ./my-rules-cr.yaml
apiVersion: deckhouse.io/v1alpha1
kind: FalcoAuditRules
metadata:
  name: rule-example
spec:
  rules:
    - macro:
        name: spawned_process
        condition: (evt.type in (execve, execveat) and evt.dir=<)
    - rule:
        name: Linux Cgroup Container Escape Vulnerability (CVE-2022-0492)
        condition: container.id != "" and proc.name = "unshare" and
spawned_process and evt.args contains "mount" and evt.args contains "-o rdma"
and evt.args contains "/release_agent"
        desc: This rule detects an attempt to exploit a container escape
vulnerability in the Linux Kernel.
        output: Detect Linux Cgroup Container Escape Vulnerability (CVE-2022-
0492) (user=%user.loginname uid=%user.loginuid command=%proc.cmdline
args=%proc.args)
        priority: Critical
        tags:
          - process
          - mitre_privilege_escalation
```

Log collection and alerts

DP exports runtime audit events as Prometheus metrics, allowing you to set up log collection and alerts via resources of the `log-shipper` and `observability` modules. This makes it possible to:

- Connect an external log storage (for example, Loki or Elasticsearch).
- Configure alerts for critical events.

Configuring log and event collection

All runtime audit events are sent to stdout. To collect and forward events to a log storage, create a ClusterLoggingConfig resource following the example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: falco-events
spec:
  destinationRefs:
  - xxxx
  kubernetesPods:
    namespaceSelector:
      labelSelector:
        matchExpressions:
        - key: "kubernetes.io/metadata.name"
          operator: In
          values: [d8-runtime-audit-engine]
  labelFilter:
  - operator: Regex
    values: ["\\{.*"] # Collect only JSON-formatted logs.
    field: "message"
  type: KubernetesPods
```

Configuring critical event alerts

To create alerts for critical events:

1. Make sure the `observability` module is enabled.
2. Create a ClusterObservabilityMetricsRulesGroup or ObservabilityMetricsRulesGroup resource:
   - ClusterObservabilityMetricsRulesGroup: Intended for cluster-wide rules applied to system namespaces.
   - ObservabilityMetricsRulesGroup: Intended for rules that operate within a specific namespace.

Configuration example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterObservabilityMetricsRulesGroup
metadata:
  name: falco-critical-alerts
spec:
  groups:
    - name: falco-critical-alerts
      rules:
        - alert: FalcoCriticalAlertsAreFiring
          for: 1m
          annotations:
            description: |
              There is a suspicious activity on a node {{ $labels.node }}.
              Check your events journal for more details.
            summary: Falco detected a critical security incident.
          expr: |
            sum by (node)
(rate(falcosecurity_falcosidekick_falco_events_total{priority_raw="critical"}[5m]) >
0)
```

Viewing metrics

To retrieve Prometheus metrics, use the PromQL query `falcosecurity_falcosidekick_falco_events_total{}`:

```
d8 k -n d8-monitoring exec -it prometheus-main-0 prometheus -- \
  curl -s "http://127.0.0.1:9090/api/v1/query?
query=falcosecurity_falcosidekick_falco_events_total" | jq
```

The event severity is carried by two labels: `priority` holds a numeric value, and `priority_raw` holds the lowercase severity name. Use `priority_raw` to filter events by severity:

priority	priority_raw
`8`	`emergency`
`7`	`alert`
`6`	`critical`
`5`	`error`
`4`	`warning`
`3`	`notice`
`2`	`informational`
`1`	`debug`

Debugging and simulating events

For debugging and simulating runtime audit events in DP, you can use:

- The `event-generator` utility.
- The `/test` HTTP endpoint of the `falcosidekick` service.

Enabling debug logging

Falco uses the `debug` logging level by default.

In Falcosidekick, debug logging is disabled by default. To enable it, set the `spec.settings.debugLogging` parameter to `true`, for example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: runtime-audit-engine
spec:
  version: 1
  enabled: true
  settings:
    debugLogging: true
```

Simulating events

Falco

The `event-generator` utility allows you to generate various suspicious actions (for example, system calls or Kubernetes API audit events).

Run the following command to generate a test set of events in a Kubernetes cluster:

```
d8 k run falco-event-generator --image=falcosecurity/event-generator run
```

If you need to simulate a specific action, refer to the utility's documentation.

Falcosidekick

To simulate sending test events to the `falcosidekick` service, use its `/test` HTTP endpoint:

1. Create a test event by running:

   ```
   nsenter -t $(pidof falcosidekick) curl -X POST -H "Content-Type: application/json" -H
   "Accept: application/json" http://localhost:2801/test
   ```

2. Check the event metric:

   ```
   d8 k -n d8-monitoring exec -it prometheus-main-0 prometheus -- \
     curl -s "http://127.0.0.1:9090/api/v1/query?
   query=falcosecurity_falcosidekick_falco_events_total" \
     | jq '.data.result.[] | select (.metric.priority_raw == "debug")'
   ```

   Example output:

```
{
  "metric": {
    "__name__": "falcosecurity_falcosidekick_falco_events_total",
    "container": "kube-rbac-proxy",
    "hostname": "falcosidekick",
    "instance": "192.168.208.7:4212",
    "job": "runtime-audit-engine",
    "node": "dev-master-0",
    "priority": "1",
    "priority_raw": "debug",
    "rule": "Test rule",
    "source": "internal",
    "tier": "cluster"
  },
  "value": [
    1744234729.799,
    "1"
  ]
}
```

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtualization event audit

The audit records actions on virtual machines (VMs) and on the module itself, so that you can investigate an incident and reconstruct the sequence of events.

Enabling the audit

To enable the security event audit, follow these steps:

1. Enable the `log-shipper` and `runtime-audit-engine` modules.
2. Enable the Kubernetes API audit by setting `.spec.settings.apiserver.auditPolicyEnabled` to `true` in the `control-plane-manager` module.
3. Set `.spec.settings.audit.enabled` to `true` in the module settings:

```
spec:
  settings:
    audit:
      enabled: true
```

Until all three conditions are met, the audit component doesn’t start in the cluster. For the other parameters, see the module settings.

Event types

The event type is recorded in the `type` field. The audit distinguishes the following types:

- `Access to VM`: A connection to a VM over the console, VNC, or port forwarding. Both the start and the end of the session are recorded.
- `Manage VM`: Creating, updating, or deleting a VirtualMachine resource.

- `Control VM`: A change of the VM state, including start, stop, restart, migration, and eviction through the VirtualMachineOperation resource, as well as a shutdown or restart from the guest OS and an abnormal termination.
- `Module control`: Creating, updating, disabling, or deleting a ModuleConfig.
- `Virtualization control`: Creating or deleting a system component of the module in the `d8-virtualization` namespace.
- `Integrity check`: A mismatch between the VM configuration checksum and the reference one.
- `Forbidden operation`: An attempt to perform a forbidden operation.

Regardless of the type, every event contains the same fields:

- `name`: A description of what happened.
- `datetime`: The time of the event.
- `request_subject`: The user or ServiceAccount that performed the action.
- `operation_result`: The result of the operation.
- `uid`: The identifier of the record in the Kubernetes audit.

Additional fields depend on the event type. For example, VM events contain the `virtual_machine_name` and `virtual_machine_namespace` fields, while forbidden operations report the request source in the `source_ip` field and the denial reason in the `forbid_reason` field.

Viewing events

Events are collected by the `virtualization-audit` system component in the `d8-virtualization` namespace. To forward them to the cluster logging system, for example to Loki, create a ClusterLoggingConfig:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: virtualization-audit-logs
spec:
  destinationRefs:
    - d8-loki
  kubernetesPods:
    namespaceSelector:
      matchNames:
        - d8-virtualization
    labelSelector:
      matchLabels:
        app: virtualization-audit
  type: KubernetesPods
```

To view the events in Grafana, use a Loki query:

```
{namespace="d8-virtualization", pod=~"virtualization-audit-.*"}
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Security policies

Deckhouse Platform (DP) lets you manage application security in the cluster using a set of admission

policies. These are rules that apply to objects (such as Pods and Services) at the time of their creation and modification in the cluster (but not during their operation), based on the information provided in their manifests. These policies are designed to formalize the parameters that are permitted or prohibited in object manifests. Support for admission policies in the DP cluster is implemented using the `admission-policy-engine` module.

In the DP policies are divided into three categories:

- Pod Security Standards: Policies that comply with the relevant Pod Security Standards.
- Operational policies: Policies for creating additional requirements for objects by validating the values of parameters that are **not directly related** to security (for example, a list of allowed prefixes for container images, an image download policy, a list of required container images, etc.).
- Security policies: Policies for creating additional requirements on objects by validating the values of security-related parameters (for example, container access to the host's IPC or PID namespaces, privilege lists for containers, etc.).

> **i** These policies complement each other. If multiple policies are applied to a single namespace, objects are validated against each of them. If even one policy is violated, the object will not be created.

In addition to policies that prohibit using parameters different from the set requirements, DP supports the SecurityPolicyException resource, which allows creating fine-grained exceptions from security policy checks. With this resource, you can allow using specific parameters for individual pods or containers without changing security policies applied to the entire namespace.

How validation failure messages are displayed

Depending on how pods are created, there are differences in how the API generates messages regarding validation failures (violations of established policies):

- If a pod is created directly, the validation error is returned in the API response indicating a validation failure (policy violation).
- If pods are created via Deployment, the required number of ReplicaSets is created, which in turn attempt to create the pods. In this case, the validation error is not returned in the API response but is displayed in the namespace events or the corresponding ReplicaSet events.

Pod validation when policies are modified or added

For all three policy categories (Pod Security Standards, operational, and security policies), there is no provision for automatically recreating existing pods when changing existing policies or adding new ones. Pods that existed prior to changes being made to the policy in use or prior to a new policy being added will continue to run until they are restarted. Upon restart, they will be validated against the new rules.

DP provides alerts for such cases. Each alert fires once for each policy and namespace with violating objects:

Alert	What it reports
`PodSecurityStandardsViolation`	Running pods that violate a Pod Security Standard
`OperationPolicyViolation`	Existing objects that violate an OperationPolicy
`SecurityPolicyViolation`	Existing objects that violate a SecurityPolicy
`ControllerPolicyViolation`	Pod-creating controllers that violate a policy with `enforcementAction: Deny` and are only warned about during the transition period

The `policy` label of an alert names the policy: the name of the OperationPolicy or SecurityPolicy, or `d8-pod-security-baseline` or `d8-pod-security-restricted` for the Pod Security Standards. The `namespace` label is the namespace of the violating objects.

An alert is an ObservabilityAlert resource in the namespace of the violating objects, so the users of the namespace see it. An alert for cluster-scoped objects is a ClusterObservabilityAlert resource.

To list the alerts in a namespace, run the following command, where `<NAMESPACE>` is the namespace:

```
d8 k -n <NAMESPACE> get observabilityalerts
```

Output example:

```
NAME                                                        SEVERITY   STATUS
DURATION   SUMMARY
AGE
PodSecurityStandardsViolation-07243a74fddd8234-1792744609   3          Firing   1h
Pods in the `app` namespace violate the `d8-pod-security-baseline` Pod Security
Standard.   1h
SecurityPolicyViolation-8f21cd962274a252-1792744609         3          Firing   1h
Objects in the `app` namespace violate the `restricted-app` SecurityPolicy.
1h
```

To list the alerts in every namespace and the alerts for cluster-scoped objects, run the following commands:

```
d8 k get observabilityalerts -A
d8 k get clusterobservabilityalerts
```

To view an alert, run the following command:

```
d8 k -n <NAMESPACE> get observabilityalert <ALERT_NAME> -o yaml
```

The description of the alert contains a Prometheus query that lists the violating objects and the rules they break.

Applying Pod Security Standards

DP supports three security policy levels:

- `privileged`: An unrestricted policy with the broadest possible permissions.
- `baseline`: A minimally restrictive policy that prevents the most well-known and common privilege escalation techniques. Allows the use of a standard (minimally specified) Pod configuration.
- `restricted`: A highly restrictive policy with the strictest requirements for Pods.

> **i** In the Deckhouse Platform, these policies are implemented using Gatekeeper and enforced by the admission controllers of the `admission-policy-engine` module, rather than the Kubernetes Pod Security Admission controller. Only the policy descriptions are taken from Kubernetes.

Default policy

The default policy is `baseline`. It applies to non-system namespaces without the `security.deckhouse.io/pod-policy` label.

> **⚠** In DP versions prior to v1.78, the `privileged` policy was applied by default in clusters bootstrapped with DP prior to v1.55 or when the bootstrap version could not be determined. Starting from DP v1.78, the default policy is `baseline` regardless of the cluster bootstrap version.
>
> If the `enforcementAction` parameter is set to `Deny`, pods that do not comply with the `baseline` policy are denied when recreated. Updates of such clusters to DP v1.78 are blocked until the default policy is set explicitly.
>
> If the `admission-policy-engine` module is disabled, the update is not blocked. After the module is enabled, the `baseline` policy is applied.
>
> To keep the `privileged` policy, set it explicitly in the `settings.podSecurityStandards.defaultPolicy` parameter.

Assigning a policy

You can assign a policy in the following ways:

- Globally, using the `settings.podSecurityStandards.defaultPolicy` parameter of the `admission-policy-engine` module.

- Per namespace, using the `security.deckhouse.io/pod-policy=<POLICY_NAME>` label.

  Example command to assign the `restricted` policy to all Pods in the `my-namespace` namespace:

  ```
  d8 k label ns my-namespace security.deckhouse.io/pod-policy=restricted
  ```

Enforcement modes

Allowed policy enforcement modes:

- `deny`: Blocks actions from being executed.
- `dryrun`: Does not affect execution and used for debugging. Event information can be viewed in the Deckhouse web UI or with `d8 k`.
- `warn`: Works like `dryrun` but also displays a warning with the reason the action would have been denied in `deny` mode.

By default, Pod Security Standards policies in DP are enforced in `deny` mode. In this mode, application Pods that do not comply with the policies cannot be run in the cluster.

As with policy assignment, enforcement mode can be set:

- Globally, using the `settings.podSecurityStandards.enforcementAction` parameter of the `admission-policy-engine` module.
- Per namespace, using the `security.deckhouse.io/pod-policy-action=<POLICY_ACTION>` label.

  Example command to set the `warn` mode for all Pods in the `my-namespace` namespace:

  ```
  d8 k label ns my-namespace security.deckhouse.io/pod-policy-action=warn
  ```

Policies in system namespaces

Namespaces named `d8-*` and `kube-*` hold the components of the platform itself. Policies apply to them differently from application namespaces, and that difference is not configurable. The platform also labels the namespaces it creates with `heritage: deckhouse`. A namespace that carries the label but is named otherwise is left out of policies and mutations written for application namespaces; the Pod Security Standards below follow the names.

Every namespace named `d8-*` or `kube-*` is checked against the `restricted` standard. The `security.deckhouse.io/pod-policy` label and the `settings.podSecurityStandards.defaultPolicy` parameter do not apply there. A violation is recorded in the audit and shown in the Deckhouse web UI, and the workload still starts. The exception is a namespace whose module has hardened it: there the standards are enforced and a violating workload is denied.

These checks cannot be tuned from outside the platform. The labels that govern them, and the workloads they cover, belong to the module that owns the namespace, and Deckhouse Platform returns both to their declared state the next time it applies the configuration. A module exempts its own workloads where necessary with a SecurityPolicyException that it ships with the module.

OperationPolicy and SecurityPolicy resources also apply to system namespaces in `warn` mode. A policy with `enforcementAction: Deny` blocks workloads in application namespaces and only reports violations in a system namespace. No label of the namespace changes that: a module that hardens its own namespace raises the Pod Security Standards there, which has no effect on a policy written for application workloads.

A denying policy that reaches system namespaces is therefore rendered as two Gatekeeper constraints, both visible in the audit and in the web interface:

- The policy’s own name: For application namespaces, with the action the policy asks for.
- `d8-system-default-<policy>`: For system namespaces, in `warn` mode.

For the transition to controller-level validation, a denying policy only warns about pod-creating controllers by default. It checks them in one more constraint, `d8-controllers-<policy>`, in `warn` mode, and the constraint with the policy’s own name checks Pods only. The `podSecurityStandards.controllerValidationEnforcement: Policy` module parameter, or `spec.controllerValidation.mode: Enforce` of the policy, checks controllers with the action of the policy in the single constraint instead.

The `d8-system-default-`, `d8-pod-security-` and `d8-controllers-` prefixes are reserved: a policy whose name starts with one of them is rejected on creation. A policy name is limited to 235 characters

for the same reason, so that the derived constraint names stay within the 253-character limit for a Kubernetes object name.

A policy is rendered as a single constraint when the split would change nothing:

- The policy uses the `Warn` or the `Dryrun` action.
- The namespaces the policy selects include no system namespace.
- The policy already excludes every system namespace it selects.
- The namespace list uses a leading glob, such as `*-system`, which cannot be intersected with `d8-*` exactly. The single constraint then keeps the policy's action and excludes system namespaces outright.
- The policy selects system namespaces only, in which case the single constraint keeps the policy's name and warns.

Gatekeeper mutations do not apply in system namespaces, whatever labels the namespace carries. The platform sets the parameters of its own components, so an `Assign` or a `ModifySet` resource is not allowed to change them there.

Extending a policy

You can extend the `baseline` and `restricted` policies using Gatekeeper templates by adding extra checks to the existing ones.

To extend a policy:

1. Create a validation template using a `ConstraintTemplate`.
2. Apply the template to the `baseline` or `restricted` policy.

Example template for validating the container registry address:

```
apiVersion: templates.gatekeeper.sh/v1
kind: ConstraintTemplate
metadata:
  name: k8sallowedrepos
spec:
  crd:
    spec:
      names:
        kind: K8sAllowedRepos
      validation:
        openAPIV3Schema:
          type: object
          properties:
            repos:
              type: array
              items:
                type: string
  targets:
    - target: admission.k8s.gatekeeper.sh
      rego: |
        package d8.pod_security_standards.extended

        violation[{"msg": msg}] {
          container := input.review.object.spec.containers[_]
          satisfied := [good | repo = input.parameters.repos[_] ; good =
startswith(container.image, repo)]
          not any(satisfied)
          msg := sprintf("container <%v> has an invalid image repo <%v>, allowed repos
are %v", [container.name, container.image, input.parameters.repos])
        }

        violation[{"msg": msg}] {
          container := input.review.object.spec.initContainers[_]
          satisfied := [good | repo = input.parameters.repos[_] ; good =
startswith(container.image, repo)]
          not any(satisfied)
          msg := sprintf("container <%v> has an invalid image repo <%v>, allowed repos
are %v", [container.name, container.image, input.parameters.repos])
        }
```

Example of applying the template to the `restricted` policy:

```
apiVersion: constraints.gatekeeper.sh/v1beta1
kind: K8sAllowedRepos
metadata:
  name: prod-repo
spec:
  match:
    kinds:
      - apiGroups: [""]
        kinds: ["Pod"]
    namespaceSelector:
      matchLabels:
        security.deckhouse.io/pod-policy: restricted
  parameters:
    repos:
      - "mycompany.registry.com"
```

In this example, the image address in the `image` field of all Pods in namespaces labeled `security.deckhouse.io/pod-policy: restricted` is checked. If the `image` address of a created Pod does not start with `mycompany.registry.com`, the Pod will not be created.

Helpful resources for creating extended policies:

- Custom policy examples.
- Gatekeeper documentation contains information on templates and policy language.
- Gatekeeper library contains examples of validation templates.

Operational policies

DP provides a mechanism for creating operational policies using the OperationPolicy. Operational policies define requirements for cluster objects. These include allowed container registries, required resources, probes, and more.

The DP development team recommends applying the following minimal operational policy:

```
apiVersion: deckhouse.io/v1alpha1
kind: OperationPolicy
metadata:
  name: common
spec:
  policies:
    allowedRepos:
      - myrepo.example.com
      - registry.deckhouse.io
    requiredResources:
      limits:
        - memory
      requests:
        - cpu
        - memory
    disallowedImageTags:
      - latest
    requiredProbes:
      - livenessProbe
      - readinessProbe
    maxRevisionHistoryLimit: 3
    imagePullPolicy: Always
    priorityClassNames:
    - production-high
    - production-low
    checkHostNetworkDNSPolicy: true
    checkContainerDuplicates: true
  match:
    namespaceSelector:
      labelSelector:
        matchLabels:
          operation-policy.deckhouse.io/enabled: "true"
```

This policy defines basic operational requirements for cluster objects, including allowed container registries, required resources and probes, restrictions on using images with the `latest` tag, allowed priority classes, and other settings that improve application security and stability.

To assign this operational policy, add the `operation-policy.deckhouse.io/enabled=true` label to the target namespace:

```
d8 k label ns my-namespace operation-policy.deckhouse.io/enabled=true
```

Security policies

Using the SecurityPolicy, you can create security policies that define container behavior restrictions in the cluster, such as host network access, privileges, AppArmor usage, and more.

> **i** Detailed information on pod and container security settings (such as `hostNetwork`, `hostPID`, `hostIPC` and others), available values, and practical suggestions are available on the “Pod and container security settings” page.

Example security policy:

```
apiVersion: deckhouse.io/v1alpha1
kind: SecurityPolicy
metadata:
  name: mypolicy
spec:
  enforcementAction: Deny
  policies:
    allowHostIPC: true
    allowHostNetwork: true
    allowHostPID: false
    allowPrivileged: false
    allowPrivilegeEscalation: false
    allowedFlexVolumes:
    - driver: vmware
    allowedHostPorts:
    - max: 4000
      min: 2000
    allowedProcMount: Unmasked
    allowedAppArmor:
    - unconfined
    allowedUnsafeSysctls:
    - kernel.*
    allowedVolumes:
    - hostPath
    - projected
    fsGroup:
      ranges:
      - max: 200
        min: 100
      rule: MustRunAs
    readOnlyRootFilesystem: true
    requiredDropCapabilities:
    - ALL
    runAsGroup:
      ranges:
      - max: 500
        min: 300
      rule: RunAsAny
    runAsUser:
      ranges:
      - max: 200
        min: 100
      rule: MustRunAs
    seccompProfiles:
      allowedLocalhostFiles:
      - my_profile.json
      allowedProfiles:
      - Localhost
    supplementalGroups:
      ranges:
      - max: 133
        min: 129
      rule: MustRunAs
  match:
    namespaceSelector:
      labelSelector:
        matchLabels:
          enforce: mypolicy
```

To assign this security policy, add the `enforce: "mypolicy"` label to the target namespace.

Security policy exceptions

SecurityPolicyException is a resource that lets you create fine-grained exceptions from security policy checks for individual pods and containers. It allows you to avoid excluding an entire namespace from checks and instead define only the necessary exceptions from a specific rule for a pod or container.

Adding exceptions

To add exceptions for a pod or container, do the following:

1. Create a SecurityPolicyException object describing the required exceptions.

   It is recommended that you describe the reason for each exception in the rule's `metadata` field (for example, `metadata.description`). This makes auditing and maintenance easier.

2. In the pod template (usually via `spec.template.metadata.labels` in a Deployment, StatefulSet, or DaemonSet resource), add one of the following labels referencing the exception:

   - `security.deckhouse.io/security-policy-exception: <exception-name>`: Exception for the entire pod.
   - `security.deckhouse.io/security-policy-exception.container.<container-name>: <exception-name>`: Exception for a specific container.

Priority when selecting an exception for a container:

1. The label `security.deckhouse.io/security-policy-exception.container.<container-name>` is checked first.
2. If the container-specific label is absent, the exception from `security.deckhouse.io/security-policy-exception` is used.

⚠ If a container-specific label is set for a container but it points to an invalid or non-existent SecurityPolicyException object, it still has priority over the global label and may lead to pod placement denial.

Configuration example

For this example, consider a pod that requires:

- Permission to use the `hostNetwork` parameter for the entire pod.
- Permission to use the `privileged` parameter only for the `sample-init` container.

Without the SecurityPolicyException resource, allowing these parameters would require implementing a custom security policy where these settings could be allowed for any pod in the cluster.

With SecurityPolicyException, it is enough to create only the following resources:

- Exception to allow the `hostNetwork` parameter:

```
apiVersion: deckhouse.io/v1alpha1
kind: SecurityPolicyException
metadata:
  name: allow-hostnetwork-pod
spec:
  network:
    hostNetwork:
      allowedValue: true
      metadata:
        description: >-
          Pod requires host network mode for node-level network diagnostics.
```

- Exception to allow the `privileged` parameter in the `sample-init` container:

```
apiVersion: deckhouse.io/v1alpha1
kind: SecurityPolicyException
metadata:
  name: allow-privileged-init-container
spec:
  securityContext:
    privileged:
      allowedValue: true
      metadata:
        description: >-
          Container init requires privileged mode to access host-level networking
features.
```

After that, the corresponding labels need to be added to the pod template:

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: example
spec:
  template:
    metadata:
      labels:
        # General exception applicable to the entire pod.
        security.deckhouse.io/security-policy-exception: allow-hostnetwork-pod
        # Exception applicable to the sample-init container.
        security.deckhouse.io/security-policy-exception.container.sample-init: allow-
privileged-init-container
    spec:
      hostNetwork: true
      # Other pod configuration.
    containers:
      - name: sample-init
        securityContext:
          privileged: true
```

Partial policy enforcement

To enforce specific security policies without disabling the entire predefined set, follow these steps:

1. Add the `security.deckhouse.io/pod-policy: privileged` label to the target namespace to disable the built-in policy set.
2. Create a SecurityPolicy that matches the `baseline` or `restricted` level. In the `policies` section, specify only the security settings you need.
3. Add an extra label to the namespace matching the `namespaceSelector` in the SecurityPolicy.

Example SecurityPolicy configuration for the `baseline` level:

```
apiVersion: deckhouse.io/v1alpha1
kind: SecurityPolicy
metadata:
  name: baseline
spec:
  enforcementAction: Deny
  policies:
    allowHostIPC: false
    allowHostNetwork: false
    allowHostPID: false
    allowPrivilegeEscalation: true
    allowPrivileged: false
    allowedAppArmor:
      - runtime/default
```

```
    - localhost/*
  allowedCapabilities:
    - AUDIT_WRITE
    - CHOWN
    - DAC_OVERRIDE
    - FOWNER
    - FSETID
    - KILL
    - MKNOD
    - NET_BIND_SERVICE
    - SETFCAP
    - SETGID
    - SETPCAP
    - SETUID
    - SYS_CHROOT
  allowedHostPaths: []
  allowedHostPorts:
    - max: 0
      min: 0
  allowedProcMount: Default
  allowedUnsafeSysctls:
    - kernel.shm_rmid_forced
    - net.ipv4.ip_local_port_range
    - net.ipv4.ip_unprivileged_port_start
    - net.ipv4.tcp_syncookies
    - net.ipv4.ping_group_range
    - net.ipv4.ip_local_reserved_ports
    - net.ipv4.tcp_keepalive_time
    - net.ipv4.tcp_fin_timeout
    - net.ipv4.tcp_keepalive_intvl
    - net.ipv4.tcp_keepalive_probes
  seLinux:
    - type: ""
    - type: container_t
    - type: container_init_t
    - type: container_kvm_t
    - type: container_engine_t
  seccompProfiles:
    allowedProfiles:
      - RuntimeDefault
      - Localhost
      - undefined
      - ''
    allowedLocalhostFiles:
      - '*'
 match:
  namespaceSelector:
    labelSelector:
      matchLabels:
        operation-policy.deckhouse.io/baseline-enabled: "true"
```

Example SecurityPolicy configuration for the `restricted` level:

```
apiVersion: deckhouse.io/v1alpha1
kind: SecurityPolicy
metadata:
 name: restricted
spec:
 enforcementAction: Deny
 policies:
  allowHostIPC: false
  allowHostNetwork: false
```

```
    allowHostPID: false
    allowPrivilegeEscalation: false
    allowPrivileged: false
    allowedAppArmor:
      - runtime/default
      - localhost/*
    allowedCapabilities:
      - NET_BIND_SERVICE
    allowedHostPaths: []
    allowedHostPorts:
      - max: 0
        min: 0
    allowedProcMount: Default
    allowedUnsafeSysctls:
      - kernel.shm_rmid_forced
      - net.ipv4.ip_local_port_range
      - net.ipv4.ip_unprivileged_port_start
      - net.ipv4.tcp_syncookies
      - net.ipv4.ping_group_range
      - net.ipv4.ip_local_reserved_ports
      - net.ipv4.tcp_keepalive_time
      - net.ipv4.tcp_fin_timeout
      - net.ipv4.tcp_keepalive_intvl
      - net.ipv4.tcp_keepalive_probes
    allowedVolumes:
      - configMap
      - csi
      - downwardAPI
      - emptyDir
      - ephemeral
      - persistentVolumeClaim
      - projected
      - secret
    requiredDropCapabilities:
      - ALL
    runAsUser:
      rule: MustRunAsNonRoot
    seLinux:
      - type: ""
      - type: container_t
      - type: container_init_t
      - type: container_kvm_t
      - type: container_engine_t
    seccompProfiles:
      allowedProfiles:
        - RuntimeDefault
        - Localhost
      allowedLocalhostFiles:
        - '*'
  match:
    namespaceSelector:
      labelSelector:
        matchLabels:
          operation-policy.deckhouse.io/restricted-enabled: "true"
```

Gatekeeper custom resources

Gatekeeper offers advanced capabilities for modifying Kubernetes resources using mutation policies. These policies are defined through the following custom resources:

- AssignMetadata: Modifies the `metadata` section of a resource.
- Assign: Modifies fields other than `metadata`.
- ModifySet: Adds or removes values from a list, such as container run arguments.

- AssignImage: Modifies the `image` field of a resource.

For more on modifying Kubernetes resources using mutation policies, refer to the Gatekeeper documentation.

Custom Gatekeeper policy examples

Here you can find examples of Gatekeeper policies that let you extend the standard cluster security mechanism.

Preventing deletion of a node without a specified label

> **i** The `DELETE` operations are handled by Gatekeeper by default.

You can create a Gatekeeper policy to prevent a node deletion unless it has a special label assigned.

In the following example, the `oldObject` field is used to check labels on the node being deleted:

```
apiVersion: templates.gatekeeper.sh/v1
kind: ConstraintTemplate
metadata:
  name: d8customnodedeleteguard
spec:
  crd:
    spec:
      names:
        kind: D8CustomNodeDeleteGuard

    requiredLabelKey: "admission.deckhouse.io/allow-delete"
    requiredLabelValue: "true"
```

Preventing exec and attach operations to specific Pods

The `admission-policy-engine` module's webhook routes `CONNECT` requests for `pods/exec` and `pods/attach` in namespaces other than `d8-*` and `kube-*` through Gatekeeper. This allows custom policies to allow or deny `kubectl exec` and `kubectl attach` operations.

Pods labeled heritage: deckhouse

The `deckhouse` module denies the following operations into pods of system components labeled `heritage: deckhouse` for all users, but the Deckhouse Platform system users:

- `kubectl exec`
- `kubectl attach`
- `kubectl cp`
- `kubectl port-forward`
- `kubectl debug`

The operations are denied regardless of whether the `admission-policy-engine` module is enabled in the cluster. For details, refer to the FAQ of the `deckhouse` module.

Custom policy example

You can create your own Gatekeeper policy to deny `kubectl exec` and `kubectl attach` operations in specific namespaces. In the following example, `input.review.operation` and `input.review.resource.resource` are used to check for `CONNECT` operations:

```
apiVersion: templates.gatekeeper.sh/v1
kind: ConstraintTemplate
metadata:
  name: d8customdenyexec
spec:
  crd:
    spec:
      names:
        kind: D8CustomDenyExec
      validation:
        openAPIV3Schema:
          type: object
          properties:
            forbiddenNamespaces:
              type: array
              items:
                type: string
  targets:
    - target: admission.k8s.gatekeeper.sh
      rego: |
        package d8.custom

        is_connect {
          input.review.operation == "CONNECT"
        }

        # requestSubResource is preferred, but fall back to subResource for older APIs
        subresource_is(sub) {
          sr := object.get(input.review, "requestSubResource",
input.review.subResource)
          sr == sub
        }

        is_exec_or_attach {
          input.review.resource.resource == "pods"
          subresource_is("exec")
        }

        is_exec_or_attach {
          input.review.resource.resource == "pods"
          subresource_is("attach")
        }

        is_forbidden_namespace {
          ns := input.review.namespace
          ns == input.parameters.forbiddenNamespaces[_]
        }
```

```
      violation[{"msg": msg}] {
        is_connect
        is_exec_or_attach
        is_forbidden_namespace
        msg := sprintf("Exec/attach is forbidden in namespace %q",
[input.review.namespace])
      }
---
apiVersion: constraints.gatekeeper.sh/v1beta1
kind: D8CustomDenyExec
metadata:
  name: deny-exec-in-namespaces
spec:
  enforcementAction: deny
  match:
    kinds:
      - apiGroups: ["*"]
        kinds: ["*"]
    scope: Namespaced
  parameters:
    forbiddenNamespaces:
      - production
      - staging
```

Key data and checks for `CONNECT` validation:

- Use `input.review.operation == "CONNECT"` to check for `CONNECT` operations.
- User information is available in `input.review.userInfo.username` and `input.review.userInfo.groups`.
- The namespace is available in `input.review.namespace`.

Image signature verification

DP supports container image signature verification using Cosign.
Container image signature verification allows you to ensure their integrity (that the image has not been modified since its creation) and authenticity (that the image was created by a trusted source). You can enable container image signature verification in the cluster using the policies.verifyImageSignatures parameter of the SecurityPolicy.

Images are signed by creating a special tag in the container registry that contains the image signature. The signature is generated for the digest (hash) of your image.
If your image is `my-repo/app:latest` with the hash `sha256:abc123EXAMPLE`, the tag `my-repo/app:sha256-abc123EXAMPLE.sig` will appear in the image store.

Therefore, the image signing process consists of calculating and publishing an additional tag to the container registry, without modifying the existing image.
After signing the image, there is no need to push it to the image store again. You only need to log in to the container registry with write access.

To sign an image with Cosign, do the following:

1. Make sure that Cosign version 2 or lower is used:

   Check the version: `cosign version`.

   ```
   cosign version
   ```

2. Generate a key pair (public and private):

   ```
   cosign generate-key-pair
   ```

3. Sign the image in the container registry using the generated private key:

   ```
   cosign sign --key <KEY> <REGISTRY_IMAGE_PATH>
   ```

   Here:

- `<REGISTRY IMAGE PATH>` is the path to the image that needs to be specified at startup, for example, `registry.private.io/labs/application/image:latest`.

To enable container image signature verification in a DP cluster:

1. Use the `policies.verifyImageSignatures` parameter in SecurityPolicy and specify the generated public key.

   Example SecurityPolicy configuration for verifying signatures of container images in `registry.private.ru`, located under `/labs/application/`:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: SecurityPolicy
   metadata:
     name: verify-image-test
   spec:
     enforcementAction: Deny
     match:
       namespaceSelector:
         labelSelector:
           matchLabels:
             example-security-policy/enabled: true
     policies:
       allowHostIPC: true
       allowHostNetwork: true
       allowHostPID: false
       allowPrivilegeEscalation: true
       allowPrivileged: false
       allowRbacWildcards: true
       verifyImageSignatures:
         - publicKeys:
             - |-
               -----BEGIN PUBLIC KEY-----
               ...
               -----END PUBLIC KEY-----
           reference: registry.private.io/labs/application/*
   ```

   The label name specified in `match.namespaceSelector.labelSelector.matchLabels` can be any name. The label in the policy selector must match the label on the corresponding namespace.

   For more information, see Configuring policy selectors.

2. Create an OperationPolicy that restricts running pods from third-party registries:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: OperationPolicy
   metadata:
     name: test-operation-policy
   spec:
     enforcementAction: Deny
     match:
       namespaceSelector:
         labelSelector:
           matchLabels:
             example-operation-policy/enabled: "true"
     policies:
       allowedRepos:
       - registry.private.io/labs/application/
   ```

   The label name specified in `match.namespaceSelector.labelSelector.matchLabels` can be any name. The label in the policy selector must match the label on the corresponding namespace.

   For more information, see Configuring policy selectors.

3. Add a label to the namespace where signature verification should be enabled (specify your namespace):

```
d8 k label ns <NAMESPACE> example-security-policy/enabled=true
```

4. Add a label to the namespace where running pods from third-party registries should be restricted (specify your namespace):

```
d8 k label ns <NAMESPACE> example-operation-policy/enabled=true
```

5. To verify how image signing works, deploy pods in the namespace with signed and unsigned images (specify your namespace):

```
d8 k -n <NAMESPACE> run signed-pod --image=<SIGNED_IMAGE>
d8 k -n <NAMESPACE> run unsigned-pod --image=<UNSIGNED_IMAGE>
```

According to this policy, if any container image address matches the `reference` parameter value and the image is unsigned, or the signature does not match the specified keys, pod creation will be denied.

Example error output when creating a pod with an image that fails signature verification:

```
[verify-image-signatures] Image signature verification failed: nginx:1.17.2
```

Using alternative security policy management tools

If you use an alternative solution for security policy management in a DP cluster (for example, Kyverno), configure exceptions for the following namespaces:

- `kube-system`
- all namespaces with the `d8-*` prefix (for example, `d8-system`)

Without these exceptions, policies may block or disrupt system component operations.

Additional resources

Container image vulnerability scanning

Deckhouse Platform (DP) provides a built-in tool for automatically detecting vulnerabilities in container images based on the Trivy project.

Vulnerability scanning

DP scans all container images used by cluster pods. The checks include:

- Known vulnerabilities (CVEs) in the images in use.
- Compliance with CIS benchmarks (compliance checks).

Scanning uses public vulnerability databases.

Scanning in namespaces

By default, only the `default` namespace is scanned.

To enable scanning for a specific namespace, add the label `security-scanning.deckhouse.io/enabled=""` to it.

As soon as at least one namespace with this label is detected in the cluster, scanning of the `default` namespace stops. To re-enable scanning for the `default` namespace, add the label with the following command:

```
d8 k label namespace default security-scanning.deckhouse.io/enabled=""
```

In the current version, there is no option to limit the list of resources to be scanned within a namespace. DP scans **all resources** in a namespace labeled with `security-scanning.deckhouse.io/enabled=""`.

Start conditions and scanning process

Scanning starts:

- automatically every 24 hours,
- when components with new images are deployed in namespaces with scanning enabled.

Scanning occurs according to the following process:

1. In the namespace of each scanned resource, a VulnerabilityReport object is created.
2. This object contains the annotation `trivy-operator.aquasecurity.github.io/report-ttl`, which specifies the report's time-to-live (default: `24h`).
3. When the TTL expires, the VulnerabilityReport object is deleted, and the scan is run again.

Forcing a rescan

To manually trigger a rescan of a resource, you can use either of the following methods:

- Update the `trivy-operator.aquasecurity.github.io/report-ttl` annotation with a short time-to-live value.

  Example:

  ```
  d8 k annotate VulnerabilityReport -n <NAMESPACE> <REPORT_NAME> trivy-operator.aquasecurity.github.io/report-ttl=1s --overwrite
  ```

- Delete the VulnerabilityReport object from the namespace containing the scanned resource.

  Example:

  ```
  d8 k delete VulnerabilityReport -n <NAMESPACE> <REPORT_NAME>
  ```

For details on how to view scan results, see Scanning container images for vulnerabilities.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Certificate management

Deckhouse Platform (DP) provides built-in tools for managing TLS certificates in the cluster and supports:

- Requesting certificates from all supported sources, such as Let's Encrypt, HashiCorp Vault, Venafi.
- Issuing self-signed certificates.
- Automatic renewal and expiration monitoring.
- Deploying `cm-acme-http-solver` on master nodes and dedicated nodes.

This page describes the available certificate management features in DP and the procedure for working with certificate issuers.

> Examples of certificate configuration, usage of the `tls-acme` annotation, and secure handling of credentials are described in Using TLS certificates.

Monitoring

DP exports metrics to Prometheus, allowing you to monitor:

- Certificate expiration dates
- Certificate renewal status

Access roles

DP provides several predefined roles for accessing resources:

Role	Permissions
`User`	View Certificate and Issuer resources in available namespaces, as well as global ClusterIssuer resources.
`Editor`	Manage Certificate resources in available namespaces.
`Admin`	Manage Issuer resources in available namespaces.
`ClusterEditor`	Manage Certificate and Issuer resources in all namespaces, as well as ClusterIssuer resources.
`SuperAdmin`	Manage internal system objects.

Working with certificate issuers

DP supports the following default certificate issuers (ClusterIssuer):

- `letsencrypt`: Issues TLS certificates using the public CA Let’s Encrypt and ACME HTTP validation. Suitable for automatically obtaining trusted certificates for most public services. Configuration details can be found in the official `cert-manager` documentation.
- `letsencrypt-staging`: Similar to `letsencrypt`, but uses Let’s Encrypt’s staging server. Useful for debugging configuration and testing the certificate issuance process. More details available in the Let’s Encrypt staging docs.
- `selfsigned`: Issues self-signed certificates. Useful when external trust is not required (for example, for internal services).
- `selfsigned-no-trust`: Also issues self-signed certificates but without automatically adding the root certificate to the trust store. Suitable for manual trust management.

In some cases, additional types of ClusterIssuer may be needed:

- If you want to use a Let’s Encrypt certificate with DNS validation via a third-party DNS provider.
- if you need to use a certificate authority (CA) other than Let’s Encrypt. See the full list of supported CAs in the `cert-manager` documentation.

Adding a ClusterIssuer with DNS-01 validation via webhook

To verify domain ownership with Let’s Encrypt using the `DNS-01` method, the `cert-manager` module must be able to create TXT records in the DNS zone associated with the domain.

`cert-manager` includes built-in support for popular DNS providers such as AWS Route53, Google Cloud DNS, Cloudflare, and others. A full list is available in the official `cert-manager` documentation.

The `cert-manager` module in Deckhouse Platform can automatically create ClusterIssuers for Cloudflare, Amazon Route53, DigitalOcean, Google Cloud DNS, and Yandex Cloud DNS when the corresponding module settings are filled in. For Yandex Cloud DNS, follow the steps in Issuing a DNS wildcard certificate using Yandex Cloud DNS.

If your provider is not directly supported, you can configure a webhook and deploy a custom ACME handler in the cluster that performs the necessary DNS record updates, then create a `ClusterIssuer` with `dns01.webhook` solver settings according to the webhook documentation.

Adding a ClusterIssuer that uses a custom certificate authority (CA)

1. Generate the certificate:

```
openssl ecparam -name prime256v1 -genkey -out rootCAKey.pem
openssl req -x509 -sha256 -new -nodes -key rootCAKey.pem -days 3650 -out rootCACert.pem
```

2. Create a secret in the `d8-cert-manager` namespace with an arbitrary name, containing the certificate files.
   - Example of creating a secret using the `d8 k` command:

     ```
     d8 k create secret tls internal-ca-key-pair -n d8-cert-manager --key="rootCAKey.pem" --cert="rootCACert.pem"
     ```

   - Example of creating a secret from a YAML file (the certificate file contents must be Base64-encoded):

     ```
     apiVersion: v1
     data:
       tls.crt: <output of `cat rootCACert.pem | base64 -w0`>
       tls.key: <output of `cat rootCAKey.pem | base64 -w0`>
     kind: Secret
     metadata:
       name: internal-ca-key-pair
       namespace: d8-cert-manager
     type: Opaque
     ```

3. Create a ClusterIssuer with any name using the created secret:

   ```
   apiVersion: cert-manager.io/v1
   kind: ClusterIssuer
   metadata:
     name: inter-ca
   spec:
     ca:
       secretName: internal-ca-key-pair   # Name of the created secret.
   ```

You can now use the created ClusterIssuer to issue certificates for all DP components or for a specific component.

For example, to use this ClusterIssuer for issuing certificates for all DP components, set its name in the global parameter `clusterIssuerName`:

```
spec:
  settings:
    modules:
      https:
        certManager:
          clusterIssuerName: inter-ca
        mode: CertManager
      publicDomainTemplate: '%s.<public_domain_template>'
  version: 1
```

Adding an Issuer and ClusterIssuer using HashiCorp Vault to request certificates

To configure certificate issuance using Vault, refer to the HashiCorp documentation.

After configuring the PKI and enabling Kubernetes authentication, follow these steps:

1. Create a ServiceAccount and copy the reference to its secret:

   ```
   d8 k create serviceaccount issuer

   ISSUER_SECRET_REF=$(d8 k get serviceaccount issuer -o json | jq -r ".secrets[].name")
   ```

2. Create the Issuer resource:

```
d8 k apply -f - <<EOF
apiVersion: cert-manager.io/v1
kind: Issuer
metadata:
  name: vault-issuer
  namespace: default
spec:
  vault:
    server: http://vault.default.svc.cluster.local:8200
    # Defined during PKI configuration.
    path: pki/sign/example-dot-com
    auth:
      kubernetes:
        mountPath: /v1/auth/kubernetes
        role: issuer
        secretRef:
          name: $ISSUER_SECRET_REF
          key: token
EOF
```

3. Create the Certificate resource to obtain a TLS certificate signed by Vault CA:

```
d8 k apply -f - <<EOF
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: example-com
  namespace: default
spec:
  secretName: example-com-tls
  issuerRef:
    name: vault-issuer
  # Domains must match those configured in the PKI in Vault.
  commonName: www.example.com
  dnsNames:
  - www.example.com
EOF
```

Integration with software and security solutions

Deckhouse Platform supports integration with Kaspersky Unified Monitoring and Analysis Platform (KUMA), a unified monitoring and analysis system by Kaspersky Lab. As part of the integration, security events and audit logs from the cluster are sent to KUMA for further analysis.

Sending logs to KUMA

To send logs to KUMA, configure log collection and delivery in Deckhouse Platform using the following resources:

- ClusterLogDestination: Defines log storage parameters.

- ClusterLoggingConfig: Defines cluster log collection parameters.

> **i** On the KUMA side, configure the appropriate resources for receiving events.

Example ClusterLogDestination and ClusterLoggingConfig configurations

In the following examples, you can find ClusterLogDestination and ClusterLoggingConfig configuration options for sending logs in various formats.

- In JSON format over UDP
- In JSON format over TCP
- In CEF format over TCP
- In Syslog format over TCP
- Apache Kafka

```
apiVersion: deckhouse.io/v1alpha1

        - kubelet.*
  type: File
```

KCS configuration features

Kaspersky Container Security (KCS) requires extended access rights to the OS kernel in order to monitor the execution environment. Specifically, the `kcs-ih` (Image Hub) component must run in privileged mode. To do this, certain process privilege management mechanisms at the Linux OS kernel level must be disabled. For more details, see the Kaspersky Container Security documentation.

To enable KCS runtime monitoring in a Deckhouse Platform cluster, assign the label `security.deckhouse.io/pod-policy=privileged` to the namespace where KCS components are located.

Example command for assigning a label:

```
d8 k label namespace kcs security.deckhouse.io/pod-policy=privileged
```

Antivirus scanning exclusions for nodes

If antivirus software is installed on Deckhouse Platform cluster nodes (for example, Kaspersky Endpoint Security for Linux, KESL), you may need to exclude Deckhouse service directories from scanning to avoid false positives.

List of Deckhouse service directories (also available CSV format):

Directory	Purpose
`/etc/cni/` (any node)	CNI module configuration files
`/etc/kubernetes` (any node)	Static pod manifests, PKI certificate files
`/mnt/kubernetes-data` (master node)	Only present in clusters deployed in the cloud when a separate disk is used for the etcd database
`/mnt/vector-data` (any node, `log-shipper` module)	Service data for log delivery status
`/opt/cni/bin/` (any node)	CNI module executables
`/opt/deckhouse/bin/` (any node)	Executables required for Deckhouse Platform operation
`/var/lib/bashible` (any node)	Node configuration files
`/var/lib/containerd` (any node)	Stores CRI-related data (for example, containerd). Contains container image layers, filesystem snapshots, metadata, logs, and other container information
`/var/lib/deckhouse/` (master node)	Deckhouse Platform module files dynamically loaded from the image registry
`/var/lib/etcd` (master node)	etcd database
`/var/lib/kubelet/` (any node)	kubelet configuration files
`/var/lib/upmeter` (master node, `upmeter` module)	`upmeter` module database
`/var/log/containers` (any node)	Container logs (when using containerd)
`/var/log/pods/` (any node)	Logs of all pod containers running on the node

KESL configuration recommendations

To ensure Deckhouse Platform functions correctly with KESL installed, follow these steps:

1. Disable the following KESL tasks:
   - `Firewall Management (ID: 12)`
   - `Web Threat Protection (ID: 14)`
   - `Network Threat Protection (ID: 17)`
   - `Web Control (ID: 26)`
   - `Mail Monitoring ( ID: 35 )`

> **i** The list of tasks may differ in future KESL versions.

2. Make sure node resources meet the requirements of:
    - Deckhouse Platform
    - KESL

Automatic distribution of secrets across namespaces

Deckhouse Platform (DP) lets you automatically distribute secrets across all namespaces in the cluster. This helps eliminate the need to manually copy secrets in CI/CD pipelines — for example, when pulling container images or working with Ceph RBD storage.

How it works

- Deckhouse monitors secrets in the `default` namespace that have the special label `secret-copier.deckhouse.io/enabled: ""`.
- These secrets are automatically copied to all namespaces in the cluster.
- When the original secret in the `default` namespace is updated, the new content is propagated to all namespaces.
- If the original secret in `default` is deleted, all of its copies in other namespaces are also deleted.
- If a secret copy is manually modified in a namespace, it will be automatically overwritten with the content of the original secret from `default`.
- When new namespaces are created, all secrets from `default` labeled with `secret-copier.deckhouse.io/enabled: ""` are automatically copied into them.
- There's a regular nightly synchronization that ensures all secrets remain up to date.
- Deckhouse Platform never creates, updates or deletes the secret `d8-system/cluster-key` this way: it holds the cluster key of Deckhouse Platform licensing.
- Secrets of the `bootstrap.kubernetes.io/token` type are not copied. The copies of such secrets that earlier Deckhouse Platform versions made are deleted.
- Deckhouse Platform updates and deletes only the copies it made. If a namespace already has a secret with the same name that Deckhouse Platform did not create, the secret is left as is and is not copied into that namespace.

Incompatibility with multitenancy mode

The automatic secret distribution mechanism is not compatible with the multitenancy mode.

Multitenancy mode creates isolated environments for users within projects. Automatically distributing secrets to all namespaces may violate this security model. If sensitive data accidentally reaches a user's isolated environment, it may lead to data exposure.

If you need to provide a shared certificate (for example, a wildcard certificate for an internal environment) or a shared registry access token, do not use automatic distribution. Instead, include such secrets in the project template. A cluster administrator must define them in the project configuration.

Configuring automatic secret distribution

1. Create a Secret resource in the `default` namespace.
2. Add the label `secret-copier.deckhouse.io/enabled: ""`.
3. Apply the resource using the `d8 k apply` command. It will then be automatically distributed to all namespaces.

⚠ Only secrets from the `default` namespace are automatically distributed. Secrets with the label `secret-copier.deckhouse.io/enabled: ""` created in any other namespace will be automatically deleted.

Distributing secrets to selected namespaces

To copy a secret to specific namespaces only, use the annotation with a label selector `secret-copier.deckhouse.io/target-namespace-selector: "app=custom"`. In this case, the secret will be copied only to namespaces that match the specified selector.

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Monitoring in Deckhouse Platform

Deckhouse Platform (DP) provides a Kubernetes monitoring solution based on **Prometheus** and **Grafana**. DP automatically configures metrics collection in the cluster from nodes, pods, and key cluster components (etcd, kube-apiserver, CoreDNS), which enables preset dashboards for analyzing CPU, memory, disk, and network usage.

Cluster monitoring is enabled by default in the `Default` and `Managed` module bundles.

All components, including Prometheus and Alertmanager, operate in a fault-tolerant mode and can be used in cloud environments and on bare-metal servers.

The principles of Prometheus operation is covered in Configuring a system for collecting and storing metrics.

Several types of monitoring are implemented in DP:

- Hardware resource monitoring
- Kubernetes monitoring
- Ingress monitoring
- Control plane monitoring
- Network interaction monitoring
- Extended monitoring
- Cluster SLA monitoring

DP includes an alerting system that supports sending event notifications, including to external systems.

Hardware resource monitoring

Tracking of cluster hardware resource capacity is provided with graphs showing utilization of:

- CPU
- Memory
- Disk
- Network

Graphs are available with aggregation by:

- Pods
- Controllers
- Namespaces
- Nodes

Kubernetes monitoring

The module `monitoring-kubernetes` is designed for basic cluster node monitoring.

It provides secure metrics collection and offers a basic set of rules for monitoring:

- Current container runtime version (docker, containerd) on the node and its compliance with versions allowed for use.
- Overall cluster monitoring subsystem health (Dead man’s switch).

- Available file descriptors, sockets, free space, and inodes.
- Operation of `kube-state-metrics`, `node-exporter`, `kube-dns`.
- Cluster node state (NotReady, drain, cordon).
- Time synchronization state on nodes.
- Cases of prolonged CPU steal exceeding.
- Conntrack table state on nodes.
- Pods with incorrect state (as a possible consequence of kubelet issues) and more.

Ingress monitoring

Statistics collection for `ingress-nginx` in Prometheus is implemented with detailed metrics (response time, codes, geography, etc.), available in different dimensions (namespace, vhost, ingress). Data is visualized in Grafana with interactive dashboards. Detailed description is available in the section about Ingress monitoring.

The module is enabled by default in the `Default` and `Managed` module bundles.

Disabling collection of detailed statistics from Ingress resources

By default, DP collects detailed statistics from all Ingress resources in the cluster, which generates a high load on the monitoring system.

To disable statistics collection, add the label `ingress.deckhouse.io/discard-metrics: "true"` to the corresponding namespace or Ingress resource.

- Example of disabling statistics (metrics) collection for all Ingress resources in the `review-1` namespace:

  ```
  d8 k label ns review-1 ingress.deckhouse.io/discard-metrics=true
  ```

- Example of disabling statistics (metrics) collection for all `test-site` Ingress resources in the `development` namespace:

  ```
  d8 k label ingress test-site -n development ingress.deckhouse.io/discard-metrics=true
  ```

Control plane monitoring

Control plane monitoring is provided by the `control-plane-manager` module. It organizes secure metrics collection and provides a basic set of monitoring rules for the following cluster components:

- kube-apiserver
- kube-controller-manager
- kube-scheduler
- kube-etcd

Cluster monitoring

DP securely collects monitoring metrics and configures rules.

DP monitoring capabilities:

- Monitoring current container runtime version (containerd) on the node and its compliance with versions allowed for use in DP.
- Monitoring cluster monitoring subsystem health (“Dead man’s switch”).
- Monitoring available file descriptors, sockets, free space, and inodes.
- Monitoring cluster node state (NotReady, drain, cordon).
- Operation of `kube-state-metrics`, `node-exporter`, `kube-dns`.
- Monitoring time synchronization state on nodes.
- Monitoring cases of prolonged CPU steal exceeding.
- Monitoring Conntrack table state on nodes.
- Monitoring pods with incorrect state (as a possible consequence of kubelet issues).
- Monitoring control plane components (implemented by the `control-plane-manager` module).

Extended monitoring mode

DP supports an extended monitoring mode via the `extended-monitoring` module, allowing you to configure:

- Monitoring secrets in the cluster (Secret objects) and TLS certificate expiration in them.
- Collecting Kubernetes cluster events as metrics.

- Monitoring container image availability in registry used by controllers (Deployments, StatefulSets, DaemonSets, CronJobs).
- Monitoring objects in namespaces that have the `extended-monitoring.deckhouse.io/enabled=""` label.

The module can send alerts based on the following metrics:

- Free space and inodes on node disks
- Node utilization
- Pod and container image availability
- Certificate expiration
- Other cluster events

Alerts

Monitoring in DP includes event notifications. The standard delivery includes a set of basic warnings covering cluster state and its components. There is also the ability to add custom alerts.

For the list of all available alerts in the DP monitoring system, refer to the corresponding documentation page.

Sending alerts to external systems

DP supports sending alerts using Alertmanager:

- Via SMTP protocol
- To PagerDuty
- To Slack
- To Telegram
- Via Webhook
- Through any other channels supported in Alertmanager

Examples of DP monitoring integration with external systems are available in Configuring integrations.

Cluster SLA monitoring

Availability assessment in DP is performed by the `upmeter` module.

Composition of the `upmeter` module:

- **agent**: Runs on master nodes and performs availability probes, sends results to the server.
- **upmeter**: Collects results and maintains an API server for their retrieval.
- **front**:
  - **status**: Shows availability level for the last 10 minutes (requires authorization, but it can be disabled).
  - **webui**: Shows a dashboard with statistics on probes and availability groups (requires authorization).
- **smoke-mini**: Maintains continuous *smoke testing* using StatefulSet.

The module sends about 100 metric readings every 5 minutes. This value depends on the number of enabled Deckhouse Platform modules.

Additional resources

- The list of alerts
- Integration with external monitoring systems
- Web interface of the monitoring
- Web interface of the platform
- Module `prometheus` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring network interaction and cluster node monitoring

Network interaction monitoring

DP can perform monitoring of network interaction between all cluster nodes, as well as between cluster nodes and external hosts. When monitoring is configured, each node sends ICMP packets twice per second to all other cluster nodes (and to optional external nodes) and exports data to the monitoring system.

Features of network interaction monitoring:

- Automatically checks the availability of all cluster nodes (and, optionally, external systems) using ICMP (ping) — testing is started every two seconds.
- All results are exported in metrics format to the Prometheus monitoring system.
- Included is a ready-made dashboard for Grafana, where current availability, delay schedules, and potential network connectivity issues are visualized in real time (for details, refer to Grafana).
- Allows you to quickly identify nodes with degraded connectivity and speeds up the response to incidents.

The `monitoring-ping` module tracks any changes to the `.status.addresses` field of a node. If changes are detected, a hook is triggered that collects the complete list of node names and their addresses, and passes it to the DaemonSet, which recreates the pods. Thus, `ping` checks always the current list of nodes.

⚠ The `monitoring-ping` module must be enabled.

Adding additional IP addresses for monitoring

To add additional monitoring IP addresses, use the `externalTargets` parameter of the `monitoring-ping` module.

Example module configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: monitoring-ping
spec:
  version: 1
  enabled: true
  settings:
    externalTargets:
    - name: google-primary
      host: 8.8.8.8
    - name: yaru
      host: ya.ru
    - host: youtube.com
```

i The `name` field is used in Grafana to display related data. If the `name` field is not specified, the required `host` field is used.

Cluster node monitoring

To enable cluster node monitoring, you need to enable the `monitoring-kubernetes` module if it’s not already enabled. You can enable cluster monitoring in the Deckhouse web interface, or using the following command:

```
d8 system module enable monitoring-kubernetes
```

In a similar way, you can enable the `extended-monitoring` module.

Additional resources

- Module `console` documentation
- Module `extended-monitoring` documentation

- Module `monitoring-kubernetes` documentation
- Module `monitoring-ping` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Writing Prometheus data to longterm storage

Prometheus supports the remote_write mechanism for sending data from a local Prometheus instance to a separate long-term storage (for example, VictoriaMetrics). In DP, support for this mechanism is implemented using the PrometheusRemoteWrite custom resource.

> For VictoriaMetrics, detailed information about ways to send data to vmagent can be found in the VictoriaMetrics documentation.

Example of minimal PrometheusRemoteWrite

Below is an example of minimal configuration for the PrometheusRemoteWrite custom resource:

```
apiVersion: deckhouse.io/v1
kind: PrometheusRemoteWrite
metadata:
  name: test-remote-write
spec:
  url: https://victoriametrics-test.domain.com/api/v1/write
```

Example of advanced PrometheusRemoteWrite

Below is an example of advanced configuration for the PrometheusRemoteWrite custom resource:

```
apiVersion: deckhouse.io/v1
kind: PrometheusRemoteWrite
metadata:
  name: test-remote-write
spec:
  url: https://victoriametrics-test.domain.com/api/v1/write
  basicAuth:
    username: username
    password: password
  writeRelabelConfigs:
  - sourceLabels: [__name__]
    action: keep
    regex: prometheus_build_.*|my_cool_app_metrics_.*
  - sourceLabels: [__name__]
    action: drop
    regex: my_cool_app_metrics_with_sensitive_data
```

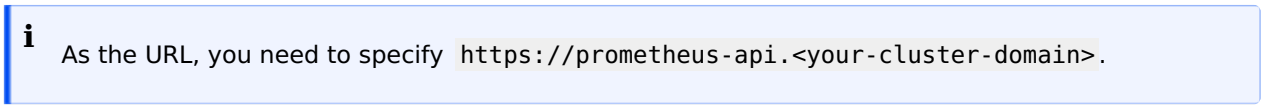
For a complete description of the custom resource fields, refer to the prometheus module documentation.

Additional resources

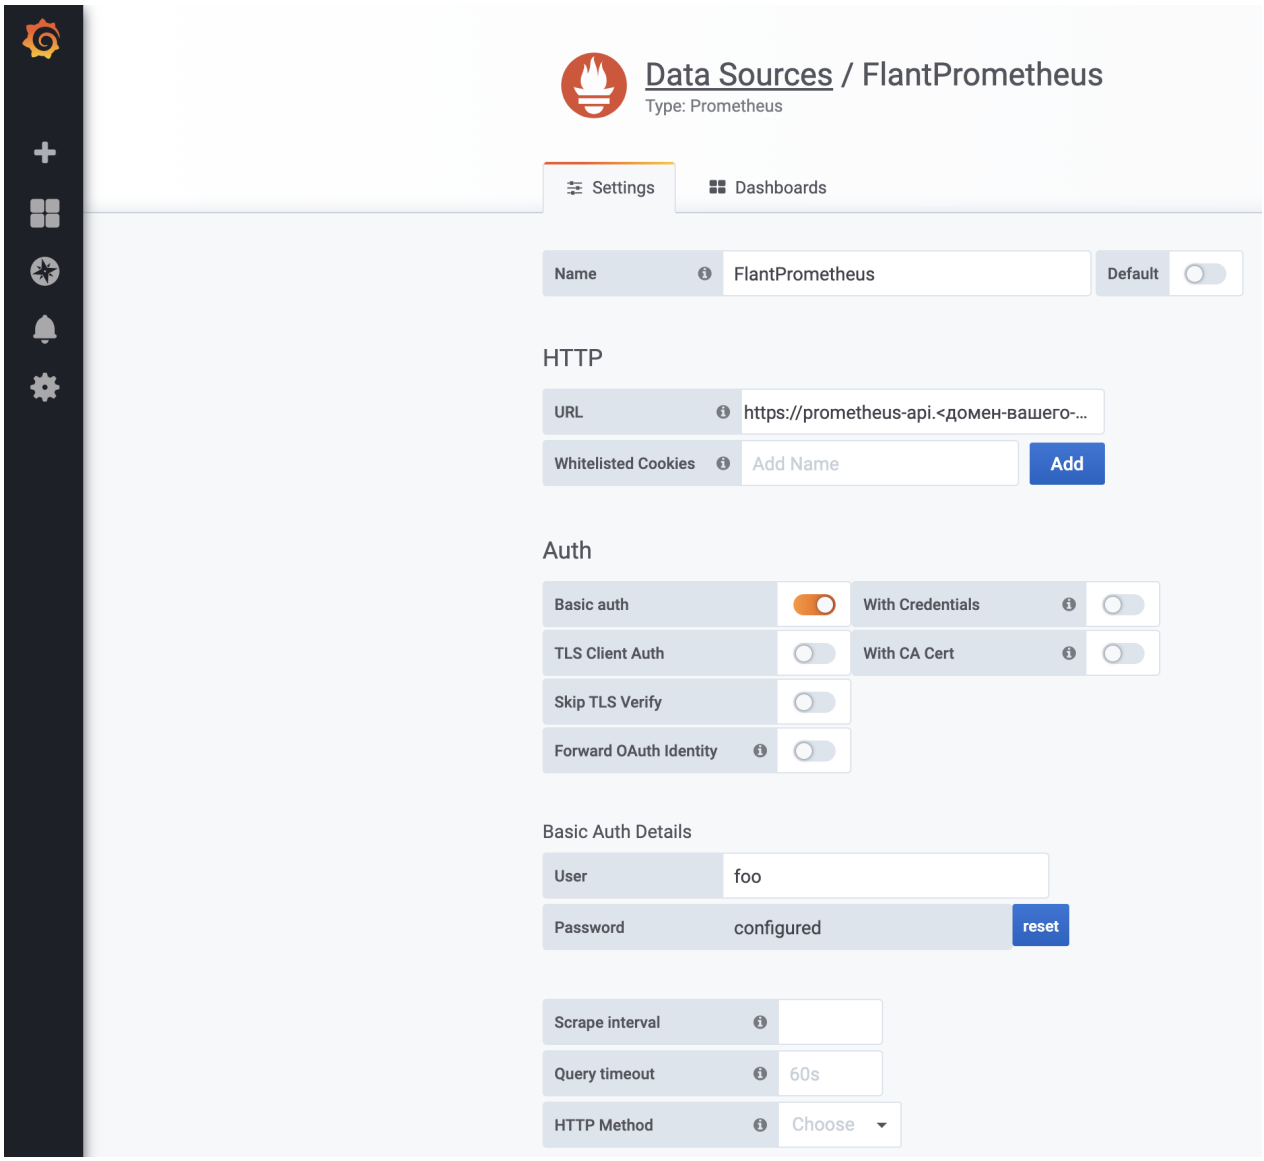
- Module `prometheus` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

External access configuration



Connecting Prometheus to Third-Party Grafana



Each `ingress-nginx-controller` has certificates that, when specified as client certificates, will allow connection to Prometheus. All you need to do is create an additional `Ingress` resource.

> The example below assumes that the Secret `example-com-tls` already exists in the d8-monitoring namespace.
>
> The names for Ingress `my-prometheus-api` and Secret `my-basic-auth-secret` are provided as examples. Replace them with more suitable ones for your setup.

```
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: my-prometheus-api
  namespace: d8-monitoring
  annotations:
    nginx.ingress.kubernetes.io/backend-protocol: HTTPS
    nginx.ingress.kubernetes.io/auth-type: basic
    nginx.ingress.kubernetes.io/auth-secret: my-basic-auth-secret
    nginx.ingress.kubernetes.io/app-root: /graph
    nginx.ingress.kubernetes.io/configuration-snippet: |
      proxy_ssl_certificate /etc/nginx/ssl/client.crt;
      proxy_ssl_certificate_key /etc/nginx/ssl/client.key;
      proxy_ssl_protocols TLSv1.2;
      proxy_ssl_session_reuse on;
spec:
  ingressClassName: nginx
  rules:
  - host: prometheus-api.example.com
    http:
      paths:
      - backend:
          service:
            name: prometheus
            port:
              name: https
        path: /
        pathType: ImplementationSpecific
  tls:
  - hosts:
    - prometheus-api.example.com
    secretName: example-com-tls
---
apiVersion: v1
kind: Secret
metadata:
  name: my-basic-auth-secret
  namespace: d8-monitoring
type: Opaque
data:
  # Basic-auth string is hashed using htpasswd.
  auth: Zm9vOiRhcHIxJE9GRzNYeWJwJGNrTDBGSERBa29YWUlsSDkuY3lzVDAK  # foo:bar
```

Add the data source to Grafana:

- **Basic authorization** is not a reliable security measure. It is recommended to implement additional security measures, such as specifying the `nginx.ingress.kubernetes.io/whitelist-source-range` annotation.
- Due to the need to create an Ingress resource in the system namespace, this connection method is **not recommended**. DP **does not guarantee** the preservation of this connection scheme's functionality due to its active continuous updates.
- This Ingress resource can be used to access the Prometheus API not only for Grafana but also for other integrations, such as Prometheus federation.

Connecting Third-Party Applications to Prometheus

The connection to Prometheus is secured using kube-rbac-proxy. To connect, create a `ServiceAccount` with the necessary permissions.

```
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: app
  namespace: default
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app:prometheus-access
rules:
- apiGroups: ["monitoring.coreos.com"]
  resources: ["prometheuses/http"]
  resourceNames: ["main", "longterm"]
  verbs: ["get"]
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: app:prometheus-access
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app:prometheus-access
subjects:
- kind: ServiceAccount
  name: app
  namespace: default
```

Execute the request using the `curl` command:

```
apiVersion: batch/v1
kind: Job
metadata:
  name: app-curl
  namespace: default
spec:
  template:
    metadata:
      name: app-curl
    spec:
      serviceAccountName: app
      containers:
      - name: app-curl
        image: curlimages/curl:7.69.1
        command: ["sh", "-c"]
        args:
        - >-
          curl -H "Authorization: Bearer $(cat
/var/run/secrets/kubernetes.io/serviceaccount/token)" -k -f
          https://prometheus.d8-monitoring:9090/api/v1/query_range?
query=up\&start=1584001500\&end=1584023100\&step=30
      restartPolicy: Never
  backoffLimit: 4
```

The `Job` should complete successfully.

Metrics Collection via Gateway (Pushgateway)

Prometheus, which is the foundation of the DP monitoring system, primarily uses a pull model for

metrics collection. In this approach, DP polls metric exporters. When applying the pull model is difficult, for example, for services without a permanent network interface, you can use metrics collection via a gateway (Pushgateway). Pushgateway allows such tasks to send metrics themselves, which can then be collected by Prometheus. It’s important to note that Pushgateway can become a single point of failure and bottleneck in the system. How to send metrics from an application to Pushgateway can be learned from the Prometheus documentation.

Example of configuring metrics collection via gateway (Pushgateway):

- Enable and configure the `prometheus-pushgateway` module.

  You can enable the module in the web interface (Deckhouse Console), or using the following command:

  ```
  d8 system module enable prometheus-pushgateway
  ```

- Specify the gateway names in the `instances` parameter of the `prometheus-pushgateway` module through the web interface, or using the following command:

  ```
  d8 k edit mc prometheus-pushgateway
  ```

  Example module configuration:

  ```
  apiVersion: deckhouse.io/v1alpha1
  kind: ModuleConfig
  metadata:
    name: prometheus-pushgateway
  spec:
    version: 1
    enabled: true
    settings:
      instances:
      - first
      - second
      - another
  ```

  The address of the PushGateway instance named `first` from a pod container will be: `http://first.kube-prometheus-pushgateway:9091`.

- Check metrics sending.

  Example of sending metrics via curl:

  ```
  echo "test_metric{env="dev"} 3.14" | curl --data-binary @- http://first.kube-prometheus-pushgateway:9091/metrics/job/myapp
  ```

- Check that the metric appeared in the monitoring system. It will be available 30 seconds after data collection.

  Example PromQL query:

  ```
  test_metric{container="prometheus-pushgateway", env="dev", exported_job="myapp",
      instance="10.244.1.155:9091", job="prometheus-pushgateway", pushgateway="prometheus-pushgateway", tier="cluster"} 3.14
  ```

Removing Metrics from Gateway (Pushgateway)

Example of removing all metrics from group `{instance="10.244.1.155:9091",job="myapp"}` via curl:

```
curl -X DELETE http://first.kube-prometheus-pushgateway:9091/metrics/job/myapp/instance/10.244.1.155:9091
```

Note that PushGateway stores received metrics in memory. When the PushGateway pod restarts, all metrics will be lost.

Additional resources

- Module `prometheus-pushgateway` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring a system for collecting and storing metrics

> Starting from version 1.71, Deckhouse Platform uses Deckhouse Prom++ instead of Prometheus.

Prometheus capabilities

Prometheus collects metrics and executes rules:

- For each *target* (monitoring target) at a specified interval `scrape_interval`, Prometheus makes an HTTP request to this *target*, receives metrics in its own format in response, and stores them in its database.
- Every `evaluation_interval` it processes rules (*rules*), based on which:
  - it sends alerts;
  - or stores new metrics (result of rule execution) in its database.

Prometheus operation

Prometheus is installed by the `prometheus` module of DP, which performs the following functions:

- Defines the following custom resources:
  - `Prometheus`: Defines the *Prometheus* installation (cluster).
  - `ServiceMonitor`: Defines how to collect metrics from services.
  - `Alertmanager`: Defines the *Alertmanager* cluster.
  - `PrometheusRule`: Defines the list of *Prometheus rules*.
- Monitors these resources, and also:
  - Generates `StatefulSet` with *Prometheus* itself.
  - Creates secrets with configuration files necessary for Prometheus operation (`prometheus.yaml` — Prometheus configuration, and `configmaps.json` — configuration for `prometheus-config-reloader`).
  - Monitors `ServiceMonitor` and `PrometheusRule` resources and updates *Prometheus* configuration files by modifying secrets based on them.

The module can be enabled using the following ModuleConfig:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: prometheus
spec:
  version: 2
  enabled: true
  settings:
    auth:
      password: xxxxxx
    retentionDays: 7
    storageClass: rbd
    nodeSelector:
      node-role/monitoring: ""
    tolerations:
    - key: dedicated.deckhouse.io
      operator: Equal
      value: monitoring
```

Using the `global.modules.storageClass` parameter for Prometheus

This module uses the global `global.modules.storageClass` parameter as the default StorageClass when creating a new PersistentVolumeClaim (if the `storageClass` parameter is not specified in the module's configuration).

If a Prometheus PVC already exists, changing the global parameter does not affect the existing PVC or trigger disk recreation. The module continues to use the existing PVC and its StorageClass.

If the module configuration defines its own `storageClass` or `longtermStorageClass` value, the module-specific value takes precedence over the global default.

⚠ Changing the `storageClass` or `longtermStorageClass` parameter in the module configuration deletes and recreates the existing PVC. All data will be lost. Back up your data before making this change.

A complete description of all settings is available in the prometheus module documentation.

Additional resources

- Global parameters
- Module `prometheus` documentation

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Cluster SLA monitoring

DP can collect statistics about the availability of cluster components and DP components themselves. This data allows evaluating SLA compliance and provides availability information in the web interface.

Additionally, using the UpmeterRemoteWrite custom resource, you can export availability metrics via the Prometheus Remote Write protocol.

To start collecting availability metrics and activate the interface, enable the `upmeter` module in the Deckhouse web interface or use the following command:

```
d8 system module enable upmeter
```

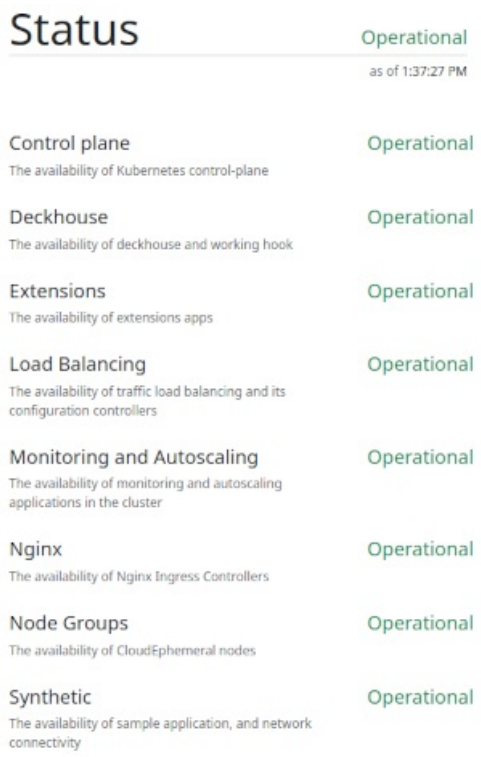
Module configuration

The `upmeter` module is configured using the `upmeter` ModuleConfig:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: upmeter
spec:
  version: 3
  enabled: true
  settings:
```

A complete list of all settings is available in the module documentation.

Interface



DP provides two web interfaces for availability assessment:

- Status page.

You can get the page address in the web interface on the main page in the “Tools” section (Status page block), or by running the command:

```
d8 k -n d8-upmeter get ing status -o jsonpath='{.spec.rules[*].host}'
```

Example of the status page web interface:

- Component availability page.

  You can get the page address in the web interface on the main page in the “Tools” section (Component availability block), or by running the command:

  ```
  d8 k -n d8-upmeter get ing webui -o jsonpath='{.spec.rules[*].host}'
  ```

  Example of the component availability page:

Status metrics export

Example of UpmeterRemoteWrite configuration for exporting status metrics via the Prometheus Remote Write protocol:

```
apiVersion: deckhouse.io/v1
kind: UpmeterRemoteWrite
metadata:
  labels:
    heritage: upmeter
    module: upmeter
  name: victoriametrics
spec:
  additionalLabels:
    cluster: cluster-name
    some: fun
  config:
    url: https://upmeter-victoriametrics.whatever/api/v1/write
    basicAuth:
      password: "Cdp#Cd.OxfZsx4*89SZ"
      username: upmeter
  intervalSeconds: 300
```

Authentication

By default, the `user-authn` module is used for authentication. You can also configure authentication via `externalAuthentication`. If these options are disabled, the module will enable basic authentication with a generated password.

You can view the generated password using the following command:

```
d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller module values upmeter
-o json | jq '.upmeter.internal.auth.webui.password'
```

To generate a new password, you need to delete the Secret:

```
d8 k -n d8-upmeter delete secret/basic-auth-webui
```

You can view the generated password for the status page using the following command:

```
d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller module values upmeter
-o json | jq '.upmeter.internal.auth.status.password'
```

To generate a new password for the status page, you need to delete the secret:

```
d8 k -n d8-upmeter delete secret/basic-auth-status
```

> **Attention!** The `auth.status.password` and `auth.webui.password` parameters are no longer supported.

Behavior of upmeter pods

Upmeter tests create temporary pods to check that Kubernetes components are working. As a result, some pods are periodically deleted, remain in the `Pending` state, or move between nodes.

The following objects take part in the checks:

- `upmeter-probe-scheduler`: Checks the scheduler. The test creates a pod, schedules it to a node, and then deletes it.
- `upmeter-probe-controller-manager`: Checks `kube-controller-manager`. The test creates a StatefulSet and verifies that the StatefulSet created a pod. This test does not check pod placement on a node, so it creates a pod that cannot be scheduled and stays in the `Pending` state. Then the StatefulSet is deleted, and the test verifies that the spawned pod is deleted as well.
- `smoke-mini`: Checks network connectivity between nodes. Five StatefulSets with one replica each are created. The test checks connectivity between `smoke-mini` pods and `upmeter-agent` pods on master nodes. Once a minute, one of the `smoke-mini` pods is moved to another node.

Additional resources

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring integrations

Redirecting alerts to Zabbix

Deckhouse Platform supports integration with the Zabbix monitoring system. For this purpose, an external script is used that receives alerts from Deckhouse via `kubectl` and sends them to Zabbix using the Zabbix agent.

The script requires:

- installed and configured zabbix-agent;
- utilities `bash`, `jq`;
- `kubectl` with a working configuration file and permissions to execute the `kubectl get clusteralerts` command.

Installation

1. Import the template into Zabbix:
   - In the Zabbix web interface, go to the “Data collection → Templates” section
   - Click “Import” and upload the `zbx_export_templates.yaml` file:

```
zabbix_export:
  version: '6.4'
  template_groups:
    - uuid: 7df96b18c230490a9a0a9e2307226338
      name: Templates
  templates:
    - uuid: 91d9cf9d023749a3997bc6429ef45fe1
      template: 'Module d8alerts'
      name: 'Deckhouse Alerts'
      groups:
        - name: Templates
      discovery_rules:

               description: |
                 Summary: {#SUMMARY}

                 {#DESCRIPTION}

                 Labels: {#LABELS}
                 To get more information: `kubectl describe clusteralert
{#ALERTID}`
```

- After installing the template, assign it to the group corresponding to the agents from which metrics will be collected.

2. Configure the Zabbix agent:
   - Copy the `d8alerts.conf` file to the directory specified in the `Include` parameter of the main Zabbix agent config (usually located at `/etc/zabbix/zabbix_agentd.d/`):

     ```
     # LLD of deckhouse cluster alerts
     UserParameter=d8alerts.discovery,/etc/zabbix/scripts/clusteralerts.sh
     discovery

     # Severity of a specific alert by its ID
     UserParameter=d8alerts.severity[*],/etc/zabbix/scripts/clusteralerts.sh
     severity "$1"
     ```

   - Copy the `clusteralerts.sh` script to the `/etc/zabbix/scripts/` directory:

```
#!/bin/bash

MODE="$1"
ALERT_ID="$2"

get_alerts_json() {
  kubectl get clusteralerts -o json
}

get_alert_by_id() {
  local id="$1"
  kubectl get clusteralerts "$id" -o json
}

if [[ "$MODE" == "discovery" ]]; then
  get_alerts_json | jq -c '{
      data: [.items[] | {
        "{#ALERTID}": .metadata.name,
        "{#ALERTNAME}": .alert.name,
        "{#SEVERITY}": (.alert.severityLevel | tonumber),
        "{#DESCRIPTION}": .alert.description,
        "{#SUMMARY}": .alert.summary,
        "{#LABELS}": (.alert.labels | to_entries | map("\(.key)=\(.value)") |
join(","))
      }]
    }'

elif [[ "$MODE" == "severity" && -n "$ALERT_ID" ]]; then
  get_alert_by_id "$ALERT_ID" | jq -r '.alert.severityLevel'

else
  echo "Invalid usage"
  exit 1
fi
```

- Make sure the script has execute permissions:

```
chmod +x /etc/zabbix/scripts/clusteralerts.sh
```

3. Check access:
   - Ensure the script has access to the cluster and can retrieve alert information:

     ```
     /etc/zabbix/scripts/clusteralerts.sh discovery
     ```

     The output should contain a list of alerts with their statuses and severity levels.
4. Restart the Zabbix agent to apply changes:

   ```
   systemctl restart zabbix-agent
   ```

Troubleshooting

1. Check Zabbix agent logs:

   ```
   tail -f /var/log/zabbix/zabbix_agentd.log
   ```

2. Check script operation:

   ```
   /etc/zabbix/scripts/clusteralerts.sh discovery
   /etc/zabbix/scripts/clusteralerts.sh severity "ALERT_ID"
   ```

Make sure the script executes correctly and returns expected data.

3. Check the `zabbix` user permissions. Ensure the agent runs the script as a user with the necessary cluster access rights:
   - The script runs as the `zabbix` user:

     ```
     sudo -u zabbix /etc/zabbix/scripts/clusteralerts.sh
     ```

   - The `KUBECONFIG` variable is available to the user:

     If the Kubernetes configuration file is not available by default, specify it explicitly. To do this, save the kubeconfig, for example, in `/etc/zabbix/kubeconfig` and add to the agent configuration:

     ```
     UserParameter=d8alerts.discovery,export
     KUBECONFIG=/etc/zabbix/kubeconfig;/etc/zabbix/scripts/clusteralerts.sh discovery
     ```

Sending alerts to Telegram

Alertmanager supports direct sending of alerts to Telegram.

Create a Secret in the `d8-monitoring` namespace:

```
apiVersion: v1
kind: Secret
metadata:
  name: telegram-bot-secret
  namespace: d8-monitoring
stringData:
  token: "562696849:AAExcuJ8H6z4pTlPuocbrXXXXXXXXXXx"
```

Deploy the CustomAlertManager custom resource:

```
apiVersion: deckhouse.io/v1alpha1
kind: CustomAlertmanager
metadata:
  name: telegram
spec:
  type: Internal
  internal:
    receivers:
      - name: telegram
        telegramConfigs:
          - botToken:
              name: telegram-bot-secret
              key: token
            chatID: -30490XXXXX
    route:
      groupBy:
        - job
      groupInterval: 5m
      groupWait: 30s
      receiver: telegram
      repeatInterval: 12h
```

The `token` field in the Secret and `chatID` in the `CustomAlertmanager` resource need to be set to your own values. More details about the Telegram API.

Example of sending alerts to Slack with filter

```
apiVersion: deckhouse.io/v1alpha1
kind: CustomAlertmanager
metadata:
  name: slack
spec:
  internal:
    receivers:
    - name: devnull
    - name: slack
      slackConfigs:
      - apiURL:
          key: apiURL
          name: slack-apiurl
        channel: {{ dig .Values.werf.env .Values.slack.channel._default
.Values.slack.channel }}
        fields:
        - short: true
          title: Severity
          value: '{{`{{  .CommonLabels.severity_level }}`}}'
        - short: true
          title: Status
          value: '{{`{{ .Status }}`}}'
        - title: Summary
          value: '{{`{{ range .Alerts }}`}}{{`{{ .Annotations.summary }}`}} {{`{{ end
}}`}}'
        - title: Description
          value: '{{`{{ range .Alerts }}`}}{{`{{ .Annotations.description }}`}} {{`{{
end }}`}}'
        - title: Labels
          value: '{{`{{ range .Alerts }}`}} {{`{{ range .Labels.SortedPairs }}`}}{{`{{
printf "%s:
            %s\n" .Name .Value }}`}}{{`{{ end }}`}}{{`{{ end }}`}}'
        - title: Links
          value: '{{`{{ (index .Alerts 0).GeneratorURL }}`}}'
        title: '{{`{{ .CommonLabels.alertname }}`}}'
    route:
      groupBy:
      - '...'
      receiver: devnull
      routes:
        - matchers:
          - matchType: =~
            name: severity_level
            value: "^[4-9]$"
          receiver: slack
      repeatInterval: 12h
  type: Internal
```

Example of sending alerts to Opsgenie

```
- name: opsgenie
      opsgenieConfigs:
        - apiKey:
            key: data
            name: opsgenie
          description: |
            {{ range .Alerts }}{{ .Annotations.summary }} {{ end }}
            {{ range .Alerts }}{{ .Annotations.description }} {{ end }}
          message: '{{ .CommonLabels.alertname }}'
          priority: P1
          responders:
            - id: team_id
              type: team
```

Example of sending alerts via email

Create a secret with the email account password. Specify the password encoded in Base64 format in the `password` field:

```
apiVersion: v1
kind: Secret
metadata:
  name: am-mail-server-pass
  namespace: d8-monitoring
data:
  password: BASE64_ENCODED_PASSWORD_HERE
```

Modify the values in the CustomAlertManager resource example according to the values relevant to your infrastructure and apply it:

```
apiVersion: deckhouse.io/v1alpha1
kind: CustomAlertmanager
metadata:
  name: mail
spec:
  type: Internal
  internal:
    receivers:
      - name: devnull
      - name: mail
        emailConfigs:
          - to: oncall@example.com
            from: prom@example.com
            smarthost: mx.example.com:587
            authIdentity: prom@example.com
            authUsername: prom@example.com
            authPassword:
              key: password
              name: am-mail-server-pass
            # If you use a custom CA on the server, you can place the public part of
the CA in a ConfigMap in the d8-monitoring namespace
            # tlsConfig:
            #   insecureSkipVerify: true
            #   ca:
            #     configMap:
            #       key: ca.pem
            #       name: alertmanager-mail-server-ca
            sendResolved: true
            requireTLS: true
    route:
      groupBy:
        - job
      groupInterval: 5m
      groupWait: 30s
      receiver: devnull
      repeatInterval: 24h
      routes:
        - matchers:
          - matchType: =~
            name: severity_level
            value: "^[1-4]$"
          receiver: mail
```

Additional resources

- Module `prometheus` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Logging

Deckhouse Platform (DP) provides built-in tools for log collection, delivery, and short-term storage.

DP logging capabilities:

- Collect logs from cluster pods and nodes.
- Process logs, including metadata enrichment and message filtering.

- Deliver to various storage and analysis systems, including Loki, Elasticsearch, Splunk, and others.
- Short-term log storage in the cluster with search and visualization capabilities through Grafana.

The following sections describe how to configure log collection and delivery, as well as organize their short-term storage within the cluster.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Log collection and delivery

Deckhouse Platform (DP) provides log collection and delivery from cluster nodes and pods to internal or external storage systems.

DP allows you to:

- Collect logs from all or specific pods and namespaces.
- Filter logs by labels, message content, and other criteria.
- Send logs to multiple storage systems simultaneously (e.g., Loki and Elasticsearch).
- Enrich logs with Kubernetes metadata.
- Use log buffering to improve performance.

The general mechanism of log collection, delivery, and filtering is described in detail in the Architecture section.

DP administrators can configure log collection and delivery using three custom resources:

- ClusterLoggingConfig: Describes log sources at the cluster level, including collection, filtering, and parsing rules.
- PodLoggingConfig: Describes log sources within a specified namespace, including collection, filtering, and parsing rules.
- ClusterLogDestination: Defines log storage parameters.

Based on these resources, a *pipeline* is formed, which is used in DP to read logs and further work with them using the `log-shipper` module. A complete list of `log-shipper` module settings is available in the separate documentation section.

Configuring log collection and delivery

Below is a basic DP configuration option where logs from all cluster pods are sent to Elasticsearch-based storage.

To configure, follow these steps:

1. Enable the `log-shipper` module using the following command:

   ```
   d8 system module enable log-shipper
   ```

2. Create a ClusterLoggingConfig resource that defines log collection rules. This resource allows you to configure log collection from pods in a specific namespace and with specific labels, flexibly configure multi-line log parsing, and set other rules.

   In this example, it is specified that logs should be collected from all pods and sent to Elasticsearch:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ClusterLoggingConfig
   metadata:
     name: all-logs
   spec:
     type: KubernetesPods
     destinationRefs:
     - es-storage
   ```

3. Create a ClusterLogDestination resource, which describes the parameters for sending logs to

storage. This resource allows you to specify one or more storage systems and describe connection parameters, buffering, and additional labels that will be applied to logs before sending.

In this example, Elasticsearch is specified as the receiving storage:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: es-storage
spec:
  type: Elasticsearch
  elasticsearch:
    endpoint: http://192.168.1.1:9200
    index: logs-%F
    auth:
      strategy: Basic
      user: elastic
      password: c2VjcmV0IC1uCg==
```

Integration with external systems

You can configure DP to work with external log storage and analysis systems, such as Elasticsearch, Splunk, Logstash, and others, using the `type` parameter of the ClusterLogDestination resource.

Elasticsearch

To send logs to Elasticsearch, create a ClusterLogDestination resource following this example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: es-storage
spec:
  type: Elasticsearch
  elasticsearch:
    endpoint: http://192.168.1.1:9200
    index: logs-%F
    auth:
      strategy: Basic
      user: elastic
      password: c2VjcmV0IC1uCg==
```

Using index templates

To send messages to specific indices based on metadata using index templates, use the following configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: es-storage
spec:
  type: Elasticsearch
  elasticsearch:
    endpoint: http://192.168.1.1:9200
    index: "k8s--%F"
```

In the example above, a separate index will be created in Elasticsearch for each Kubernetes namespace.

This feature is useful in combination with the `extraLabels` parameter:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: es-storage
spec:
  type: Elasticsearch
  elasticsearch:
    endpoint: http://192.168.1.1:9200
    index: "k8s---%F"
  extraLabels:
    service: ""
```

- If the message has JSON format, the `service_name` field of this JSON document is moved to the metadata level.
- The new metadata field `service` is used in the index template.

Support for Elasticsearch < 6.X

To work with Elasticsearch versions prior to 6.0, enable support for `docType` indices using the ClusterLogDestination resource:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: es-storage
spec:
  type: Elasticsearch
  elasticsearch:
    endpoint: http://192.168.1.1:9200
    docType: "myDocType" # Specify the value here. It should not start with '_'.
    auth:
      strategy: Basic
      user: elastic
      password: c2VjcmV0IC1uCg==
```

Splunk

To configure sending events to Splunk, follow these steps:

1. Configure Splunk:
   - Define the endpoint. It should match your Splunk instance name with port `8088`, but without specifying the path, for example, `https://prd-p-xxxxxx.splunkcloud.com:8088`.
   - Create an access token. To do this, in Splunk, open the **Setting** -> **Data inputs** section, add a new **HTTP Event Collector** and copy the generated token.
   - Specify the Splunk index for storing logs, for example, `logs`.
2. Configure DP by adding a ClusterLogDestination resource to send logs to Splunk:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: splunk
spec:
  type: Splunk
  splunk:
    endpoint: https://prd-p-xxxxxx.splunkcloud.com:8088
    token: xxxx-xxxx-xxxx
    index: logs
    tls:
      verifyCertificate: false
      verifyHostname: false
```

> **i** `destination` does not support pod labels for indexing. To add the required labels, use the `extraLabels` option:
>
> ```
> extraLabels:
>  pod_label_app: ''
> ```

Logstash

To configure sending logs to Logstash, do the following:

1. Configure an incoming `tcp` stream with `json` codec on the Logstash side.

   Example Logstash configuration:

   ```
   input {
     tcp {
       port => 12345
       codec => json
     }
   }
   output {
     stdout { codec => json }
   }
   ```

2. Add a ClusterLogDestination resource:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ClusterLogDestination
   metadata:
     name: logstash
   spec:
     type: Logstash
     logstash:
       endpoint: logstash.default:12345
   ```

Graylog

To configure sending logs to Graylog, do the following:

1. Ensure that Graylog has an incoming stream configured to receive messages via TCP protocol on the specified port.
2. Create a ClusterLogDestination resource following the example:

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ClusterLogDestination
   metadata:
     name: test-socket2-dest
   spec:
     type: Socket
     socket:
       address: graylog.svc.cluster.local:9200
       mode: TCP
       encoding:
         codec: GELF
   ```

Message formats

You can choose the format of sent messages using the `.encoding.codec` parameter of the ClusterLogDestination resource:

- CEF

- GELF
- JSON
- Syslog
- Text

Below are configuration examples for some of them.

Syslog

Use the following configuration example to send messages via socket using TCP protocol in syslog format:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: rsyslog
spec:
  type: Socket
  socket:
    mode: TCP
    address: 192.168.0.1:3000
    encoding:
      codec: Syslog
  extraLabels:
    syslog.severity: "alert"
    # The request_id field must be present in the message.
    syslog.message_id: ""
```

CEF

DP can send logs in CEF format by using `codec: CEF`, with overriding `cef.name` and `cef.severity` based on values from the `message` field of the application log in JSON format.

In the example below, `app` and `log_level` are keys containing values for overriding:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: siem-kafka
spec:
  extraLabels:
    cef.name: ''
    cef.severity: ''
  type: Kafka
  kafka:
    bootstrapServers:
      - my-cluster-kafka-brokers.kafka:9092
    encoding:
      codec: CEF
    tls:
      verifyCertificate: false
      verifyHostname: true
    topic: logs
```

You can also set values manually:

```
extraLabels:
  cef.name: 'TestName'
  cef.severity: '1'
```

Log transformation

You can configure one or more types of transformations that will be applied to logs before sending to

storage.

Converting records to structured objects

The `ParseMessage` transformation allows you to convert a string in the `message` field to a structured JSON object based on one or more specified formats (String, Klog, SysLog, and others).

> ⚠ When using multiple `ParseMessage` transformations, string conversion (`sourceFormat: String`) must be performed last.

Example configuration for converting mixed format records:

```
apiVersion: deckhouse.io/v1alpha2
kind: ClusterLogDestination
metadata:
  name: parse-json
spec:
  ...
  transformations:
  - action: ParseMessage
    parseMessage:
      sourceFormat: JSON
  - action: ParseMessage
    parseMessage:
      sourceFormat: Klog
  - action: ParseMessage
    parseMessage:
      sourceFormat: String
      string:
        targetField: "text"
```

Example of the original log record:

```
/docker-entrypoint.sh: Configuration complete; ready for start up
{"level" : { "severity": "info" },"msg" : "fetching.module.release"}
I0505 17:59:40.692994   28133 klog.go:70] hello from klog
```

Transformation result:

```
{... "message": {
  "text": "/docker-entrypoint.sh: Configuration complete; ready for start up"
  }
}
{... "message": {
  "level" : "{ "severity": "info" }",
  "msg" : "fetching.module.release"
  }
}
{... "message": {
  "file":"klog.go",
  "id":28133,
  "level":"info",
  "line":70,
  "message":"hello from klog",
  "timestamp":"2025-05-05T17:59:40.692994Z"
  }
}
```

Label replacement

The `ReplaceKeys` transformation allows you to recursively replace all matches of the `source` pattern

with the `target` value in the specified label keys.

> ⚠ Before applying the `ReplaceKeys` transformation to the `message` field or its nested fields, convert the log record to a structured object using the `ParseMessage` transformation.

Example configuration for replacing dots with underscores in labels:

```
apiVersion: deckhouse.io/v1alpha2
kind: ClusterLogDestination
metadata:
  name: replace-dot
spec:
  ...
  transformations:
    - action: ReplaceKeys
      replaceKeys:
        source: "."
        target: "_"
        labels:
          - .pod_labels
```

Example of the original log record:

```
{"msg" : "fetching.module.release"} # Pod label pod.app=test
```

Transformation result:

```
{... "message": {
  "msg" : "fetching.module.release"
  },
  "pod_labels": {
    "pod_app": "test"
  }
}
```

Label removal

The `DropLabels` transformation allows you to remove specified labels from a structured JSON message.

> ⚠ Before applying the `DropLabels` transformation to the `message` field or its nested fields, convert the log record to a structured object using the `ParseMessage` transformation.

Example configuration with label removal and preliminary `ParseMessage` transformation:

```
apiVersion: deckhouse.io/v1alpha2
kind: ClusterLogDestination
metadata:
  name: drop-label
spec:
  ...
  transformations:
    - action: ParseMessage
      parseMessage:
        sourceFormat: JSON
    - action: DropLabels
      dropLabels:
        labels:
          - .message.example
```

Example of the original log record:

```
{"msg" : "fetching.module.release", "example": "test"}
```

Transformation result:

```
{... "message": {
  "msg" : "fetching.module.release"
  }
}
```

Log filtering

DP provides filters to exclude unnecessary messages to optimize the log collection process:

- `labelFilter` — applied to metadata, such as container name (`container`), namespace (`namespace`), or pod name (`pod_name`);
- `logFilter` — applied to message fields, if the message is in JSON format.

Collecting logs from a specific container

To configure filtering using `labelFilter`, create a ClusterLoggingConfig resource, using the configuration below as an example.

In this case, the filter selects logs from containers named `nginx`, and then sends them to internal Loki-based storage.

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: nginx-logs
spec:
  type: KubernetesPods
  labelFilter:
  - field: container
    operator: In
    values: [nginx]
  destinationRefs:
  - loki-storage
```

Collecting logs without a specific string

Example configuration for collecting logs with filtering via `labelFilter`, where the `NotRegex` operator excludes strings matching the specified regular expression.

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: all-logs
spec:
  type: KubernetesPods
  destinationRefs:
  - loki-storage
  labelFilter:
  - field: message
    operator: NotRegex
    values:
    - .*GET /status" 200$
```

Kubelet audit events

Example configuration for collecting and filtering audit events related to kubelet operation, stored in the `/var/log/kube-audit/audit.log` file. Filtering is performed using `logFilter`, which searches for records in the `userAgent` field matching the regular expression `"kubelet.*"`.

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: kubelet-audit-logs
spec:
  type: File
  file:
    include:
    - /var/log/kube-audit/audit.log
  logFilter:
  - field: userAgent
    operator: Regex
    values: ["kubelet.*"]
  destinationRefs:
  - loki-storage
```

DP system logs

Example configuration for collecting DP system logs located in the `/var/log/syslog` file. Message filtering using `labelFilter` allows you to select only those records that relate to the following components: `d8-kubelet-forker`, `containerd`, `bashible`, and `kernel`.

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: system-logs
spec:
  type: File
  file:
    include:
    - /var/log/syslog
  labelFilter:
  - field: message
    operator: Regex
    values:
    - .*d8-kubelet-forker.*
    - .*containerd.*
    - .*bashible.*
    - .*kernel.*
  destinationRefs:
  - loki-storage
```

> **i** If you need logs from only one pod or a small group of pods, use `kubernetesPods` to limit the collection scope. Filters should be used only for fine-tuning.

Log buffering

Using buffering improves the reliability and performance of the log collection system. Buffering can be useful in the following cases:

- **Temporary connection issues**. If there are temporary interruptions or connection instability with the log storage system (e.g., Elasticsearch), the buffer allows temporarily storing logs and sending them when the connection is restored.
- **Load spike smoothing**. During sudden log volume spikes, the buffer helps smooth the peak load on the storage system, preventing its overload and potential data loss.
- **Performance optimization**. Buffering helps optimize the performance of the log collection system by accumulating logs and sending them in batches, which reduces the number of network requests and improves overall throughput.

The `buffer` parameter of the ClusterLogDestination resource is responsible for configuring buffering.

Example of enabling in-memory buffering

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: loki-storage
spec:
  buffer:
    memory:
      maxEvents: 4096
    type: Memory
  type: Loki
  loki:
    endpoint: http://loki.loki:3100
```

Example of enabling disk buffering

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: loki-storage
spec:
  buffer:
    disk:
      maxSize: 1Gi
    type: Disk
  type: Loki
  loki:
    endpoint: http://loki.loki:3100
```

Example of defining buffer overflow behavior

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: loki-storage
spec:
  buffer:
    disk:
      maxSize: 1Gi
    type: Disk
    whenFull: DropNewest
  type: Loki
  loki:
    endpoint: http://loki.loki:3100
```

Debugging and advanced features

Enabling debug logs for the log-shipper agent

To enable debug logs for the `log-shipper` agent on nodes with information about HTTP requests, connection reuse, tracing, and other data, enable the `debug` parameter in the `log-shipper` module configuration.

Example module configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: log-shipper
spec:
  version: 1
  enabled: true
  settings:
    debug: true
```

Additional information about log transmission channels

Using Vector commands, you can get additional information about data transmission channels.

First, connect to one of the `log-shipper` pods:

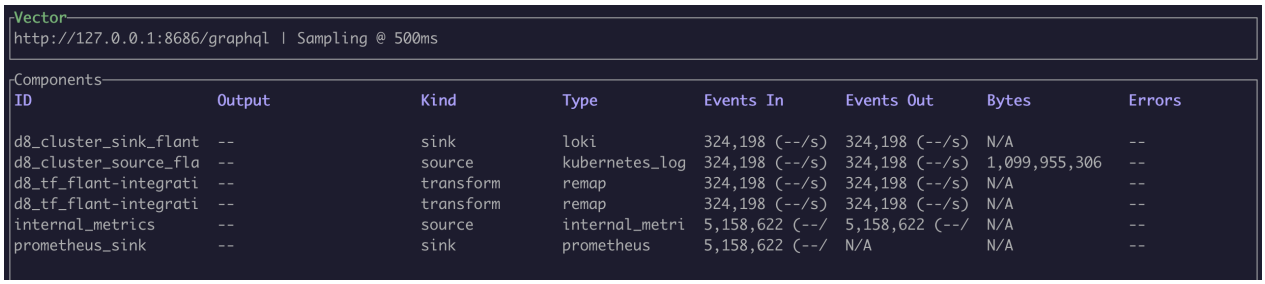
```
d8 k -n d8-log-shipper get pods -o wide | grep $node
d8 k -n d8-log-shipper exec $pod -it -c vector -- bash
```

Execute subsequent commands from the pod’s command shell.

Topology overview

To get a diagram of your configuration topology:

1. Run the `vector graph` command. A diagram in DOT format will be generated.
2. Use WebGraphviz or a similar service to render the diagram based on the DOT file content.



Example diagram for one log transmission channel in ASCII format:

```
+-----------------------------------------------+
|  d8_cluster_source_flant-integration-d8-logs  |
+-----------------------------------------------+
  |
  |
  v
+-----------------------------------------------+
|       d8_tf_flant-integration-d8-logs_0       |
+-----------------------------------------------+
  |
  |
  v
+-----------------------------------------------+
|       d8_tf_flant-integration-d8-logs_1       |
+-----------------------------------------------+
  |
  |
  v
+-----------------------------------------------+
| d8_cluster_sink_flant-integration-loki-storage |
+-----------------------------------------------+
```

Monitoring channel load

To view the traffic volume at each log processing stage, use the `vector top` command.

Example command output:

Getting raw and intermediate logs

To view input data at different log processing stages, use the `vector tap` command. By specifying the ID of a specific processing stage, you can see logs that arrive at that stage. Glob pattern selections are also supported, for example, `cluster_logging_config/*`.

Examples:

- Viewing logs before applying transformation rules (`cluster_logging_config/*` is the first processing stage according to the `vector graph` command output):

  ```
  vector tap 'cluster_logging_config/*'
  ```

- Modified logs entering the input of the next components in the channel chain:

  ```
  vector tap 'transform/*'
  ```

Debugging VRL rules

To debug rules in Vector Remap Language (VRL), use the `vector vrl` command.

Example VRL program:

```
. = {"test1": "lynx", "test2": "fox"}
del(.test2)
.
```

Adding support for new source or sink

The `log-shipper` module in DP is built based on Vector with a limited set of cargo features, to minimize the size of the executable file and speed up the build.

To view the complete list of supported features, run the `vector list` command.

If the required source or sink is missing, add the corresponding cargo feature to the Dockerfile.

Special cases

Collecting logs from production namespaces using the labelSelector option

If your cluster namespaces are labeled (e.g., `environment=production`), you can use the `labelSelector` option to collect logs from production namespaces.

Example configuration:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLoggingConfig
metadata:
  name: production-logs
spec:
  type: KubernetesPods
  kubernetesPods:
    namespaceSelector:
      labelSelector:
        matchLabels:
          environment: production
  destinationRefs:
  - loki-storage
```

Label for excluding pods and namespaces

DP provides the `log-shipper.deckhouse.io/exclude=true` label for excluding specific pods and namespaces. It helps stop log collection from pods and namespaces without changing the global configuration.

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: test-namespace
  labels:
    log-shipper.deckhouse.io/exclude: "true"
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: test-deployment
spec:
  ...
  template:
    metadata:
      labels:
        log-shipper.deckhouse.io/exclude: "true"
```

- Module `log-shipper` documentation

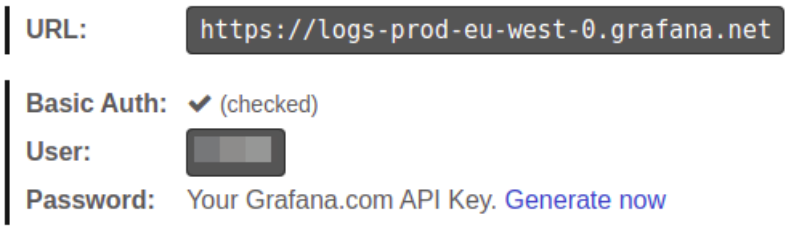
> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Short-term log storage

Deckhouse Platform (DP) provides a built-in solution for short-term log storage based on the Grafana Loki project.

The storage is deployed in the cluster and integrated with the log collection system. After configuring ClusterLoggingConfig, PodLoggingConfig, and ClusterLogDestination resources, logs automatically flow from all system components. The configured storage is added to Grafana as a data source for visualization and analysis.

Log collection from user applications is configured separately.



Short-term storage parameters are set in the `loki` module settings. You can configure disk size and retention period, specify the StorageClass to use, and set resource limits.

> ⚠ Short-term storage based on Grafana Loki does not support high availability mode. For long-term storage of important logs, use external storage.

Integration with Grafana Cloud

To configure DP to work with the Grafana Cloud platform, follow these steps:

1. Create a Grafana Cloud API access key.
2. Encode the Grafana Cloud access token in Base64 format:

```
echo -n "<YOUR-GRAFANACLOUD-TOKEN>" | base64 -w0
```

3. Create a ClusterLogDestination resource following the example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ClusterLogDestination
metadata:
  name: loki-storage
spec:
  loki:
    auth:
      password: PFlPVVItR1JBRkFOQUNMT1VELVRPS0VOPg==
      strategy: Basic
      user: "<YOUR-GRAFANACLOUD-USERNAME>"
    endpoint: <YOUR-GRAFANACLOUD-URL> # For example https://logs-prod-us-
central1.grafana.net or https://logs-prod-eu-west-0.grafana.net
  type: Loki
```

Migration from Grafana Promtail

To migrate from Promtail, edit the Loki URL by removing the `/loki/api/v1/push` path from it.

The Vector logging agent used in DP will automatically add this path when sending data to Loki.

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Multitenancy

Multitenancy is the ability to create isolated environments (projects) within a Kubernetes cluster. Projects are similar to namespaces but offer more capabilities. While namespaces are used for logical separation of resources in Kubernetes, they do not, for example, restrict network communication, pod resource consumption, or host directory mounts. These limitations make namespaces insufficient for modern development needs. By default, namespaces also do not include logging, auditing, and vulnerability scanning.

Using projects helps address these limitations and offers the following benefits:

- For platform administrators:
  - **Consistency**: Administrators can create projects using a shared template, which ensures consistency and simplifies management.
  - **Security**: Projects ensure isolation for resources and access policies between different tenants, supporting a secure multitenant environment.
  - **Resource consumption**: Administrators can easily set resource quotas and limits for each project to prevent resource overconsumption.
  - **Resource access management**: Administrators can control which cluster-wide resources (such as StorageClass, ClusterIssuer, ClusterRole, and LoadBalancerClass) each project may use, and set per-project default values. For details, refer to grants section in the usage guide.
- For platform users:
  - **Immediate start**: Developers can request projects created per templates from administrators to quickly start developing new applications.
  - **Isolation**: Each project provides an isolated environment, allowing developers to deploy and test their applications without affecting others.

> Secret copying across all namespaces is incompatible with projects in multitenancy mode.
>
> This mode creates isolated environments for users within their projects, while `secret-copier` automatically distributes secrets to all namespaces. If sensitive data is present in a user's private environment, it could lead to a data leak and a security model breach.

Additional namespaces

A project is not limited to a single namespace: if an application needs several namespaces (for example, a separate one for a cache or a queue), they can be added to the project as additional namespaces. The project's access grants and namespaced template policies (network isolation, log shipping) automatically apply to every namespace of the project, not just the main one.

Additional resources

- Module `secret-copier` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Project management

Deckhouse Platform includes a set of templates for creating projects. They are cumulative: each one includes the capabilities of the previous one and adds its own. Parameter values are set in the `.spec.parameters` field of a Project:

- `simple` is a minimal template that creates only the project namespace. Use it when you only need an isolated namespace managed as a project, while access and restrictions are configured through the standard project fields and project role bindings.

  Parameters:

  - `namespace.labels` and `namespace.annotations` — extra labels and annotations for the project namespace.
  - `requiredRequests` (default `false`) — rendered only if the parameter is declared in the template schema and is `true`. If `true`, the project pods must specify CPU and memory requests (an OperationPolicy in the `Deny` mode).

- `default` is a template for basic project use cases. On top of the namespace, it sets up network isolation, a pod security profile, extended monitoring, and log shipping.

  Parameters (in addition to the ones for `simple`):

  - `networkPolicy` — `Isolated` (default) allows incoming traffic only from the project namespaces, Prometheus, the ingress-nginx controller and the service-with-healthchecks agent, and outgoing traffic only to the project namespaces and to DNS in `kube-system`; `NotRestricted` allows all traffic.
  - `podSecurityProfile` — the Pod Security Standards profile for the project namespaces: `Baseline` (default) prevents known privilege escalations, `Restricted` applies the strictest hardening practices, `Privileged` restricts nothing. An empty string sets no profile: the project puts no `security.deckhouse.io/pod-policy` label on its namespaces, and the default policy of the `admission-policy-engine` module applies to them.
  - `extendedMonitoringEnabled` (default `true`) — alerts on controller outages and restarts, 5xx errors in ingress-nginx, and low free space on the project's persistent volumes.
  - `clusterLogDestinationName` — the name of the ClusterLogDestination to ship the project logs to. Left unset, the project logs are not shipped anywhere.
  - `requiredRequests` (default `true` in this template) — if `true`, the project pods must specify CPU and memory requests (an OperationPolicy in the `Deny` mode). When an existing namespace is adopted, the parameter is set to `false` so that the workloads already running are not blocked.

- `secure` includes all the capabilities of the `default` template, and additionally restricts the users and groups inside containers, audits their calls to the kernel, and scans images for vulnerabilities.

  Parameters (in addition to the ones for `default`):

  - `allowedUIDs` and `allowedGIDs` — the ranges (`min`, `max`) of IDs permitted for users and groups inside the project containers. See Security Context.
  - `runtimeAuditEnabled` (default `false`) — audit rules that catch calls to the kernel and find malicious activity. They work only if the UID/GID ranges are set.
  - `securityScanningEnabled` (default `true`) — periodic scanning of the launched images for known vulnerabilities (CVE) with Trivy, every 24 hours.

- `secure-with-dedicated-nodes` includes all the capabilities of the `secure` template, and additionally places the pods of the main namespace of the project on dedicated nodes.

  Parameters (in addition to the ones for `secure`). If `dedicatedNodes` is set, at least one of its two fields must be set. Without `dedicatedNodes`, the pods are not placed on dedicated nodes:

  - `dedicatedNodes.nodeSelector` — the node selector of the main namespace. It is merged into the node selector of every pod there, and a pod whose selector conflicts with it is rejected.
  - `dedicatedNodes.defaultTolerations` — tolerations in the format of the pod's `spec.tolerations`. They are **added** to the pods created in the main namespace.

The `default`, `secure`, and `secure-with-dedicated-nodes` templates are described in structured form (`deckhouse.io/v1alpha2`). The `simple` template is a minimal structured template that creates the namespace, sets its labels and annotations from the project parameters and, with `requiredRequests: true`, creates the OperationPolicy.

For the exact set of parameters, check the template installed in your cluster — it matches your platform version.

To view the parameter schema of a template, run the following command:

```
d8 k get projecttemplates <PROJECT_TEMPLATE_NAME> -o
jsonpath='{.spec.parametersSchema.openAPIV3Schema}' | jq
```

To view the whole template, run the following command:

```
d8 k get projecttemplates <PROJECT_TEMPLATE_NAME> -o yaml
```

Project creation

To create a project, follow these steps:

1. Create a custom resource Project with the project template name specified in the .spec.projectTemplateName field.
2. Set the standard fields — .spec.administrators and .spec.quota — which are managed directly by the Project resource regardless of the template.
3. In the .spec.parameters field, specify the values for the .spec.parametersSchema.openAPIV3Schema section of the custom resource ProjectTemplate.

   An example of creating a project using Project from the `default` ProjectTemplate is shown below:

   ```
   apiVersion: deckhouse.io/v1alpha3
   kind: Project
   metadata:
     name: my-project
   spec:
     description: This is an example from the Deckhouse documentation.
     projectTemplateName: default
     # Standard fields, managed by the Project resource itself, independently of
   the template.
     administrators:
       - kind: Group
         name: k8s-admins
     quota:
       requests.cpu: "5"
       requests.memory: 5Gi
       requests.storage: 1Gi
       limits.cpu: "5"
       limits.memory: 5Gi
     # Template-specific parameters.
     parameters:
       networkPolicy: Isolated
       podSecurityProfile: Restricted
       extendedMonitoringEnabled: true
   ```

> **i** The Project API is served as `deckhouse.io/v1alpha3`. `v1alpha2` manifests keep working: a conversion webhook automatically lifts `parameters.administrators` and `parameters.resourceQuota` into the `.spec.administrators` and `.spec.quota` standard fields. If one administrator does not fit `.spec.administrators` (for example, it has `accessLevel`), the whole list stays in `parameters`, and `.spec.administrators` is not filled. The same holds for a quota with anything other than quantities (for example, `scopes`), for a quota with the number `0` anywhere in it, and for an empty list or quota. The `deckhouse.io/v1alpha1` version is no longer served, and the API server refuses a manifest with `apiVersion: deckhouse.io/v1alpha1`. Before applying such a manifest, change `apiVersion` to `deckhouse.io/v1alpha3`, rename `spec.projectTypeName` to `spec.projectTemplateName` (a ProjectTemplate with that name must exist) and `spec.template` to `spec.parameters`, and move `administrators` and `resourceQuota` from the parameters to `.spec.administrators` and `.spec.quota`.

4. To check the project status, run the following command:

   ```
   d8 k get projects my-project
   ```

   A successfully created project should have the `Deployed` (synchronized) status. If the `Error` status is displayed, add the `-o yaml` flag to the command (for example, `d8 k get projects my-project -o yaml`) to get more details about the cause of the error.

Automatic project creation for a namespace

A namespace created directly (for example, `d8 k create ns test`) automatically becomes a project with the same name — no annotation is required:

- the template is picked from what the namespace already carries: `secure` if it has the `security-scanning.deckhouse.io/enabled` label, `default` if it has `security.deckhouse.io/pod-policy` or `extended-monitoring.deckhouse.io/enabled`, and `simple` otherwise;
- the project parameters are filled in from the current state of the namespace, so nothing inside it changes: the network policy stays unrestricted and the Pod Security Standard keeps the value the namespace already had;
- from then on the project is the source of truth and is edited like any other project. The namespace of the project cannot be deleted directly: the request is refused with the `Manual modification is forbidden` message. To remove the environment, delete the Project: `d8 k delete project <NAME>` deletes the namespace with it and returns once the namespace is gone. Only a user allowed to delete the namespace can delete its Project (see Additional project namespaces).

Users can create a namespace directly only while the `allowNamespacesWithoutProjects` parameter is `true` (the default). With `false`, only cluster administrators (`system:masters`, `system:sudouser`), Deckhouse, the module controller and system components create namespaces directly. Other users create a Project or a ProjectNamespace instead.

System namespaces (`d8-*`, `kube-*`, `upmeter-*`, `default`, and anything labeled `heritage: deckhouse` or `heritage: upmeter`) are never adopted this way: they belong to the virtual `deckhouse`/`default` projects (see Virtual projects). A namespace whose name is longer than 61 characters is not adopted either: that is the Project name limit.

A namespace that gets the `default` or `secure` template because of its monitoring or scanning label and has no `security.deckhouse.io/pod-policy` label gets `podSecurityProfile: ""`. The project puts no such label on it, and the default policy of the `admission-policy-engine` module keeps applying to it.

A namespace that already belongs to another Helm release (its `meta.helm.sh/release-name` annotation names a release other than the project's) is not taken over: the project gets the `HelmOwnership` condition with the name of that release and retries, and the namespace is left as it is. Remove the foreign release or its ownership annotations to let the project proceed.

Existing RoleBinding and AuthorizationRule objects inside the namespace keep working after adoption. The namespace Admin is **not** copied into `.spec.administrators` and does **not** become `d8:project:admin`. To make them a project administrator, add them to `.spec.administrators` or create a ProjectRoleBinding.

For example:

1. Create a new namespace:

   ```
   d8 k create ns test
   ```

2. Make sure the project has been created:

   ```
   d8 k get projects
   ```

   A new project matching the namespace will appear in the list of projects:

   ```
   NAME        STATE      PROJECT TEMPLATE   DESCRIPTION
   AGE
   deckhouse   Deployed   virtual            This is a virtual project
   181d
   default     Deployed   virtual            This is a virtual project
   181d
   test        Deployed   simple
   1m
   ```

To change the template of such a project, set another template in `.spec.projectTemplateName`.

⚠ If the namespace already has an object of the same kind and name as one that the new template creates, for example the `isolated` NetworkPolicy, the project switches to `Error`, and the `ResourcesUpgraded` condition names the object. Delete or rename the object first.

Creating a project without specifying a template

The `projectTemplateName` field is optional: when omitted, the `simple` template is used. Such a project consists only of the namespace and the standard fields (administrators, quota) — no template policies are created in it. This is convenient when no settings are needed or they are managed by other means:

```
apiVersion: deckhouse.io/v1alpha3
kind: Project
metadata:
  name: my-plain-project
spec:
  administrators:
    - kind: Group
      name: k8s-admins
  quota:
    requests.cpu: "2"
```

A template can be assigned later by setting it in `.spec.projectTemplateName`.

Project naming rules

The project name is also the name of its main namespace, so the following rules are checked when a project is created:

- the name cannot start with `d8-` or `kube-` — these prefixes are reserved for system namespaces;
- the name cannot be `default` or `deckhouse` — these names belong to the virtual projects;
- the name cannot be longer than 61 characters;
- the name cannot be the name of an existing namespace, or of a namespace that a ProjectNamespace has claimed (the name is taken from the moment the ProjectNamespace is created, before the controller creates the namespace);
- the name cannot be the name of a namespace whose ServiceAccounts are still named among the subjects of a ClusterProjectRoleBinding, or of a ProjectRoleBinding of a project that the name extends with a dash and a suffix (`foo` for `foo-extra`). Such subjects are often left from a deleted additional namespace. Remove them from the binding first.

A project can be named after another project with a dash and a suffix (`foo-bar` beside `foo`). It is a separate project with a namespace of its own, not an additional namespace of `foo`, and the template, administrators, quota and bindings of `foo` do not apply to it. The webhook allows such a project with a warning, and the controller sends the `NamedLikeAdditionalNamespace` Warning event on the new project. The `MultitenancyManagerProjectNamedLikeAdditionalNamespace` alert lists every such pair of projects. To add a namespace to a project, create a ProjectNamespace.

Project status and diagnostics

The `.status.state` field of a project is either `Deployed` (all project resources are in sync, or the objects of `manifests` wait for their binding) or `Error`. The cause of an error is described in the conditions (`.status.conditions`):

```
d8 k get project my-project -o jsonpath='{range .status.conditions[*]}{.type}={.status}:
{.message}{"\n"}{end}'
```

Condition	False means
`ProjectTemplateFound`	The template referenced in `.spec.projectTemplateName` was not found.
`Validated`	The project parameters failed validation against the template schema (`parametersSchema`).
`ResourcesUpgraded`	The project resources could not be created or updated from the template (details in `message`).
`StandardFieldsApplied`	The standard fields (quota or administrators) could not be applied.
`TemplateRolesAllowed`	The template creates a binding to a role forbidden for granting in projects — the project switches to `Error`, the role is named in `message`.
`ManifestsApplied`	The objects of the template's `manifests` are not applied. The `message` says what they wait for, why none of them is applied, which existing objects they leave alone, or which objects the API server refused, with the code of each refusal (for example, `403 Forbidden`).
`HelmOwnership`	The namespace of the project belongs to another Helm release. The `message` names the release (see Automatic project creation for a namespace).
`NamespaceDeleted`	The project is being deleted, and its namespace is still terminating. The `message` says since when and what remains in it.

The `HandoverPending` condition is read the other way round. It is `True` while AuthorizationRule and ResourceQuota objects kept from a Helm text wait for the standard fields that replace them, and it is removed once they are deleted (see Switching a project from a Helm text).

Other useful status fields:

- `.status.namespaces` — all namespaces of the project with their kind (`Main`/`Additional`);
- `.status.usage` — the current quota usage (populated when `.spec.quota` is set);
- `.status.resources` — the state of the individual resources created from the template;
- `.status.keptObjects` — the objects of a Helm text that were left in place instead of being deleted;
- `.status.manifestObjects` — the objects applied from the template's `manifests`.

Service objects of a project

The controller creates service objects in the project namespaces. They are managed automatically — editing them manually is not possible (the attempt is rejected):

Object	Where	Comes from
`ResourceQuota/d8-project-quota`	The main namespace	The `.spec.quota` field of the project.
`ProjectRoleBinding/d8-administrators`	The main namespace	The `.spec.administrators` field of the project.

Object	Where	Comes from
`ProjectRoleBinding/d8-manifests`	The main namespace	The `manifests` field of the project template. It grants the `d8:project:admin` role to the user that applies these objects.
`RoleBinding/d8:prb:<name>`	Every namespace of the project	The fan-out of the ProjectRoleBinding named `<name>`.
`RoleBinding/d8:cprb:<name>`	Every namespace of every project	The fan-out of the ClusterProjectRoleBinding named `<name>`.

When the source object (a binding, the quota field, etc.) is removed, the corresponding service objects are removed automatically.

Virtual projects

Besides the user-created projects, the `d8 k get projects` list always contains two **virtual** projects (labeled `projects.deckhouse.io/virtual-project: "true"`):

- `deckhouse` — groups system namespaces (`d8-*`, `kube-*`, `upmeter-*`, `heritage: deckhouse` / `heritage: upmeter`);
- `default` — groups remaining namespaces that do not belong to any project (the `default` namespace itself).

Virtual-project status is rebuilt from the live namespace list: a deleted namespace disappears from that list. Virtual projects do not recreate namespaces.
