       podSecurityProfile: Restricted
       extendedMonitoringEnabled: true
   ```

   > **i** The Project API is served as `deckhouse.io/v1alpha3`. `v1alpha2` manifests keep working: a conversion webhook automatically lifts `parameters.administrators` and `parameters.resourceQuota` into the `.spec.administrators` and `.spec.quota` standard fields. If one administrator does not fit `.spec.administrators` (for example, it has `accessLevel`), the whole list stays in `parameters`, and `.spec.administrators` is not filled. The same holds for a quota with anything other than quantities (for example, `scopes`), for a quota with the number `0` anywhere in it, and for an empty list or quota. The `deckhouse.io/v1alpha1` version is no longer served, and the API server refuses a manifest with `apiVersion: deckhouse.io/v1alpha1`. Before applying such a manifest, change `apiVersion` to `deckhouse.io/v1alpha3`, rename `spec.projectTypeName` to `spec.projectTemplateName` (a ProjectTemplate with that name must exist) and `spec.template` to `spec.parameters`, and move `administrators` and `resourceQuota` from the parameters to `.spec.administrators` and `.spec.quota`.

4. To check the project status, run the following command:

   ```
   d8 k get projects my-project
   ```

A successfully created project should have the `Deployed` (synchronized) status. If the `Error` status is displayed, add the `-o yaml` flag to the command (for example, `d8 k get projects my-project -o yaml`) to get more details about the cause of the error.

Automatic project creation for a namespace

A namespace created directly (for example, `d8 k create ns test`) automatically becomes a project with the same name — no annotation is required:

- the template is picked from what the namespace already carries: `secure` if it has the `security-scanning.deckhouse.io/enabled` label, `default` if it has `security.deckhouse.io/pod-policy` or `extended-monitoring.deckhouse.io/enabled`, and `simple` otherwise;
- the project parameters are filled in from the current state of the namespace, so nothing inside it changes: the network policy stays unrestricted and the Pod Security Standard keeps the value the namespace already had;
- from then on the project is the source of truth and is edited like any other project. The namespace of the project cannot be deleted directly: the request is refused with the `Manual modification is forbidden` message. To remove the environment, delete the Project: `d8 k delete project <NAME>` deletes the namespace with it and returns once the namespace is gone. Only a user allowed to delete the namespace can delete its Project (see Additional project namespaces).

Users can create a namespace directly only while the `allowNamespacesWithoutProjects` parameter is `true` (the default). With `false`, only cluster administrators (`system:masters`, `system:sudouser`), Deckhouse, the module controller and system components create namespaces directly. Other users create a Project or a ProjectNamespace instead.

System namespaces (`d8-*`, `kube-*`, `upmeter-*`, `default`, and anything labeled `heritage: deckhouse` or `heritage: upmeter`) are never adopted this way: they belong to the virtual `deckhouse`/`default` projects (see Virtual projects). A namespace whose name is longer than 61 characters is not adopted either: that is the Project name limit.

A namespace that gets the `default` or `secure` template because of its monitoring or scanning label and has no `security.deckhouse.io/pod-policy` label gets `podSecurityProfile: ""`. The project puts no such label on it, and the default policy of the `admission-policy-engine` module keeps applying to it.

A namespace that already belongs to another Helm release (its `meta.helm.sh/release-name` annotation names a release other than the project's) is not taken over: the project gets the `HelmOwnership` condition with the name of that release and retries, and the namespace is left as it is. Remove the foreign release or its ownership annotations to let the project proceed.

Existing RoleBinding and AuthorizationRule objects inside the namespace keep working after adoption. The namespace Admin is **not** copied into `.spec.administrators` and does **not** become `d8:project:admin`. To make them a project administrator, add them to `.spec.administrators` or create a ProjectRoleBinding.

For example:

1. Create a new namespace:

   ```
   d8 k create ns test
   ```

2. Make sure the project has been created:

   ```
   d8 k get projects
   ```

   A new project matching the namespace will appear in the list of projects:

   ```
   NAME         STATE      PROJECT TEMPLATE   DESCRIPTION
   AGE
   deckhouse    Deployed   virtual            This is a virtual project
   181d
   default      Deployed   virtual            This is a virtual project
   181d
   test         Deployed   simple
   1m
   ```

To change the template of such a project, set another template in `.spec.projectTemplateName`.

⚠ If the namespace already has an object of the same kind and name as one that the new template creates, for example the `isolated` NetworkPolicy, the project switches to `Error`, and the `ResourcesUpgraded` condition names the object. Delete or rename the object first.

Creating a project without specifying a template

The `projectTemplateName` field is optional: when omitted, the `simple` template is used. Such a project consists only of the namespace and the standard fields (administrators, quota) — no template policies are created in it. This is convenient when no settings are needed or they are managed by other means:

```
apiVersion: deckhouse.io/v1alpha3
kind: Project
metadata:
  name: my-plain-project
spec:
  administrators:
    - kind: Group
      name: k8s-admins
  quota:
    requests.cpu: "2"
```

A template can be assigned later by setting it in `.spec.projectTemplateName`.

Project naming rules

The project name is also the name of its main namespace, so the following rules are checked when a project is created:

- the name cannot start with `d8-` or `kube-` — these prefixes are reserved for system namespaces;
- the name cannot be `default` or `deckhouse` — these names belong to the virtual projects;
- the name cannot be longer than 61 characters;
- the name cannot be the name of an existing namespace, or of a namespace that a ProjectNamespace has claimed (the name is taken from the moment the ProjectNamespace is created, before the controller creates the namespace);
- the name cannot be the name of a namespace whose ServiceAccounts are still named among the subjects of a ClusterProjectRoleBinding, or of a ProjectRoleBinding of a project that the name extends with a dash and a suffix (`foo` for `foo-extra`). Such subjects are often left from a deleted additional namespace. Remove them from the binding first.

A project can be named after another project with a dash and a suffix (`foo-bar` beside `foo`). It is a separate project with a namespace of its own, not an additional namespace of `foo`, and the template, administrators, quota and bindings of `foo` do not apply to it. The webhook allows such a project with a warning, and the controller sends the `NamedLikeAdditionalNamespace` Warning event on the new project. The `MultitenancyManagerProjectNamedLikeAdditionalNamespace` alert lists every such pair of projects. To add a namespace to a project, create a ProjectNamespace.

Project status and diagnostics

The `.status.state` field of a project is either `Deployed` (all project resources are in sync, or the objects of `manifests` wait for their binding) or `Error`. The cause of an error is described in the conditions (`.status.conditions`):

```
d8 k get project my-project -o jsonpath='{range .status.conditions[*]}{.type}={.status}:
{.message}{"\n"}{end}'
```

Condition	False means
`ProjectTemplateFound`	The template referenced in `.spec.projectTemplateName` was not found.
`Validated`	The project parameters failed validation against the template schema (`parametersSchema`).
`ResourcesUpgraded`	The project resources could not be created or updated from the template (details in `message`).

Condition	False means
`StandardFieldsApplied`	The standard fields (quota or administrators) could not be applied.
`TemplateRolesAllowed`	The template creates a binding to a role forbidden for granting in projects — the project switches to `Error`, the role is named in `message`.
`ManifestsApplied`	The objects of the template's `manifests` are not applied. The `message` says what they wait for, why none of them is applied, which existing objects they leave alone, or which objects the API server refused, with the code of each refusal (for example, `403 Forbidden`).
`HelmOwnership`	The namespace of the project belongs to another Helm release. The `message` names the release (see Automatic project creation for a namespace).
`NamespaceDeleted`	The project is being deleted, and its namespace is still terminating. The `message` says since when and what remains in it.

The `HandoverPending` condition is read the other way round. It is `True` while AuthorizationRule and ResourceQuota objects kept from a Helm text wait for the standard fields that replace them, and it is removed once they are deleted (see Switching a project from a Helm text).

Other useful status fields:

- `.status.namespaces` — all namespaces of the project with their kind (`Main`/`Additional`);
- `.status.usage` — the current quota usage (populated when `.spec.quota` is set);
- `.status.resources` — the state of the individual resources created from the template;
- `.status.keptObjects` — the objects of a Helm text that were left in place instead of being deleted;
- `.status.manifestObjects` — the objects applied from the template's `manifests`.

Service objects of a project

The controller creates service objects in the project namespaces. They are managed automatically — editing them manually is not possible (the attempt is rejected):

Object	Where	Comes from
`ResourceQuota/d8-project-quota`	The main namespace	The `.spec.quota` field of the project.
`ProjectRoleBinding/d8-administrators`	The main namespace	The `.spec.administrators` field of the project.
`ProjectRoleBinding/d8-manifests`	The main namespace	The `manifests` field of the project template. It grants the `d8:project:admin` role to the user that applies these objects.
`RoleBinding/d8:prb:<name>`	Every namespace of the project	The fan-out of the ProjectRoleBinding named `<name>`.
`RoleBinding/d8:cprb:<name>`	Every namespace of every project	The fan-out of the ClusterProjectRoleBinding named `<name>`.

When the source object (a binding, the quota field, etc.) is removed, the corresponding service objects are removed automatically.

Virtual projects

Besides the user-created projects, the `d8 k get projects` list always contains two **virtual** projects (labeled `projects.deckhouse.io/virtual-project: "true"`):

- `deckhouse` — groups system namespaces (`d8-*`, `kube-*`, `upmeter-*`, `heritage: deckhouse` /

`heritage: upmeter`);
- `default` — groups remaining namespaces that do not belong to any project (the `default` namespace itself).

Virtual-project status is rebuilt from the live namespace list: a deleted namespace disappears from that list. Virtual projects do not recreate namespaces.

Virtual projects exist for completeness: with them, every namespace of the cluster belongs to some project. They cannot be managed: they are not editable, ProjectNamespace and ProjectRoleBinding resources cannot be created in them, and ClusterProjectRoleBinding does not extend to them. Their project template, `virtual`, is reserved for them: a user project with `projectTemplateName: virtual` is refused by the webhook. No ClusterResourceGrantPolicy applies to their namespaces either, even one whose selectors match a virtual Project, because the cluster resource availability rules apply only in namespaces with the `projects.deckhouse.io/project` label, and the namespaces of virtual projects do not carry it.

No ProjectTemplate object named `virtual` exists, and the webhook refuses to create one. A template with this name that is already in the cluster is not used by any project and can be deleted.

Additional project namespaces

If an application needs several namespaces (for example, a separate one for a cache or a queue), add them to the project with the ProjectNamespace resource. It is created **in the main namespace of the project**; the resulting namespace is named `<project name>-<spec.name>`:

```
apiVersion: deckhouse.io/v1alpha3
kind: ProjectNamespace
metadata:
  name: cache
  namespace: my-project
spec:
  name: cache  # The my-project-cache namespace will be created.
```

You can check the project composition in its status:

```
d8 k get project my-project -o jsonpath='{.status.namespaces}'
```

The rules for working with ProjectNamespace:

- The `spec.name` field is immutable: to rename a namespace, delete the resource and create a new one.
- The resulting name `<project name>-<spec.name>` cannot be longer than 63 characters (the Kubernetes limit on namespace names).
- A ProjectNamespace can only be created in the main namespace of a project — it cannot be “nested” into an additional namespace or a foreign project.
- The resulting name must be free. The request is rejected when a namespace with that name exists and is not a namespace of this project, when a project has that name, or when another ProjectNamespace already claims it (the ProjectNamespace `a-backend` of project `team` and the ProjectNamespace `backend` of project `team-a` both claim `team-a-backend`).
- The request is also rejected when the ServiceAccounts of a namespace with the resulting name are still named among the subjects of a ClusterProjectRoleBinding, or of a ProjectRoleBinding of another project that the resulting name extends with a dash and a suffix. Remove these subjects from the binding first.
- Deleting a ProjectNamespace resource deletes its namespace. Deleting the project deletes all of its namespaces.
- A project can be deleted only by a user allowed to delete each of its namespaces (the `delete` verb on `namespaces`). Otherwise the request is refused, and the refusal names the namespace the user may not delete.

What applies to the additional namespaces

The following automatically applies in **all** namespaces of the project (the main and the additional ones alike):

- **Access**: the ProjectRoleBinding and ClusterProjectRoleBinding bindings, including the automatic access of the project administrators. When a new namespace is added, all existing bindings fan out into it without any user action.
- **Namespaced template objects**: the network policy (`networkPolicy.mode: Isolated`) and the log collection setup (`logShipping`) are created in every namespace of the project. The network isolation allows traffic between the namespaces of one project. A Helm `resourcesTemplate`

creates its objects in the main namespace unless an object names another namespace of the project. So does `manifests`, whose objects are not applied while one of them names a namespace outside the project.
- **Cluster-scoped template policies** (`OperationPolicy`, the `SecurityPolicy` from `allowedUIDs`/`allowedGIDs`): they select namespaces by the `projects.deckhouse.io/project` label, that is, they cover the whole project.
- **Inherited labels**: the pod security profile (`security.deckhouse.io/pod-policy`), extended monitoring (`extended-monitoring.deckhouse.io/enabled`), vulnerability scanning (`security-scanning.deckhouse.io/enabled`), the template label (`projects.deckhouse.io/project-template`) and the labels the template sets through `namespaceMetadata.labels` are synced from the main namespace to the additional ones. The sync is complete: if a feature is turned off or a label is removed in the template, the label is removed from the additional namespaces as well. The labels of the template are listed in the `projects.deckhouse.io/template-labels` annotation of each project namespace; they are changed through the Project or its ProjectTemplate, and a direct edit of one on an additional namespace is reverted. Thanks to the template label, the cluster resource availability rules also apply in all namespaces of the project.

The following stays in the **main** namespace only:

- the project quota (the `ResourceQuota` from `.spec.quota`);
- the annotations from the template's `namespaceMetadata`;
- the labels and annotations set on the main namespace directly or by a GitOps tool, including the ones the namespace had before it became a project, other than the pod security, monitoring and scanning labels above;
- the GitOps tracking labels (`app.kubernetes.io/instance`, `argocd.argoproj.io/*`, `kustomize.toolkit.fluxcd.io/*`, `helm.toolkit.fluxcd.io/*`, `kapp.k14s.io/*`), even when the template sets them;
- the node placement annotations (from the template's `nodeSelector` and `tolerations` fields).

When a namespace becomes a project automatically, its own labels and annotations are not copied into the Project, so the additional namespaces of the project do not inherit them. The pod security, monitoring and scanning labels are the exception: adoption turns them into parameters of the project. To put another label of such a namespace on the additional namespaces too, declare it in `spec.parameters.namespace.labels` of the Project, or set it on each additional namespace directly.

Labels of the project namespaces

Label	Main	Additional	Purpose
`projects.deckhouse.io/project: <project name>`	✓	✓	Project ownership — the common label of all namespaces of the project.
`projects.deckhouse.io/project-namespace: <spec.name>`	—	✓	Marks an additional namespace (the name of the ProjectNamespace resource).
`projects.deckhouse.io/project-template: <template name>`	✓	✓	The project template; the cluster resource availability rules match by it.
`heritage: multitenancy-manager`	✓	✓	The namespace is managed by the project controller: its `spec`, finalizers and the labels listed in this table are changed through the Project; other labels and annotations may be changed directly.

Label	Main	Additional	Purpose
`security.deckhouse.io/pod-policy`, `extended-monitoring.deckhouse.io/enabled`, `security-scanning.deckhouse.io/enabled`	✓	✓ (inherited)	Policies and features from the project template.
Labels from the template's `namespaceMetadata.labels`	✓	✓ (inherited)	Labels of the project template. They are listed in the `projects.deckhouse.io/template-labels` annotation of the namespace and changed through the Project or its ProjectTemplate.
Any other label set on a namespace directly or by a GitOps tool	—	—	Not set by the module. The project release neither reverts nor restores it, and the additional namespaces do not inherit it.

The common `projects.deckhouse.io/project` label makes it possible to select the project namespaces with a plain `get ns`.

To get all namespaces of the project (main + additional):

```
d8 k get ns -l projects.deckhouse.io/project=my-project
```

To get additional namespaces only:

```
d8 k get ns -l 'projects.deckhouse.io/project=my-
project,projects.deckhouse.io/project-namespace'
```

To get the main namespace only:

```
d8 k get ns -l 'projects.deckhouse.io/project=my-
project,!projects.deckhouse.io/project-namespace'
```

Standard project fields

Project administrators and resource quotas are not project template parameters — they are top-level fields of the Project resource and work with any template (including `simple`):

- `.spec.administrators` — a list of subjects (`kind: User` or `kind: Group` and `name`) that receive administrative access to the project. The controller implements this access through an auto-generated ProjectRoleBinding named `d8-administrators` in the project's main namespace. A name cannot start with `system:multitenancy-manager:`, the prefix of the users that the controller acts as.
- `.spec.quota` — a set of hard ResourceQuota limits (for example, `requests.cpu`, `limits.memory`). The controller maintains a `ResourceQuota` in the project's main namespace and reports current usage in `.status.usage`. For `memory` and `storage`, a unit is required (for example, `2Gi`). Numbers without a unit mean bytes, and all of them except 0 are rejected. An update that leaves such a value as it was is accepted with a warning, and so is a create through `deckhouse.io/v1alpha2` with such numbers in `parameters.resourceQuota`.

⚠ A Helm `resourcesTemplate` that renders a ResourceQuota or an AuthorizationRule keeps rendering it, next to the ResourceQuota and the ProjectRoleBinding that the standard fields create. A pod in such a project has to fit every ResourceQuota of its namespace, and the access such AuthorizationRules grant adds to the access of the standard fields.

Granting access within a project

To grant access to project namespaces for users beyond the project administrators, use role bindings that reference cluster-wide roles and fan out into the appropriate project namespaces automatically:

- ProjectRoleBinding (namespaced, short name `prb`) — grants a role within a **single** project. It must be created in the project's main namespace. The controller creates a RoleBinding in every namespace of that project.
- ClusterProjectRoleBinding (cluster-scoped, short name `cprb`) — grants a role across **all** non-virtual projects.

`roleRef` must reference a `ClusterRole` whose name starts with one of the allowed prefixes (`d8:project:`, `d8:namespace:`, `d8:project-capability:`, `d8:namespace-capability:`, `d8:custom:`). See the user-authz module documentation for the description of the roles.

The following checks apply when a binding is created:

- **Privilege escalation protection**: a binding can only be created by a user who has the right to bind (`bind`) the referenced role; the right is checked by the role's name. A project administrator (`d8:project:admin`) has `bind` on exactly eight roles: `d8:project:viewer`, `d8:project:user`, `d8:project:manager`, `d8:project:admin`, `d8:namespace:viewer`, `d8:namespace:user`, `d8:namespace:manager`, and `d8:namespace:admin`. A binding to any other role — a custom `d8:custom:*` role, a capability role, or `d8:project:superadmin` — is rejected for a project administrator, even if it is within their own permissions, because nobody granted them `bind` on that name. Such bindings are created by a cluster administrator, or the cluster administrator grants `bind` on that role to project administrators separately via a dedicated ClusterRole.
- The role must exist: a binding to a non-existent role is rejected.
- A ServiceAccount used as a ProjectRoleBinding subject must belong to a namespace of that same project: its main namespace, its additional namespaces or a namespace a ProjectNamespace of the project has claimed. A namespace that is only named like an additional namespace (`<project>-*`) but belongs to a separate project does not qualify.
- System and subsystem roles (`d8:system:*`, `d8:subsystem:*`), as well as arbitrary roles outside the listed prefixes, cannot be granted through project bindings.
- Roles with the `rbac.deckhouse.io/disabled-for-direct-use-in-projects: "true"` annotation are forbidden for granting in projects. A cluster administrator can put this annotation on a role to stop new grants of it: existing bindings keep working, but no new ones are created. If a project template uses such a role, the project switches to `Error` with the reason in the `TemplateRolesAllowed` condition.

The controller checks the ServiceAccounts by the same rule every time it updates the RoleBindings of a ProjectRoleBinding, and also when a namespace appears, is deleted or moves to another project. The subjects that do not pass stay in `.spec.subjects` but get no rights: the `SubjectsBound` condition of the binding is `False` and lists them. Once the namespace is a namespace of the project again, the subjects get the rights back without a change to the binding.

The `d8-administrators` binding, created by the controller from the `.spec.administrators` field, is managed by the controller only — it cannot be edited manually. To change the set of administrators, change the project's `.spec.administrators` field instead. The ServiceAccount rule above does not apply to this binding.

The following bindings give the `viewer@example.com` user the `d8:project:viewer` role in every namespace of `my-project`, and the `platform` group the same role in every project except the virtual ones:

```
---
apiVersion: deckhouse.io/v1alpha3
kind: ProjectRoleBinding
metadata:
  name: viewers
  namespace: my-project
spec:
  subjects:
    - kind: User
      name: viewer@example.com
  roleRef:
    kind: ClusterRole
    name: d8:project:viewer
---
apiVersion: deckhouse.io/v1alpha3
kind: ClusterProjectRoleBinding
metadata:
  name: platform-viewers
spec:
  subjects:
    - kind: Group
      name: platform
  roleRef:
    kind: ClusterRole
    name: d8:project:viewer
```

Roles available in a RoleBinding inside a project

Besides the project bindings, a plain RoleBinding can also be used inside a project namespace — the role then applies in that single namespace only. However, in projects the set of roles available to a plain RoleBinding is restricted: only cluster roles carrying the `rbac.deckhouse.io/delegatable: "true"` label are allowed. Among the built-in ones these are the `d8:namespace:*` and `d8:project:*` roles, as well as the access-level roles of the basic role model (`user-authz:user`, `user-authz:privileged-user`, `user-authz:editor`, `user-authz:admin`).

A RoleBinding to any other cluster role (for example, `cluster-admin`, system roles, or capabilities) is rejected in a project with the message `references "<role>" which is not available to project`. This protects the project isolation from being bypassed by binding to an overly broad role.

To use a custom role in projects, add the `rbac.deckhouse.io/delegatable: "true"` label to it:

```
d8 k label clusterrole d8:custom:namespace:developer rbac.deckhouse.io/delegatable=true
```

The restriction applies in the namespaces of every project, including the ones adopted from a standalone namespace.

Structured templates

Starting with the `deckhouse.io/v1alpha2` API version, a project template is described by **structured fields** — instead of a text Helm template, you declaratively specify which settings the project namespaces get. The controller itself creates the corresponding objects (network policies, security policies, log collection settings, etc.) from these fields in every namespace of the project and keeps them up to date. Other objects of the project namespaces are described in `manifests`.

Available fields (all optional; the complete reference is in the ProjectTemplate resource description):

Field	What it configures
`podSecurityStandard`	Pod security profile: `Privileged`, `Baseline`, or `Restricted`.
`networkPolicy.mode`	Network isolation: `Isolated` (traffic is only allowed within the project and from the platform system components) or `NotRestricted`.
`features.monitoring`	Extended monitoring of the project namespaces.

Field	What it configures
`features.vulnerabilityScanning`	Scanning of container images for vulnerabilities.
`logShipping.clusterDestinationRef`	Collecting the logs of the project pods into the given destination (`ClusterLogDestination`).
`nodeSelector`, `tolerations`	Placing the pods of the main namespace on dedicated nodes.
`allowedUIDs`, `allowedGIDs`	The allowed UID/GID ranges of the project containers.
`runtimeAudit.enabled`	Auditing the project processes' access to the Linux kernel.
`namespaceMetadata.labels`, `namespaceMetadata.annotations`	Extra labels and annotations of the project namespaces. The labels the module manages cannot be set here: a template or a Project that sets one is refused.
`resources`, `grantPolicies`	Granting cluster-scoped resources through a project template — see Managing access to cluster-wide resources.
`manifests`	Other objects in the project namespaces, applied with the rights of a project administrator. See Describing other objects in manifests.
`parametersSchema.openAPIV3Schema`	The schema of parameters set when creating a project.

An example of a structured template:

```
apiVersion: deckhouse.io/v1alpha2
kind: ProjectTemplate
metadata:
  name: my-template
spec:
  title: "Team template"
  description: "Isolated project with monitoring"
  podSecurityStandard: Baseline
  networkPolicy:
    mode: Isolated
  features:
    monitoring: true
    vulnerabilityScanning: true
```

Template parametrization

Twelve fields of the template can be turned into a parameter: `podSecurityStandard`, `networkPolicy.mode`, `features.monitoring`, `features.vulnerabilityScanning`, `logShipping.clusterDestinationRef`, `nodeSelector`, `tolerations`, `allowedUIDs`, `allowedGIDs`, `runtimeAudit.enabled`, `namespaceMetadata.labels` and `namespaceMetadata.annotations`. Instead of a concrete value, specify `{fromParam: <parameter name>}` and declare the parameter in `parametersSchema`. The value does not have to be a scalar: a map (`nodeSelector`, `namespaceMetadata.labels`), a list (`tolerations`) or an object (`allowedUIDs`) works just as well. The other fields — `title`, `description`, `resources`, `grantPolicies` and `parametersSchema` itself — take literal values only. Each project then sets its own value in `.spec.parameters`; if the value is not set, the `default` from the schema is used.

```
apiVersion: deckhouse.io/v1alpha2
kind: ProjectTemplate
metadata:
  name: my-parametrized-template
spec:
  podSecurityStandard:
    fromParam: securityProfile
  networkPolicy:
    mode:
      fromParam: networkMode
  parametersSchema:
    openAPIV3Schema:
      type: object
      properties:
        securityProfile:
          type: string
          enum: [Baseline, Restricted]
          default: Baseline
        networkMode:
          type: string
          enum: [Isolated, NotRestricted]
          default: Isolated
```

A project using such a template:

```
apiVersion: deckhouse.io/v1alpha3
kind: Project
metadata:
  name: my-project
spec:
  projectTemplateName: my-parametrized-template
  parameters:
    securityProfile: Restricted
```

The `fromParam` references are checked when a template is created or changed: a reference to an undeclared parameter or to a parameter of an incompatible type (for example, a string parameter for a boolean field) is rejected.

The `requiredRequests` parameter is read by name, without `fromParam`. The controller renders an OperationPolicy in the `Deny` mode that requires CPU and memory requests from the pods in every namespace of the project only when the template declares the parameter in `parametersSchema` with `type: boolean` and its value for the project is `true`. A template that does not declare the parameter renders no such policy, even if the project sets `requiredRequests` as an undeclared key.

Template checks

The following rules apply to template operations:

- A template cannot be deleted while at least one project uses it or a project namespace is still rendered from it. After a project switches to another template, the old template stays until the new one has rendered.
- A change to a template is automatically applied to all projects created from it.
- An existing template can describe its objects with a Helm text in `resourcesTemplate` instead of structured fields. This form is deprecated, and the `resourcesTemplate` field will be removed together with `deckhouse.io/v1alpha1` in one of the upcoming releases. The `MultitenancyManagerHelmProjectTemplate` alert names every template that still renders from a Helm text, except the built-in ones. Describe new templates with structured fields and `manifests`, and move the existing ones as Moving a template from a Helm text describes.
- A template cannot get a new `resourcesTemplate` through either version. A create with a non-empty `resourcesTemplate` and an update that sets it on a template whose `resourcesTemplate` is empty are refused. A template that has a Helm text keeps it, and the text can be changed through either version. So a template with a Helm text cannot be created again, for example from a manifest exported from another cluster, from a backup, or from Git after the template was deleted. Move such a template to structured fields and `manifests` first.
- The `deckhouse.io/v1alpha1` version of ProjectTemplate is served and deprecated, and the API server returns a warning on every request through it. A template is created through

`deckhouse.io/v1alpha2` only, and a create through `deckhouse.io/v1alpha1` is refused. The templates created through `deckhouse.io/v1alpha1` earlier are read, changed and deleted through it as before. A change through `v1alpha1` to a template that has fields `v1alpha1` cannot describe, such as `title`, `grantPolicies`, `podSecurityStandard` or `manifests`, is refused, because it would erase them. Change such a template through `deckhouse.io/v1alpha2`.

Creating a custom project template

The default project templates cover common baseline scenarios and also serve as examples of what templates can do.

To create your own template:

1. Use one of the default templates as a starting point, for example, `default`.
2. Export it to a separate file, for example, `my-project-template.yaml`, using the following command:

   ```
   d8 k get projecttemplates default -o yaml > my-project-template.yaml
   ```

3. Edit the `my-project-template.yaml` file: adjust the structured fields and the input parameters schema to your needs.
4. Change the template name in the `.metadata.name` field.
5. Remove the `heritage` label, the `metadata.resourceVersion`, `metadata.uid`, `metadata.creationTimestamp`, `metadata.generation` and `metadata.managedFields` fields and the `status` section from the file.
6. Apply the resulting template with the following command:

   ```
   d8 k apply -f my-project-template.yaml
   ```

7. Check that the new template is available by running:

   ```
   d8 k get projecttemplates <NEW_TEMPLATE_NAME>
   ```

Labels for the objects of a Helm text

The following labels change how the module handles the objects of a Helm text in `resourcesTemplate`. Only existing templates have such a text, because no template can get a new `resourcesTemplate`. The objects of `manifests` never get the `heritage: multitenancy-manager` label, and the module does not read these labels on them.

Skipping the heritage label

By default, every object of the Helm text gets the `heritage: multitenancy-manager` label. This label prohibits changes to the object by users or any other controller except `multitenancy-manager`. To allow changes to the object (for example, for compatibility with other systems, or to control the created objects yourself), add the `projects.deckhouse.io/skip-heritage-label` label to it.

Example:

```
apiVersion: v1
kind: ConfigMap
metadata:
  name: my-config
  namespace: {{ .projectName }}
  labels:
    projects.deckhouse.io/skip-heritage-label: "true"
    app: my-app
data:
  key: value
```

In this case, the object gets the `projects.deckhouse.io/project` and `projects.deckhouse.io/project-template` labels, but does not get the `heritage: multitenancy-manager` label.

Excluding objects from management

To exclude an object from management by the module (for example, when it is managed manually or by another controller), add the `projects.deckhouse.io/unmanaged` label to it.

Example:

```
apiVersion: v1
kind: Secret
metadata:
  name: external-secret
  namespace: {{ .projectName }}
  labels:
    projects.deckhouse.io/unmanaged: "true"
type: Opaque
data:
  token: <base64-encoded-value>
```

Objects with the `projects.deckhouse.io/unmanaged` label:

- are created **only once**, when the project release is first installed, so an object added to the template later is not created in existing projects;
- **are not updated** when the template changes;
- are not tracked in the project status;
- get the `projects.deckhouse.io/project` and `projects.deckhouse.io/project-template` labels, but **not** the `heritage: multitenancy-manager` label;
- get the `helm.sh/resource-policy: keep` annotation, so the project release does not delete them.

⚠ After it is created, an `unmanaged` object does not depend on the template and must be managed manually.

Implementing validation of object changes with a custom label

The `multitenancy-manager` module uses ValidatingAdmissionPolicy to protect resources labeled `heritage: multitenancy-manager` from manual changes.
You can implement similar validation for resources with any label.

How validation works in multitenancy-manager

`multitenancy-manager` validates objects labeled `heritage: multitenancy-manager`.
The following resources are used for this:

1. ValidatingAdmissionPolicy: Defines validation rules:
   - Operations: `CREATE`, `UPDATE` and `DELETE`.
   - Exclusions: requests from cluster components are not checked, that is, from system groups (`system:nodes`, the `kube-system` and `d8-system` service accounts) and system users (`system:apiserver`, `system:kube-controller-manager`, `system:kube-scheduler` and others).
   - Check: only operations on behalf of the controller's service account are allowed.
   - Applies to all resources and API groups.
2. ValidatingAdmissionPolicyBinding: Defines which objects the validation applies to:
   - Uses `namespaceSelector` and `objectSelector` to select resources by the label `heritage: multitenancy-manager`.

Creating your own validation

To implement validation for resources with a different label (for example, `heritage: my-custom-label`):

1. Create a file with the ValidatingAdmissionPolicy and ValidatingAdmissionPolicyBinding resource manifests:

```
apiVersion: admissionregistration.k8s.io/v1
kind: ValidatingAdmissionPolicy
metadata:
  name: my-custom-label-validation
spec:
  failurePolicy: Fail
  matchConstraints:
    resourceRules:
      - apiGroups:   ["*"]
        apiVersions: ["*"]
        operations:  ["CREATE", "UPDATE", "DELETE"]
        resources:   ["*"]
        scope: "*"
  matchConditions:
    # Let the cluster components through, as the policy of the module does.
    - name: exclude-system-groups
      expression: '!(["system:nodes", "system:serviceaccounts:kube-system",
"system:serviceaccounts:d8-system"].exists(e, (e in request.userInfo.groups)))'
    - name: exclude-system-users
      expression: '!(["system:apiserver", "system:kube-controller-manager",
"system:kube-scheduler"].exists(e, (e == request.userInfo.username)))'
  variables:
    # A DELETE request carries no object, only oldObject.
    - name: subject
      expression: 'object == null ? oldObject : object'
  validations:
    - expression: 'request.userInfo.username == "system:serviceaccount:my-
namespace:my-service-account"' # Replace with your ServiceAccount.
      reason: Forbidden
      messageExpression: 'variables.subject.kind == ''Namespace'' ? ''This
resource is managed by '' + variables.subject.metadata.name + '' system. Manual
modification is forbidden.''
       : ''This resource is managed by '' + variables.subject.metadata.namespace
+ '' system. Manual modification is forbidden.'''
---
apiVersion: admissionregistration.k8s.io/v1
kind: ValidatingAdmissionPolicyBinding
metadata:
  name: my-custom-label-validation
spec:
  policyName: my-custom-label-validation
  validationActions: [Deny, Audit]
  matchResources:
    objectSelector:
      matchLabels:
        heritage: my-custom-label
```

2. Configure the validation parameters:
   - `policyName`: Unique policy name (must match in Policy and Binding).
   - `request.userInfo.username`: The name of the ServiceAccount allowed to change objects (replace with your ServiceAccount).
   - `heritage: my-custom-label`: The value of the `heritage` label for your resources (replace with your value). The use of the values `multitenancy-manager`, `deckhouse` is prohibited.
   - `failurePolicy`: What happens when the policy cannot be evaluated, for example when an expression fails: `Fail` rejects the request, `Ignore` admits it. A validation that returns `false` rejects the request with the `Deny` action in any case.
   - `matchConditions`: Requests that the policy does not check. Keep the cluster components in this list, otherwise the policy blocks the deletion of namespaces and the garbage collection of the labeled objects.
   - `validationActions`: Validation actions:
     - `Deny`: Deny unauthorized operations.
     - `Audit`: Record operations in the audit log.

3. Apply the policy:

3. Apply the policy:

```
d8 k apply -f my-validation-policy.yaml
```

4. Ensure your resources have the corresponding `heritage` label:

```
apiVersion: v1
kind: ConfigMap
metadata:
  name: my-resource
  labels:
    heritage: my-custom-label
```

Managing access to cluster-wide resources

The `multitenancy-manager` module allows cluster administrators to define, for each project, which cluster-wide resources (such as StorageClass, ClusterIssuer, ClusterRole, and LoadBalancerClass) can be used from project namespaces and which values are used by default.

This mechanism works independently of RBAC. RBAC determines *who can create and modify* objects, while the cluster-wide resource access mechanism determines *which resources* those objects can use.

The mechanism uses four custom resources:

- GrantableClusterResourceDefinition registers a type of cluster-wide resource whose access can be managed. These resources are provided by DP or module developers.
- GrantableClusterResourceReference defines where a registered cluster-wide resource is used, for example, which resource field contains a reference to it. These resources are provided by modules.
- ClusterResourceGrantPolicy defines access rules: the allowed and denied resources, as well as the resource used by default. A cluster administrator selects the namespaces to which the policy applies with two selectors: `projectSelector` matches the labels of the Project, and `namespaceSelector` matches the labels of the Namespace. A policy with neither selector is a library policy: it applies to a project only through `grantPolicies` of its ProjectTemplate.
- AvailableClusterResource is a read-only list of cluster-wide resources available to the project under the policies that apply. The controller keeps one in every namespace of every project for each GrantableClusterResourceDefinition.

Until the administrator creates a ClusterResourceGrantPolicy, resource availability is determined by their registration: resources are available to all projects if `defaultAvailability: All` (the default value) is set in GrantableClusterResourceDefinition and the resource does not match the `excluded` or `reserved` filters. Access checks are performed only for objects in project namespaces. If an access policy changes, cluster-wide resources already used by existing objects remain available to those objects.

The webhooks reject requests while the module controller is unavailable. Until it is back, objects of the registered kinds (for example, PersistentVolumeClaim, Service or RoleBinding) cannot be created or changed in project namespaces, except by the platform components and members of the `system:masters` group. To keep the controller available, enable `highAvailability`.

For a detailed description of the access management mechanism, refer to the `multitenancy-manager` module documentation.

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Overview

Managed services in Deckhouse Platform let you run ready-to-use application services in a cluster, such as databases, message queues, and big data services, without having to manage their lifecycle manually. DP handles the technical tasks of administration, scaling, backup, and updates, while the administrator manages managed services at the level of classes, limits, and architectural decisions.

How it works

Each managed service adds its own Kubernetes resources and controllers to the cluster. A user describes the desired state of the managed service in a namespaced resource. The controller creates and updates the related objects: workload instances, Services, secrets, snapshots, and other resources supported by the specific managed service. The administrator manages cluster-wide resources that define allowed configurations and default values for user resources.

Use this section to:

- prepare the cluster to work with managed services;
- configure shared settings and limits;
- define available managed service classes and configurations;
- verify that the infrastructure is ready to run managed services.

For PostgreSQL administration, see Managed PostgreSQL.

Instructions for creating managed services, configuring instances, and connecting to them are provided in the Usage section.

Managed PostgreSQL

The Managed PostgreSQL service helps you deploy and maintain PostgreSQL instances in DP. Supported PostgreSQL version — 17.6.

This page describes the settings a cluster administrator can configure: managing resource limits and topology, configuring parameter validation, setting default values, and binding to cluster nodes.

Enabling the service

To enable the Managed PostgreSQL service in DP, complete the following steps:

1. Make sure the requirements for the `managed-postgres` module are met.
2. Enable the `managed-postgres` module in the DP web interface or another way.
3. Create a PostgresClass with the settings that users will need when creating Postgres objects. You can also use the `default` PostgresClass that the module creates when enabled. The `default` PostgresClass contains baseline settings so users can start creating databases right after Managed PostgreSQL is enabled in DP. For production environments, it’s recommended to create separate PostgresClass resources with explicit settings and limits.

Once the module is enabled, users can create PostgreSQL databases on their own. User operations with the service are described in Usage → Managed services → Managed PostgreSQL.

Dependencies for specific features

Some module features require additional configuration of Deckhouse Platform components or cluster infrastructure:

Feature	Requirement
Backup (managed by PostgresSnapshot)	The snapshot-controller module enabled and a StorageClass with snapshot support
TLS via `cert-manager`	The cert-manager module enabled and a configured ClusterIssuer or Issuer

Feature	Requirement
Placement on dedicated nodes	Node labels (for example, `node.deckhouse.io/group=pg`) and taints if needed. For more information, see the documentation

Example of creating a PostgresClass

Before applying the example, make sure the cluster has enough resources. To estimate the available resources, run:

```
d8 k describe node worker-0 | grep -A 5 "Allocated resources"
```

Example output:

```
Allocated resources:
  (Total limits may be over 100 percent, i.e., overcommitted.)
  Resource           Requests          Limits
  --------           --------          ------
  cpu                3176m (80%)       500m (12%)
  memory             8342837084 (71%)  6400Mi (57%)
```

Below is an example of a `production-v1` PostgresClass that you can use instead of the `default` PostgresClass and adapt to your requirements for resources, topology, PostgreSQL parameters, and node placement. The following sections describe these parameters in more detail.

Create a `postgresclass-production.yaml` file with the following content:

```
apiVersion: managed-services.deckhouse.io/v1alpha1
kind: PostgresClass
metadata:
  name: production-v1
spec:
  # Limit CPU and memory resources.
  sizingPolicies:
    - cores:
        min: 1
        max: 2
      memory:
        min: 512Mi
        max: 2Gi
        step: 512Mi
      coreFractions:
        - 50
        - 100
    - cores:
        min: 3
        max: 4
      memory:
        min: 2Gi
        max: 4Gi
        step: 1Gi
      coreFractions:
        - 50
        - 100

  # Manage fault tolerance.
  topology:
    allowedTopologies:
      - Ignored
      - Zonal
      - TransZonal
```

```
    defaultTopology: TransZonal
    allowedZones:
      - zone-a
      - zone-b
      - zone-c

  # Validate PostgreSQL settings.
  validations:
    - message: "Max connections should not be more than 300"
      rule: "configuration.maxConnections <= 300"
    - message: "Shared buffers should not be more than 25% of RAM"
      rule: "configuration.sharedBuffers < instance.memory.size / 4"
    - message: "walKeepSize can not be more than 1Gi"
      rule: "configuration.walKeepSize <= 1073741824"

  # Default values and override permissions.
  configuration:
    maxConnections: 200
    sharedBuffers: 1Gi
  overridableConfiguration:
    - maxConnections
    - sharedBuffers
    - walKeepSize

  # Bind to dedicated nodes.
  nodeAffinity:
    requiredDuringSchedulingIgnoredDuringExecution:
      nodeSelectorTerms:
        - matchExpressions:
          - key: "node.deckhouse.io/group"
            operator: "In"
            values:
              - "pg"
              - "postgres"
  nodeSelector:
    "node.deckhouse.io/group": "pg"
  tolerations:
    - key: primary-role
      operator: Equal
      value: pg
      effect: NoSchedule
```

Apply the manifest:

```
d8 k apply -f postgresclass-production.yaml
```

Check the created PostgresClass:

```
d8 k describe postgresclass production-v1
```

Example output...

```
Name:         production-v1

    Message:  walKeepSize can not be more than 1Gi
```

```
    Rule:     configuration.walKeepSize <= 1073741824
Events:       <none>
```

Users can use the created PostgresClass by specifying it in the postgresClassName parameter of Postgres.

⚠ Once a PostgresClass is created, its parameters can't be changed. Create a new PostgresClass with a different name to use different settings.

Change and delete a PostgresClass

Before deleting an old class, check whether it's used by any existing Postgres objects. Run:

```
d8 k get postgres --all-namespaces -o custom-columns=NAMESPACE:.metadata.namespace,NAME:.metadata.name,CLASS:.spec.postgresClassName | grep production-v1
```

If Postgres objects using this PostgresClass are found, keep the following in mind:

- Databases created based on the deleted PostgresClass keep running. Their settings stay the same, since they were fixed at creation time.
- Users won't be able to create a new Postgres object that references the deleted class.

If the PostgresClass is no longer used, you can delete it.

Example of deleting the `production-v1` PostgresClass via the CLI:

```
d8 k delete postgresclass production-v1
```

Example output:

```
postgresclass.managed-services.deckhouse.io "production-v1" deleted
```

i If you need to change PostgresClass settings, it's recommended to create a new one with a different name rather than recreating a PostgresClass with the same name.

Limit CPU and memory resources

Policies, in the `spec.sizingPolicies` parameter section, are used to define the allowed CPU and memory combinations for PostgreSQL instances. The administrator can set several core ranges, each with a minimum and maximum amount of memory and a step. These policies are useful when several independent teams work in the same cluster and create Postgres objects without coordinating with the administrator. Policies prevent Postgres objects with unrealistic resource requests and ensure predictable node utilization.

The policy is selected by the number of CPU cores. The `coreFractions` parameter defines what percentage of the CPU limits (`limits`) becomes the guaranteed request (`requests`). For example, if the administrator specifies `coreFractions: [50, 100]`, a user creating a Postgres object can choose `coreFraction: 50` or `coreFraction: 100`.

With `coreFraction: 50`:

- The CPU `limits` equal the number of requested cores (for example, 4 cores).
- The CPU `requests` are 50% of `limits` (2 cores).

The scheduler guarantees the pod 2 cores but allows it to use up to 4 if they're available. This increases pod placement density on nodes.

With `coreFraction: 100`:

- `limits` and `requests` are equal (4 cores).
- The pod gets a guaranteed resource allocation, but loses the ability to reuse unused cores from other pods.

Below is a fragment of a PostgresClass manifest showing the allowed CPU and memory combinations. The complete example is provided in Example of creating a PostgresClass.

```
spec:
  sizingPolicies:
    - cores:
        min: 1
        max: 2
      memory:
        min: 512Mi
        max: 2Gi
        step: 512Mi
      coreFractions:
        - 50
        - 100
```

In this fragment, the available memory values for 1–2 cores are 512Mi, 1Gi, 1.5Gi, and 2Gi.

The `step` parameter defines the increment for the memory amount. A user can only specify a memory value that's a multiple of `step`. For example, if `step: 512Mi`, the allowed values are 512Mi, 1Gi, 1.5Gi, 2Gi, and so on. A value of 700Mi is rejected because it isn't a multiple of 512Mi.

The choice of memory depends on the number of cores. If a user requests 5 cores, the Postgres object isn't created, since this configuration isn't provided by the administrator.

⚠ Within a single PostgresClass, the `cores.min`–`cores.max` ranges of different policies must not overlap.

For example, in the `production-v1` PostgresClass, the first policy can't cover 1–4 cores while the second covers 2–6 cores, since cores 2–4 would belong to both policies. Ranges can overlap across different PostgresClass resources, for example `production-v1` and `production-v2`.

The user can see the available options and pick a suitable one when creating a Postgres object.

Manage fault tolerance across availability zones

The administrator can manage the fault tolerance of users' PostgreSQL instances by setting their availability zone distribution topology in the `spec.topology` parameter section. This can be useful in production environments with data-center-level fault tolerance requirements.

Three topologies are available:

- `Ignored`: standard scheduling with no zone binding;
- `Zonal`: all instances are placed in one zone (minimal latency between replicas). Suits low-latency environments where losing a zone is acceptable;
- `TransZonal`: instances are distributed across different zones (one primary instance, one synchronous replica, one asynchronous replica). Protects against the loss of an entire zone but requires more resources.

The administrator can specify the allowed topology options (`allowedTopologies`), the default topology (`defaultTopology`), and the list of available zones (`allowedZones`).

Below is a fragment of a PostgresClass manifest showing the topology parameters. The complete example is provided in Example of creating a PostgresClass.

```
spec:
  topology:
    allowedTopologies:
      - Zonal
      - TransZonal
    defaultTopology: TransZonal
    allowedZones:
      - zone-a
      - zone-b
```

In this fragment, `Zonal` and `TransZonal` modes are allowed, with `TransZonal` applied by default. The `allowedZones` field lists placeholder zones — replace them with the actual zone names from your cloud provider or data center.

Users can choose the fault tolerance level when creating a Postgres object. If not specified explicitly, the default value applies (as set in the `defaultTopology` parameter).

Automatically validate PostgreSQL settings

To reject undesirable combinations of PostgreSQL parameters chosen by users, the administrator can define validation rules in Common Expression Language (CEL) in the `spec.validations` parameter section of PostgresClass. These rules are checked on the API server before Postgres objects are created.

These rules are useful for guarding against common configuration mistakes that can lead to performance issues. For example, too large a `shared_buffers` value can leave PostgreSQL with too little memory for other operations, and a large number of connections can significantly increase overall memory consumption.

The following variables are available in the rules:

- `configuration.maxConnections`;
- `configuration.workMem`;
- `configuration.sharedBuffers`;
- `configuration.walKeepSize`;
- `instance.memory.size`;
- `instance.cpu.cores`.

Below is a fragment of a PostgresClass manifest showing validation rules. The complete set of rules is provided in Example of creating a PostgresClass.

```
spec:
  validations:
    - message: "Shared buffers should not be more than 25% of RAM"
      rule: "configuration.sharedBuffers < instance.memory.size / 4"
```

In this fragment, the rule prevents allocating more than 25% of the requested memory to `shared_buffers`.

The user gets a validation error when trying to apply invalid parameters, which helps avoid configuration mistakes without manual review.

Set default values and allow overrides

To set default PostgreSQL parameters and define which of them users can change, the administrator can use the `spec.configuration` and `spec.overridableConfiguration` parameters.

If no values are specified in `configuration`, the module controller applies the following:

- `maxConnections`: `100`;
- `sharedBuffers`: 25% of `memory.size`;
- `workMem`: `(memory.size - sharedBuffers) * 4 / maxConnections`;
- `walKeepSize`: `512Mi`.

Below is a fragment of a PostgresClass manifest showing the default service settings. The complete example is provided in Example of creating a PostgresClass.

```
spec:
  configuration:
    maxConnections: 200
    sharedBuffers: 1Gi
  overridableConfiguration:
    - maxConnections
    - sharedBuffers
    - walKeepSize
```

In this example:

- `maxConnections` and `sharedBuffers` default to 200 and 1Gi, respectively.
- The user can override `maxConnections`, `sharedBuffers`, and `walKeepSize`.
- `workMem` isn’t included in `overridableConfiguration`, so the user can’t change it.

Automatic workMem calculation

To limit the amount of memory used for sort and hash operations within a single query, use the

workMem parameter.

In PostgreSQL, this limit applies to each operation in each active session. A complex query can run several such operations at once. With a large number of connections, total memory consumption can far exceed the configured value and lead to memory exhaustion. A value that's too small, on the other hand, forces PostgreSQL to use temporary files on disk and reduces performance.

If `workMem` isn't set explicitly, the `managed-postgres` module automatically calculates its value based on the allocated resources.

The module calculates `workMem` using the following formula:

```
workMem = (instance.memory.size - configuration.sharedBuffers) * 4 / configuration.maxConnections
```

For example, for Postgres with the following parameters:

- `instance.memory.size: 4Gi`
- `configuration.sharedBuffers: 1Gi`
- `configuration.maxConnections: 200`

The `workMem` calculation looks as follows:

```
workMem = (4Gi - 1Gi) * 4 / 200
workMem = 3Gi * 4 / 200
workMem = 12Gi / 200
workMem = 61.44Mi
```

The `* 4` multiplier is a safety margin for the case of several concurrent sort and hash operations within a single query.

The controller calculates `workMem` using the formula above, based on the instance's memory size, `sharedBuffers`, `maxConnections`, and the safety margin.

Bind to dedicated nodes

The standard Kubernetes mechanisms — `spec.nodeSelector`, `spec.tolerations`, and `spec.nodeAffinity` — let you specify which nodes PostgreSQL pods can be placed on.

Placement on dedicated nodes helps isolate PostgreSQL instances from user applications and makes disk and network resource usage more predictable.

Below is a fragment of a PostgresClass manifest showing `spec.nodeAffinity`, `spec.nodeSelector`, and `spec.tolerations`. The complete example is provided in Example of creating a PostgresClass.

```
spec:
  nodeAffinity:
    requiredDuringSchedulingIgnoredDuringExecution:
      nodeSelectorTerms:
        - matchExpressions:
            - key: "node.deckhouse.io/group"
              operator: "In"
              values:
                - "pg"
  nodeSelector:
    "node.deckhouse.io/group": "pg"
  tolerations:
    - key: primary-role
      operator: Equal
      value: pg
      effect: NoSchedule
```

In this example:

- Pods are placed only on nodes with the `node.deckhouse.io/group=pg` label.
- Nodes have the `primary-role=pg:NoSchedule` taint, which prevents scheduling pods without a matching toleration.
- `tolerations` allows PostgreSQL pods to be scheduled on such nodes.

Users don't need to worry about node selection. Pods are automatically placed on the prepared infrastructure according to the PostgresClass settings.

If no node meets the placement rules, users' Postgres objects will remain in the `Pending` state. To determine the cause, you can check the events in the namespace, the Postgres object information, and the PVC status:

```
d8 k describe pods -n my-postgres <POD_NAME>
d8 k get events -n my-postgres --sort-by=.lastTimestamp
d8 k get pvc -n my-postgres
```

Backup and restore

Manual cluster restore

Restoring a cluster with a single control plane node

To properly restore the cluster, follow these steps on the master node:

1. Prepare the `etcdutl` utility. Locate and copy the executable on the node:

   ```
   ETCD_PID=$(crictl inspect $(crictl ps --name etcd -q | head -1) | jq .info.pid)
   cp /proc/${ETCD_PID}/root/usr/bin/etcdutl /usr/local/bin/etcdutl
   chmod +x /usr/local/bin/etcdutl
   ```

   Check the version of `etcdutl`:

   ```
   etcdutl version
   ```

   Make sure the output of `etcdutl version` is displayed without errors.

   If `etcdutl` is not found, download the binary from the official etcd repository, choosing a version that matches your cluster's etcd version:

   ```
   wget "https://github.com/etcd-io/etcd/releases/download/v3.6.1/etcd-v3.6.1-linux-amd64.tar.gz"
   tar -xzvf etcd-v3.6.1-linux-amd64.tar.gz && mv etcd-v3.6.1-linux-amd64/etcdutl /usr/local/bin/etcdutl
   ```

2. Check the etcd version in the cluster (if the Kubernetes API is accessible):

   ```
   d8 k -n kube-system exec -ti etcd-$(hostname) -- etcdutl version
   ```

   If the command executes successfully, it will display the current etcd version.

3. Stop etcd. Move the etcd manifest to prevent kubelet from launching the etcd pod:

   ```
   mv /etc/kubernetes/manifests/etcd.yaml ~/etcd.yaml
   ```

4. Make sure the etcd pod is stopped:

   ```
   crictl ps | grep etcd
   ```

If the command returns nothing, the etcd pod has been successfully stopped.

5. Backup current etcd data. Create a backup copy of the `member` directory:

   ```
   cp -r /var/lib/etcd/member/ /var/lib/deckhouse-etcd-backup
   ```

   This backup will allow you to roll back in case of issues.

6. Place the etcd snapshot file. Copy or move the `etcd-backup.snapshot` file to the current user's (root) home directory:

   ```
   cp /path/to/backup/etcd-backup.snapshot ~/etcd-backup.snapshot
   ```

   Ensure the file is readable:

   ```
   ls -la ~/etcd-backup.snapshot
   ```

7. Clean the etcd directory. Remove old data to prepare for restore:

   ```
   rm -rf /var/lib/etcd
   ```

   Verify that `/var/lib/etcd` is now empty or does not exist:

   ```
   ls -la /var/lib/etcd
   ```

8. Restore the etcd database from the snapshot using `etcdutl`:

   ```
   ETCDCTL_API=3 etcdutl snapshot restore ~/etcd-backup.snapshot  --data-dir=/var/lib/etcd
   ```

   After the command completes, check that files have appeared in `/var/lib/etcd/`, reflecting the restored state.

9. Start etcd. Move the manifest back so that kubelet relaunches the etcd pod:

   ```
   mv ~/etcd.yaml /etc/kubernetes/manifests/etcd.yaml
   ```

10. Wait for the pod to be created and reach `Running` state. Make sure it is up and running:

    ```
    crictl ps --label io.kubernetes.pod.name=etcd-$HOSTNAME
    ```

    Pod startup may take some time. Once etcd is running, the cluster will be restored from the snapshot.

    Output example:

    ```
    CONTAINER        IMAGE            CREATED              STATE     NAME
    ATTEMPT     POD ID          POD
    4b11d6ea0338f    16d0a07aa1e26    About a minute ago   Running   etcd      0
    ee3c8c7d7bba6   etcd-gs-test
    ```

11. Restart the master node.

Restoring a multi-master cluster

To properly restore a multi-master cluster, follow these steps:

1. Enable High Availability (HA) mode. This is necessary to preserve at least one Prometheus replica and its PVC, since HA is disabled by default in single-master clusters.
2. Enable maintenance mode on the remaining master node to prevent `control-plane-manager` from creating new operations on it during the restore procedure (CPM will continue to remove components from the nodes being detached):

```
d8 k label cpn <REMAINING_MASTER_NAME> control-plane-manager.deckhouse.io/maintenance=""
```

3. Switch the cluster to single master mode:
   - In a cloud cluster, follow the instructions.
   - In a static cluster, remove any unnecessary master nodes from the `control-plane` role by following the instructions and then remove them from the cluster.
   - In a static cluster with the configured HA mode based on two master nodes and an arbiter node, remove the arbiter node and additional master nodes.
   - In a cloud cluster with the configured HA mode based on two master nodes and an arbiter node, use the instructions to remove the additional master nodes and the arbiter node.
4. Restore etcd from the backup on the only remaining master node. Follow the instructions for restoring a cluster with a single control-plane node.
5. Make sure the maintenance mode label is removed from the remaining master node (after restoring from the backup it is usually already gone, but it is better to verify explicitly):

   ```
   d8 k label cpn <REMAINING_MASTER_NAME> control-plane-manager.deckhouse.io/maintenance-
   ```
6. Once etcd is restored, remove the records of the previously deleted master nodes from the cluster using the following command (replace with the actual node name):

   ```
   d8 k delete node <MASTER_NODE_NAME>
   ```

   > **Warning.** If the `d8 k` or `kubectl` commands are unavailable on the node, check the `/etc/kubernetes/kubernetes-api-proxy/upstreams.json` configuration file. It should only specify your current API server. If the configuration contains lines with IP addresses of old master nodes, remove them. Edit the configuration in a similar way on all other nodes.
7. Reboot the master node. Ensure that the other nodes transition to the `Ready` state.
8. Wait for Deckhouse to process all tasks in the queue:

   ```
   d8 system queue main
   ```
9. Switch the cluster back to multi-master mode. For cloud clusters, follow the instructions.

Once you go through these steps, the cluster will be successfully restored in the multi-master configuration.

Restoring individual objects

Restoring Kubernetes objects from an etcd backup

To restore individual cluster objects (e.g., specific Deployments, Secrets, or ConfigMaps) from an etcd snapshot, follow these steps:

1. Launch a temporary etcd instance. Create a separate etcd instance that runs independently from the main cluster.
2. Load data from backup copy into temporary etcd instance. Use the existing etcd snapshot file to populate the temporary instance with the necessary data.
3. Unload the manifests of the necessary objects in YAML format.
4. Restore cluster objects from uploaded YAML files.

Example of steps to restore objects from an etcd backup

In the example below, `etcd-backup.snapshot` is a etcd shapshot, `infra-production` is the namespace in which objects need to be restored.

- To decode objects from `etcd` you would need auger. It can be built from source on any machine that has Docker installed (it cannot be done on cluster nodes).

```
git clone -b v1.0.1 --depth 1 https://github.com/etcd-io/auger
cd auger
make release
build/auger -h
```

- Resulting executable `build/auger`, and also the `snapshot` from the backup copy of etcd must be uploaded on master-node, on which following actions would be performed.

Following actions are performed on a master node, to which `etcd snapshot` file and `auger` tool were copied:

1. Set the correct access permissions for the backup file:

   ```
   chmod 644 etcd-backup.snapshot
   ```

2. Set full path for snapshot file and for the tool into environmental variables:

   ```
   SNAPSHOT=/root/etcd-restore/etcd-backup.snapshot
   AUGER_BIN=/root/auger
   chmod +x $AUGER_BIN
   ```

3. Run a Pod with temporary instance of `etcd`.

   - Create Pod manifest. It should schedule on current master node by `$HOSTNAME` variable, and mounts snapshot file by `$SNAPSHOT` variable, which it then restores in temporary `etcd` instance:

```
cat <<EOF >etcd.pod.yaml
apiVersion: v1
kind: Pod
metadata:
  name: etcdrestore
  namespace: default
spec:
  nodeName: $HOSTNAME
  tolerations:
  - operator: Exists
  initContainers:
  - command:
    - etcdutl
    - snapshot
    - restore
    - "/tmp/etcd-snapshot"
    - --data-dir=/default.etcd
    image: $(kubectl -n kube-system get pod -l component=etcd -o jsonpath="
{.items[*].spec.containers[*].image}" | cut -f 1 -d ' ')
    imagePullPolicy: IfNotPresent
    name: etcd-snapshot-restore
    # Uncomment the fragment below to set limits for the container if the
node does not have enough resources to run it.
    # resources:
    #   requests:
    #     ephemeral-storage: "200Mi"
    #   limits:
    #     ephemeral-storage: "500Mi"
    volumeMounts:
    - name: etcddir
      mountPath: /default.etcd
    - name: etcd-snapshot
      mountPath: /tmp/etcd-snapshot
      readOnly: true
  containers:
  - command:
    - etcd
    image: $(kubectl -n kube-system get pod -l component=etcd -o jsonpath="
{.items[*].spec.containers[*].image}" | cut -f 1 -d ' ')
    imagePullPolicy: IfNotPresent
    name: etcd-temp
    volumeMounts:
    - name: etcddir
      mountPath: /default.etcd
  volumes:
  - name: etcddir
    emptyDir: {}
    # Use the snippet below instead of emptyDir: {} to set limits for the
container if the node's resources are insufficient to run it.
    # emptyDir:
    #  sizeLimit: 500Mi
  - name: etcd-snapshot
    hostPath:
      path: $SNAPSHOT
      type: File
EOF
```

- Create Pod from the resulting manifest:

```
d8 k create -f etcd.pod.yaml
```

4. Set environment variables. In this example:
   - `infra-production` — namespace which we will search resources in.
   - `/root/etcd-restore/output` — path for outputting recovered resource manifests.
   - `/root/auger` — path to `auger` executable.

   ```
   FILTER=infra-production
   BACKUP_OUTPUT_DIR=/root/etcd-restore/output
   mkdir -p $BACKUP_OUTPUT_DIR && cd $BACKUP_OUTPUT_DIR
   ```

5. Commands below will filter needed resources by `$FILTER` and output them into `$BACKUP_OUTPUT_DIR` directory:

   ```
   files=($(kubectl -n default exec etcdrestore -c etcd-temp -- etcdctl  --
   endpoints=localhost:2379 get / --prefix --keys-only | grep "$FILTER"))
   for file in "${files[@]}"
   do
     OBJECT=$(kubectl -n default exec etcdrestore -c etcd-temp -- etcdctl  --
   endpoints=localhost:2379 get "$file" --print-value-only | $AUGER_BIN decode)
     FILENAME=$(echo $file | sed -e "s#/registry/##g;s#/#_#g")
     echo "$OBJECT" > "$BACKUP_OUTPUT_DIR/$FILENAME.yaml"
     echo $BACKUP_OUTPUT_DIR/$FILENAME.yaml
   done
   ```

6. Restore objects from exported YAML files.
7. Delete the Pod with a temporary instance of etcd:

   ```
   d8 k -n default delete pod etcdrestore
   ```

Restoring cluster objects from exported YAML files

To restore objects from exported YAML files, follow these steps:

1. Prepare the YAML files for restoration. Before applying them to the cluster, remove technical fields that may be outdated or interfere with the recovery process:
   - `creationTimestamp`
   - `UID`
   - `status`

   You can edit these fields manually or use YAML/JSON processing tools such as `yq` or `jq`.
2. Create the objects in the cluster. To restore individual resources, run:

   ```
   d8 k create -f <PATH_TO_FILE>.json
   ```

   You can specify either a single file or a directory path.
3. To restore multiple objects at once, use the `find` command:

   ```
   find $BACKUP_OUTPUT_DIR -type f -name "*.yaml" -exec d8 k create -f {} \;
   ```

   This will locate all `.yaml` files within the specified `$BACKUP_OUTPUT_DIR` and apply them sequentially using `d8 k create`.

After completing these steps, the selected objects will be recreated in the cluster based on the definitions in the YAML files.

Restoring the licensing cluster key

Deckhouse Platform licensing keeps the cluster key and the registration counter in two objects:

- Secret `d8-system/cluster-key` holds the cluster key.
- ConfigMap `d8-system/license-registration` holds the counter of cluster data files. The

customer portal accepts a cluster data file only if its number is greater than the numbers of the files uploaded before.

A license key is issued for the cluster UUID, the one in the ConfigMap `kube-system/d8-cluster-uuid`, and can also be bound to the cluster key.

If the cluster has these objects, include both of them in its backups. An etcd backup contains them. To save them separately, run:

```
d8 k -n d8-system get configmap license-registration -o yaml > license-registration.yaml
d8 k -n d8-system get secret cluster-key -o yaml > cluster-key.yaml
```

Store `cluster-key.yaml` as securely as the other secrets of the cluster.

If the cluster key is damaged, or Deckhouse Platform has created a new one because the Secret was lost or the cluster was rebuilt from a backup, the license keys bound to the old cluster key stop applying. If the cluster still has the UUID the license keys were issued for, restore the cluster key from a backup. A cluster with another UUID needs license keys of its own whatever its cluster key: get them in the customer portal.

Only Deckhouse Platform and `system:sudouser` may change the two objects, so a backup tool cannot restore them on behalf of its own account. Restore them manually:

1. Take the manifests of both objects from the same backup, the most recent one, and prepare them as described in Restoring cluster objects from exported YAML files. Also remove the `resourceVersion` and `managedFields` fields.
2. Apply the manifests on behalf of `system:sudouser`. The command replaces the objects that Deckhouse Platform has created in their place:

   ```
   d8 k --as=system:sudouser apply --server-side --force-conflicts -f license-registration.yaml -f cluster-key.yaml
   ```

Deckhouse Platform picks up the restored key within an hour. After that, the license keys issued for the cluster apply again: both the ones restored from the backup and the ones uploaded again in the Deckhouse web UI section “Licensing”. To list the records that are still rejected as issued for another cluster key, run:

```
d8 k get clusterlicenses -o jsonpath='{range .items[*]}{range .status.records[?(@.reason=="ClusterKeyMismatch")]}{.id}: {.message}{"\n"}{end}{range .status.records[?(@.reason=="ClusterKeyMissing")]}{.id}: {.message}{"\n"}{end}{end}'
```

Once the key is picked up, the output is empty. A record rejected with the reason `ClusterMismatch` was issued for another cluster UUID, and restoring the key does not change it.

Restoring control plane component manifests from a control-plane-manager backup

Before applying any change to a control plane component (`etcd`, `kube-apiserver`, `kube-controller-manager`, or `kube-scheduler`), the `control-plane-manager` module automatically backs up the files it is about to overwrite on that node. Backups are stored per component and per operation in:

```
/etc/kubernetes/deckhouse/backup/<Component>/<operation-name>/
```

The `control-plane-manager` module keeps the 7 most recent operations per component. Older backups are removed automatically. The contents of a backup directory depend on the component. For example, for `kube-apiserver`, its static pod manifest, TLS certificates, and the `admin.conf` file are saved:

```
/etc/kubernetes/deckhouse/backup/KubeAPIServer/kubeapiserver-ef53e5-n2snk/
├── manifests/kube-apiserver.yaml
├── pki/apiserver.crt
├── pki/apiserver.key
└── admin.conf
```

Next to the backup in the `/etc/kubernetes/deckhouse/diffs/<component>/<operation-name>/` directory, the module keeps a unified diff file containing the differences of the changes made. For example:

```
/etc/kubernetes/deckhouse/diffs/KubeAPIServer/kubeapiserver-ef53e5-n2snk/
├── manifests/kube-apiserver.yaml.diff
└── extra-files/...
```

You can use these backups to revert a control plane component to its previous state — for example, after a change applied by `control-plane-manager` (such as one triggered by editing a ModuleConfig) broke the component.

To restore a control plane component file from a `control-plane-manager` backup, do the following:

1. On the target master node, list the available backups for the component and pick the operation to restore from:

   ```
   ls -lt /etc/kubernetes/deckhouse/backup/<COMPONENT>/
   ```

   Optionally, inspect the corresponding diff file to see what changed in that operation:

   ```
   cat /etc/kubernetes/deckhouse/diffs/<COMPONENT>/<OPERATION_NAME>/manifests/*.diff
   ```

2. Enable maintenance mode on the node's ControlPlaneNode resource. This prevents `control-plane-manager` from starting new operations on the node while you are restoring files manually. An operation already in progress is not affected.

   ```
   d8 k label cpn <NODE_NAME> control-plane-manager.deckhouse.io/maintenance=""
   ```

3. Copy the required file(s) from the backup directory back to their original location, preserving their relative path under `/etc/kubernetes`. For example, to restore the `kube-apiserver` manifest:

   ```
   cp /etc/kubernetes/deckhouse/backup/KubeAPIServer/<OPERATION_NAME>/manifests/kube-apiserver.yaml
   /etc/kubernetes/manifests/kube-apiserver.yaml
   ```

   Restoring a static pod manifest is enough to trigger kubelet to restart the pod automatically, and no manual restart is required.

4. If you restored certificates, keys, `admin.conf`, and similar files under `pki/` but didn't change the manifest itself, restart the corresponding component's pod manually. Kubelet only tracks changes in the manifest file and doesn't restart the container when mounted files are changed.

   Deleting the pod is enough for kubelet to recreate it from the unchanged static manifest:

   ```
   d8 k -n kube-system delete po <COMPONENT_POD_NAME>
   ```

   Here `<COMPONENT_POD_NAME>` is the static pod's name, for example, `kube-apiserver-<NODE_NAME>`.

   If the API server itself is unreachable (for example, if you are restoring a certificate of a single control plane node, making the API server unreachable), restart the container directly on the node instead:

   ```
   crictl stopp $(crictl pods --name=<COMPONENT_NAME> -q)
   ```

5. Make sure the component came back up healthy:

   ```
   d8 k -n kube-system wait pod \
     --timeout=10m \
     --for=condition=ContainersReady \
     -l app=d8-control-plane-manager \
     --field-selector spec.nodeName=<NODE_NAME>
   ```

6. Disable maintenance mode:

   ```
   d8 k label cpn <NODE_NAME> control-plane-manager.deckhouse.io/maintenance-
   ```

⚠ Restoring files from a backup only reverts their on-disk state. If the change you're reverting is still requested by the current cluster configuration (for example, set in a ModuleConfig), `control-plane-manager` will detect the drift and create a new operation to reapply it as soon as maintenance mode is disabled. If you want to keep the restored state, modify the initial cluster configuration first.

Restoring objects after changing the master node IP address

⚠ This section describes a scenario where only the IP address of the master node has changed, and all other objects in the etcd backup (such as CA certificates) remain valid. It assumes the restoration is performed in a single-master-node cluster.

To restore etcd objects after changing the master node's IP address, follow these steps:

1. Restore etcd from the backup. Use the standard etcd restore procedure with a snapshot. Make sure not to change any parameters during restoration other than the etcd data itself.
2. Update the IP address in static configuration files:
   - Check the Kubernetes component manifest files located in `/etc/kubernetes/manifests/`.
   - Review kubelet's system configuration files (typically found in `/etc/systemd/system/kubelet.service.d/` or similar directories).
   - Update the IP address in any other configurations that reference the old address, if necessary.
3. Back up the current certificates:

   ```
   cp -r /etc/kubernetes/pki ./pki-backup
   ```

4. Renew control-plane certificates with the new IP address added to SANs:

   ```
   d8 tools pki certs renew all --san <NEW_IP>
   ```

5. Restart all services so that components load the updated certificates and configurations.
6. Wait for kubelet to regenerate its own certificate.

These actions can be performed either automatically using a script, or manually by running the required commands step-by-step.

Automated object extraction when changing IP address

To simplify cluster recovery after the master node's IP address changes, use the script provided below. Before running the script:

1. Specify the correct paths and IP addresses:
   - `ETCD_SNAPSHOT_PATH`: The path to the etcd snapshot backup.
   - `OLD_IP`: The old master node IP address used when the backup was created.
   - `NEW_IP`: The new IP address of the master node.
2. Download `etcdutl` if it is not installed.
3. After running the script, wait for the kubelet to regenerate its certificate with the new IP address. You can verify this in the `/var/lib/kubelet/pki/` directory, where a new certificate should appear.

Object extraction script

```
ETCD_SNAPSHOT_PATH="./etcd-backup.snapshot" # Path to the etcd snapshot.
OLD_IP=10.242.32.34                         # Old master node IP address.
NEW_IP=10.242.32.21                         # New master node IP address.
NODE_NAME=master-0                          # Must match --name in the etcd static pod
manifest.

mv /etc/kubernetes/manifests/etcd.yaml ~/etcd.yaml
mkdir ./etcd_old
mv /var/lib/etcd ./etcd_old
ETCD_PID=$(crictl inspect $(crictl ps --name etcd -q | head -1) | jq .info.pid)
ETCDUTL_PATH=/proc/${ETCD_PID}/root/usr/bin/etcdutl

$ETCDUTL_PATH snapshot restore "$ETCD_SNAPSHOT_PATH" \
  --data-dir=/var/lib/etcd \
  --name="$NODE_NAME" \
  --initial-advertise-peer-urls="https://$NEW_IP:2380" \
  --initial-cluster="$NODE_NAME=https://$NEW_IP:2380"

find /etc/kubernetes/ -type f -exec sed -i "s/$OLD_IP/$NEW_IP/g" {} ';'
find /etc/systemd/system/kubelet.service.d -type f -exec sed -i "s/$OLD_IP/$NEW_IP/g" {} ';'
find /var/lib/bashible/ -type f -exec sed -i "s/$OLD_IP/$NEW_IP/g" {} ';'
sed -i "s/$OLD_IP/$NEW_IP/g" ~/etcd.yaml

cp -r /etc/kubernetes/pki ./pki-backup

d8 tools pki certs renew all --san $NEW_IP

mv ~/etcd.yaml /etc/kubernetes/manifests/etcd.yaml

crictl ps --name 'kube-apiserver' -o json | jq -r '.containers[0].id' | xargs crictl stop
crictl ps --name 'kubernetes-api-proxy' -o json | jq -r '.containers[0].id' | xargs crictl
stop
crictl ps --name 'etcd' -o json | jq -r '.containers[].id' | xargs crictl stop

systemctl daemon-reload
systemctl restart kubelet.service
```

Manual object restore after changing the IP address

If you prefer to manually make changes during cluster recovery after the master node’s IP address has changed, follow these steps:

1. Restore etcd from the backup:
   - Move the etcd manifest so that kubelet stops the corresponding pod:

     ```
     mv /etc/kubernetes/manifests/etcd.yaml ~/etcd.yaml
     ```

   - Create a directory to temporarily store the previous etcd data:

     ```
     mkdir ./etcd_old
     mv /var/lib/etcd ./etcd_old
     ```

   - Find or download the `etcdutl` utility if it’s not available, and perform the snapshot restore:

```
ETCD_SNAPSHOT_PATH="./etcd-backup.snapshot" # Path to the etcd snapshot.
NEW_IP=10.242.32.21                         # New master node IP address.
NODE_NAME=master-0                          # Must match --name in the etcd static
pod manifest.
ETCD_PID=$(crictl inspect $(crictl ps --name etcd -q | head -1) | jq .info.pid)
ETCDUTL_PATH=/proc/${ETCD_PID}/root/usr/bin/etcdutl

$ETCDUTL_PATH snapshot restore "$ETCD_SNAPSHOT_PATH" \
  --data-dir=/var/lib/etcd \
  --name="$NODE_NAME" \
  --initial-advertise-peer-urls="https://$NEW_IP:2380" \
  --initial-cluster="$NODE_NAME=https://$NEW_IP:2380"
```

2. Update the IP address in static configuration files. If the old IP address is used in manifests or kubelet services, replace it with the new one:

```
OLD_IP=10.242.32.34                     # Old master node IP address.
NEW_IP=10.242.32.21                     # New master node IP address.

find /etc/kubernetes/ -type f -exec sed -i "s/$OLD_IP/$NEW_IP/g" {} ';'
find /etc/systemd/system/kubelet.service.d -type f -exec sed -i "s/$OLD_IP/$NEW_IP/g" {}
';'
find /var/lib/bashible/ -type f -exec sed -i "s/$OLD_IP/$NEW_IP/g" {} ';'
sed -i "s/$OLD_IP/$NEW_IP/g" ~/etcd.yaml
```

3. Back up the current certificates:

```
cp -r /etc/kubernetes/pki ./pki-backup
```

4. Renew control-plane certificates with the new IP address added to SANs:

```
d8 tools pki certs renew all --san <NEW_IP>
```

5. Restore the etcd manifest (so kubelet starts the etcd pod again) and restart all services so that components load the updated certificates and configurations. To immediately stop active containers, run:

```
mv ~/etcd.yaml /etc/kubernetes/manifests/etcd.yaml

crictl ps --name 'kube-apiserver' -o json | jq -r '.containers[0].id' | xargs crictl
stop
crictl ps --name 'kubernetes-api-proxy' -o json | jq -r '.containers[0].id' | xargs
crictl stop
crictl ps --name 'etcd' -o json | jq -r '.containers[].id' | xargs crictl stop

systemctl daemon-reload
systemctl restart kubelet.service
```

   Verify etcd is running by checking the pod list using `crictl ps | grep etcd` or reviewing the kubelet logs.

6. Wait for kubelet to regenerate its own certificate. Kubelet will automatically generate a new certificate with the updated IP address:
   - Check the `/var/lib/kubelet/pki/` directory.
   - Ensure the new certificate is present and valid.

Once these steps are completed, the cluster will be successfully restored and fully functional with the new master node IP address.

Creating backups with Deckhouse CLI

Deckhouse CLI (`d8`) provides the `backup` command for creating backups of various cluster components:

- `etcd`: Snapshot of the Deckhouse key-value data store.

- `cluster-config`: Archive containing key configuration objects of the cluster.
- `loki`: Export of logs from the built-in Loki API.

Backing up etcd

An etcd snapshot allows you to preserve the current state of the cluster at the key-value storage level. This is a full dump that can be used for recovery.

To create a snapshot, run the following command:

```
d8 backup etcd <path-to-snapshot> [flags]
```

Flags:

- `-p`, `--etcd-pod string`: Name of the etcd pod to snapshot.
- `-h`, `--help`: Show help for the etcd command.
- `--verbose`: Enable verbose output for detailed logging.

Example:

```
d8 backup etcd etcd-backup.snapshot
```

Example output:

```
2025/04/22 08:38:58 Trying to snapshot etcd-sandbox-master-0
2025/04/22 08:39:01 Snapshot successfully taken from etcd-sandbox-master-0
```

Automatic etcd backup

Deckhouse automatically performs a daily etcd backup using a CronJob that runs inside the `d8-etcd-backup` pod in the `kube-system` namespace. The job creates a snapshot of the database, compresses it, and saves the archive locally on the node at `/var/lib/etcd/`:

```
etcdctl snapshot save etcd-backup.snapshot
tar -czvf etcd-backup.tar.gz etcd-backup.snapshot
mv etcd-backup.tar.gz /var/lib/etcd/etcd-backup.tar.gz
```

To configure automatic etcd backups, use the `control-plane-manager` module. The required parameters are specified in its configuration:

Parameter	Description
`etcd.backup.enabled`	Enables daily etcd backup.
`etcd.backup.cronSchedule`	Cron-formatted schedule for running the backup. Local time of `kube-controller-manager` is used.
`etcd.backup.hostPath`	Path on master nodes where etcd backup archives will be stored.

Example configuration fragment:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  enabled: true
  settings:
    etcd:
      backup:
        cronSchedule: 0 14 * * *
        enabled: true
```

Backups on different master nodes run with a 15-minute offset from each other, so the archives on different nodes can contain snapshots taken at different times. If a backup job fails on a node, its archive can be even older. To restore, use the snapshot with the highest revision. To find out the revision, unpack the archive and run:

```
tar -xzf etcd-backup.tar.gz
etcdutl snapshot status etcd-backup.snapshot -w table
```

Cluster configuration backup

The `d8 backup cluster-config` command creates an archive containing a set of key resources related to the cluster configuration. This is not a full backup of all objects, but a specific whitelist.

To create the backup, run the following command:

```
d8 backup cluster-config <path-to-backup-file>
```

Example:

```
d8 backup cluster-config /backup/cluster-config-2025-04-21.tar
```

The archive includes only those objects that meet the following criteria:

- CustomResource objects whose CRDs are annotated with:

  ```
  backup.deckhouse.io/cluster-config=true
  ```

- StorageClasses with the label:

  ```
  heritage=deckhouse
  ```

- Secrets and ConfigMaps from namespaces starting with `d8-` or `kube-`, if they are explicitly listed in the whitelist file.
- Cluster-level Roles and Bindings (ClusterRole and ClusterRoleBinding), if they are not labeled with:

  ```
  heritage=deckhouse
  ```

> **i** The backup includes only CR objects, but not the CRD definitions themselves. To fully restore the cluster, the corresponding CRDs must already be present (e.g., installed by Deckhouse modules).

Example whitelist content:

Namespace	Object	Name
`d8-system`	Secret	`d8-cluster-terraform-state`
		`$regexp:^d8-node-terraform-state-(.*)$`
		`deckhouse-registry`
	ConfigMap	`d8-deckhouse-version-info`
`kube-system`	ConfigMap	`d8-cluster-is-bootstraped`
		`d8-cluster-uuid`
		`extension-apiserver-authentication`
	Secret	`d8-cloud-provider-discovery-data`
		`d8-cluster-configuration`
		`d8-cni-configuration`

Namespace	Object	Name
		`d8-control-plane-manager-config`
		`d8-node-manager-cloud-provider`
		`d8-pki`
		`d8-provider-cluster-configuration`
		`d8-static-cluster-configuration`
		`d8-secret-encryption-key`
`d8-cert-manager`	Secret	`cert-manager-letsencrypt-private-key`
		`selfsigned-ca-key-pair`

Exporting logs from Loki

The `d8 backup loki` command is intended for exporting logs from the built-in Loki. This is not a full backup, but rather a diagnostic export: the resulting data cannot be restored back into Loki.

To perform the export, `d8` accesses the Loki API using the `loki` ServiceAccount in the `d8-monitoring` namespace, authenticated via a token stored in a Kubernetes secret.

The `loki` ServiceAccount is automatically created starting from Deckhouse v1.69.0. However, to use the `d8 backup loki` command, you must manually create the token secret and assign the necessary Role and RoleBinding if they are not already present.

Apply the manifests below before running `d8 backup loki` to ensure the command can properly authenticate and access the Loki API.

Example manifests:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: loki-api-token
  namespace: d8-monitoring
  annotations:
    kubernetes.io/service-account.name: loki
type: kubernetes.io/service-account-token
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  name: access-to-loki-from-d8
  namespace: d8-monitoring
rules:
  - apiGroups: ["apps"]
    resources:
      - "statefulsets/http"
    resourceNames: ["loki"]
    verbs: ["create", "get"]
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: access-to-loki-from-d8
  namespace: d8-monitoring
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: Role
  name: access-to-loki-from-d8
subjects:
  - kind: ServiceAccount
    name: loki
    namespace: d8-monitoring
```

To create a log backup, run the following command:

```
d8 backup loki [flags]
```

Example:

```
d8 backup loki --days 1 > ./loki.log
```

Flags:

- `--start`, `--end`: Time range boundaries in the format “YYYY-MM-DD HH:MM:SS”.
- `--days`: The time window size for log export (default is 5 days).
- `--limit`: The maximum number of log lines per request (default is 5000).

You can list all available flags using the following command:

```
d8 backup loki --help
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Automatic assignment of namespace labels and annotations

You can automate the assignment of labels and annotations to namespaces in a Deckhouse cluster based on predefined patterns. This can be useful, for example, to automatically include new namespaces in monitoring without having to manually edit each one.

How it works

- All namespaces whose names match the patterns in `includeNames` and do not match patterns in `excludeNames` automatically receive the specified labels and annotations.
- When the configuration is changed, labels and annotations of existing namespaces are updated accordingly.
- Newly created namespaces that match the defined patterns also receive the specified labels and annotations automatically.

Configuring automatic label and annotation assignment

Enable the `namespace-configurator` module:

```
d8 system module enable namespace-configurator
```

Configure automatic label and annotation assignment in ModuleConfig `namespace-configurator`:

1. Specify the annotations and labels to be applied to namespaces in the fields `settings.configurations.annotations` and `settings.configurations.labels`, respectively;
2. Define the matching rules for namespace names:
   - In `includeNames`, list regular expressions for names you want to match.
   - In `excludeNames`, list names that should be excluded.

Example configuration

In the following configuration example, automatic addition of the label `extended-monitoring.deckhouse.io/enabled=true` and the annotation `foo=bar` is configured for all namespaces whose names start with `prod-` or `infra-`, except for `infra-test`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: namespace-configurator
spec:
  version: 1
  enabled: true
  settings:
    configurations:
    - annotations:
        foo: bar
      labels:
        extended-monitoring.deckhouse.io/enabled: "true"
      includeNames:
      - "^prod"
      - "^infra"
      excludeNames:
      - "infra-test"
```

Application delivery with Argo CD

This section describes application delivery with Argo CD in Deckhouse Platform (DP).

Argo CD is an Open Source tool for continuous delivery of applications to Kubernetes that implements the GitOps approach. A Git repository is the source of truth for describing applications, their configuration, and target environments.

Argo CD tracks changes, shows differences between the desired and actual resource state, and when needed brings the cluster to the target state automatically or manually.

Main Argo CD capabilities:

- automatic and manual application deployment in Kubernetes;
- visualization of differences between the desired and actual state;
- tracking application configuration in Git;
- working with multiple Kubernetes clusters;
- access control through its own role model;
- rollback to a previously recorded configuration and action audit;
- working through the web interface, CLI, and API, including integration with Git webhooks and external automation systems.

In DP, Argo CD is run with the operator-argo module, based on the Argo CD Operator project. The module lets you declaratively deploy and maintain one or more Argo CD instances in a DP cluster without manually installing and maintaining components.

Additionally, the module provides:

- single sign-on (SSO) support;
- integration with monitoring in DP;
- high availability mode;
- support for automatic image updates via Argo CD Image Updater;
- access control for cluster resources.

A typical administrator setup scenario:

1. Enable the `operator-argo` module and create an ArgoCD object.
2. Configure user authentication.
3. Define the role-based access model.
4. Give users access to the Argo CD instance for application delivery (for more details, see the Usage section).

The design of the `operator-argo` module is described in the Architecture section. Module parameters and custom resources are documented in the `operator-argo` module documentation.

Running Argo CD

This section describes the steps required to run an Argo CD instance in a DP cluster:

- Preparing to run Argo CD
- Deploying one or multiple Argo CD instances
- Additional settings for Argo CD

Preparing to run Argo CD

Before creating Argo CD instances, complete the following steps:

1. Enable the `operator-argo` module.
2. Wait until the module switches to the `Ready` state.

   You can check the module state in the DP web interface or with the following command:

   ```
   d8 k get module operator-argo -W
   ```

Detailed information about module settings is available in the `operator-argo` module documentation.

After you enable the `operator-argo` module, Argo CD custom resources become available in the DP cluster.

To run an Argo CD instance, create an ArgoCD object. Working with custom resources that belong to an Argo CD instance is described in the Usage section.

List of Argo CD custom resources created by the `operator-argo` module...

CRD	Scope	Purpose
`argocds.argoproj.io`	**`operator-argo` module**	A custom resource used by the `operator-argo` module to configure and maintain an Argo CD instance in the target environment. Installation parameters, component set, integrations, access policies, and other instance settings are defined through the ArgoCD object.
`appprojects.argoproj.io`	**Argo CD instance**	Used for logical segmentation of applications and for defining policies: allowed Git repositories, target clusters and namespaces, as well as access rules and restrictions on resource usage.
`applications.argoproj.io`	**Argo CD instance**	The main Argo CD application CRD for describing an application that must be synchronized from a declarative source (Git, Helm, Kustomize, and others) into Kubernetes. Defines the source, target environment, and synchronization parameters.
`applicationsets.argoproj.io`	**Argo CD instance**	Used for automated creation of a set of Application objects from a template. Suitable for mass application management scenarios across multiple clusters, environments, directories, teams, or repository branches.

CRD	Scope	Purpose
`argocdexports.argoproj.io`	**Argo CD instance**	Used for declarative export of data related to an Argo CD instance to external systems or related DP components. Typically applied in integration scenarios where configuration, status, or access information must be published in a formalized way.
`namespacemanagements.argoproj.io`	**Argo CD instance**	Used to manage the lifecycle of namespaces within GitOps processes. Can automate creation, configuration, and maintenance of namespaces into which applications are then deployed.
`notificationsconfigurations.argoproj.io`	**Argo CD instance**	Used to configure the Argo CD notification mechanism. Lets you declaratively describe delivery channels and rules for sending events related to synchronization, deployment errors, application status changes, and other operational events.
`imageupdaters.argocd-image-updater.argoproj.io`	**Argo CD instance**	Used to automatically track new container image versions and update application parameters according to the defined versioning and publishing strategy.

Deploying an Argo CD instance

Parameters available for configuring an Argo CD instance are listed in the `operator-argo` module documentation.

To deploy an Argo CD instance in the `argocd` namespace and publish the Argo CD web interface through Ingress, use the following example (provide your own values for `<ARGOCD_DOMAIN>` and `<TLS_SECRET_NAME>`):

```
apiVersion: v1
kind: Namespace
metadata:
  name: argocd
---
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  server:
    host: <ARGOCD_DOMAIN>
    ingress:
      enabled: true
      tls:
        - hosts:
            - <ARGOCD_DOMAIN>
          secretName: <TLS_SECRET_NAME>
    insecure: true
---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: argocd-ingress
  namespace: argocd
spec:
  dnsNames:
    - <ARGOCD_DOMAIN>
  issuerRef:
    kind: ClusterIssuer
    name: letsencrypt
  secretName: <TLS_SECRET_NAME>
```

⚠ The `spec.server.insecure: true` parameter in the example above disables internal TLS on the Argo CD API server. This helps avoid redirect loops when publishing through Ingress.

After you create the ArgoCD object, Argo CD components are started in the `argocd` namespace:

```
d8 k -n argocd get pods
NAME                                  READY   STATUS    RESTARTS   AGE
argocd-application-controller-0       1/1     Running   0          35m
argocd-dex-server-759fff8444-zglp4    1/1     Running   0          2d23h
argocd-redis-568f5b889c-jg5dr         1/1     Running   0          4d
argocd-repo-server-78d9d6bcc6-9rwcm   1/1     Running   0          3d22h
argocd-server-76597597f9-kfqdl        1/1     Running   0          35m
```

When all components switch to the `Running` status, the web interface of the Argo CD instance becomes available at the address specified in the `spec.server.ingress.tls.hosts` parameter (in the example — `https://<ARGOCD_DOMAIN>`). Authentication setup and credentials retrieval are described in the Configuring authentication and authorization section.

Application delivery with Argo CD is described in the Usage section.

i You can work with Argo CD not only through the web interface and custom resources, but also with the `argocd` CLI utility. You can download the binary from the “Documentation” section of the Argo CD web interface. To get help for the CLI utility, run `argocd --help`.

Deploying multiple Argo CD instances

If the cluster needs multiple Argo CD instances, create a separate namespace (or DP project) and a separate ArgoCD object for each of them.

For example, create:

- a separate instance for the production environment;
- a separate instance for test environments;
- a separate instance for a specific team or project.

With this approach, each Argo CD instance is managed independently and has its own configuration.

⚠ Creating more than one ArgoCD object in a single namespace is not supported.

Advanced settings

Enabling high availability mode

To enable high availability mode, set the `spec.ha.enabled: true` parameter in the ArgoCD object.

Example:

```
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  ha:
    enabled: true
    resources:
      requests:
        cpu: "500m"
        memory: "512Mi"
      limits:
        cpu: "1"
        memory: "1Gi"
```

⚠ High availability mode provides high availability only for the `Redis` state store using `HAProxy`. It does not automatically make all Argo CD components highly available.

i

Running Argo CD in high availability mode requires at least three cluster nodes because of `pod anti-affinity` rules. Clusters that use IPv6 only are not supported.

When high availability mode is enabled, changes in `.spec.redis.resources` are not applied. Configure resource limits and requests for `Redis` through the `.spec.ha.resources` parameter.

Granting access to cluster resources

By default, an Argo CD instance receives privileges only for the namespace where it runs and for namespaces labeled with `argocd.argoproj.io/managed-by`. The label value must match the name of the namespace where the Argo CD instance runs.

To allow creation of cluster-wide resources, specify the namespace of the target Argo CD instance in the `clusterConfigNamespaces` parameter of the `operator-argo` module settings.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: operator-argo
spec:
  enabled: true
  settings:
    clusterConfigNamespaces: argocd
  version: 1
```

If there are multiple Argo CD instances, list them in the `clusterConfigNamespaces` parameter as a comma-separated list.

After you change the `ModuleConfig`, the following ClusterRole and ClusterRoleBinding objects are created automatically:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  annotations:
    argocds.argoproj.io/name: argocd
    argocds.argoproj.io/namespace: argocd
  labels:
    app.kubernetes.io/managed-by: argocd
    app.kubernetes.io/name: argocd
    app.kubernetes.io/part-of: argocd
  name: argocd-argocd-argocd-application-controller
rules:
- apiGroups:
  - '*'
  resources:
  - '*'
  verbs:
  - '*'
- apiGroups:
  - ""
  resources:
  - serviceaccounts
  verbs:
  - impersonate
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  annotations:
    argocds.argoproj.io/name: argocd
    argocds.argoproj.io/namespace: argocd
  labels:
    app.kubernetes.io/managed-by: argocd
    app.kubernetes.io/name: argocd-application-controller
    app.kubernetes.io/part-of: argocd
  name: argocd-argocd-argocd-application-controller

roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: argocd-argocd-argocd-application-controller
subjects:
- kind: ServiceAccount
  name: argocd-argocd-application-controller
  namespace: argocd
```

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  annotations:
    argocds.argoproj.io/name: argocd
    argocds.argoproj.io/namespace: argocd
  labels:
    app.kubernetes.io/managed-by: argocd
    app.kubernetes.io/name: argocd
    app.kubernetes.io/part-of: argocd

  - update
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  annotations:
    argocds.argoproj.io/name: argocd
    argocds.argoproj.io/namespace: argocd
  labels:
    app.kubernetes.io/managed-by: argocd
    app.kubernetes.io/name: argocd-server
    app.kubernetes.io/part-of: argocd
  name: argocd-argocd-argocd-server
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: argocd-argocd-argocd-server
subjects:
- kind: ServiceAccount
```

```
  name: argocd-argocd-server
  namespace: argocd
```

> **i** If the privileges described in the default cluster roles are excessive, set `spec.defaultClusterScopedRoleDisabled: true` in the ArgoCD object settings. In this case, cluster roles are not created automatically, and you can define the required privilege level for the ServiceAccount used by the Argo CD instance yourself.

> **i** If needed, you can override the access level to cluster resources at the AppProject object level using the `spec.clusterResourceBlacklist` and `spec.clusterResourceWhitelist` parameters.

Using a custom cluster domain

If the cluster uses a domain other than `cluster.local`, specify it in the `spec.clusterDomain` parameter of the ArgoCD object.

Example:

```
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  clusterDomain: prod.local
```

Additional resources

- Official Argo CD website
- Official Argo CD Operator website
- Module `operator-argo` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring authentication and authorization

Argo CD supports local authentication and is also integrated with the Deckhouse Platform identity and access subsystem. You can learn more about configuring authentication and authorization in the DP documentation.

> **⚠** If no additional settings are defined in the ArgoCD object, the local `admin` account with the `admin` role is active by default.

You can learn about managing user and group permissions in the Configuring role-based access control section.

Local authentication

When an ArgoCD object is created, the `admin` user with the `admin` role is created automatically. The `admin` user password is generated automatically. To retrieve it, run:

```
d8 k -n argocd get secret argocd-cluster -o jsonpath='{.data.admin\.password}' | base64 -d
```

⚠ We recommend changing the automatically generated `admin` user password using Argo CD CLI command:

```
argocd login <ARGOCD_DOMAIN>:443 --username admin --password <ADMIN_PASSWORD>
argocd account update-password \
  --account admin \
  --current-password <ADMIN_PASSWORD> \
  --new-password <NEW_PASSWORD>
```

Creating additional local users

When creating a local user, you can define whether the user has access to the Argo CD web interface (the `login` attribute) and/or to the Argo CD API (the `apiKey` attribute).

To create local users, set the `spec.localUsers` parameter of ArgoCD, for example:

```
d8 k create -f - <<EOF
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  localUsers:
    # The "deploy" user with rights to sign in to the web interface and generate
tokens.
    - name: deploy
      apiKey: true
      login: true
      enabled: true
    # The "ci-bot" user for automation only, without web interface access.
    - name: ci-bot
      apiKey: true
      login: false
      enabled: true
EOF
```

After creating the user and applying the ArgoCD object manifest, generate a password for web interface access if the user has been granted the corresponding rights.

To set a password through a Secret, first calculate its bcrypt hash, then encode the result in Base64:

```
ARGOCD_USER=<USER_NAME>
ARGOCD_PASS=$(echo -n '<USER_PASSWORD>' | htpasswd -BinC 10 "" | cut -d: -f2 | tr -d '\n'
| base64 -w0)
d8 k -n argocd patch secret argocd-secret -p "{\"data\":
{\"accounts.$ARGOCD_USER.password\":\"$ARGOCD_PASS\"}}"
```

i You can set or change a local user password with the `argocd` CLI utility:

```
argocd login <ARGOCD_DOMAIN>:443 --username admin --password <ADMIN_PASSWORD>
argocd account update-password \
  --account <ACCOUNT> \
  --current-password <ADMIN_PASSWORD> \
  --new-password <NEW_PASSWORD>
```

Creating a user token

To work with the API, the user must have the corresponding rights (the `apiKey` parameter; see the

example in the section above). To issue a token, use the Argo CD web interface or the `argocd` CLI utility.

To issue a token through the web interface, go to “Settings” → “Accounts”, select the required user, and click “Generate New” in the “Tokens” section.

To issue a token with the `argocd` CLI utility, run the following commands (provide the required values):

```
argocd login <ARGOCD_DOMAIN>:443 --username admin
argocd account generate-token --account <ACCOUNT>
```

> **i** If the user does not have web interface access rights (`login`), another user with administrator rights can issue a token for them.

Disabling local authentication

To disable local authentication, disable the `admin` user by setting the `spec.disableAdmin` parameter of ArgoCD to `true`. Also remove all additional local users if they were created earlier (for details, see Creating additional local users).

After disabling local authentication, review the access rules in the Configuring role-based access control section.

SSO authentication

Before configuring the ArgoCD object, create a DexClient object. It is used as an OAuth2 client and is required for integration with Deckhouse Platform:

```
d8 k create -f -<<EOF
apiVersion: deckhouse.io/v1
kind: DexClient
metadata:
  name: argocd
  namespace: argocd
spec:
  redirectURIs:
    - https://<ARGOCD_DOMAIN>/api/dex/callback
    - https://<ARGOCD_DOMAIN>/api/dex/callback-reserve
EOF
```

`<ARGOCD_DOMAIN>` is the fully qualified domain name (FQDN) set in the `.spec.server.host` section of ArgoCD.

Wait until Deckhouse Platform creates a Secret with the client secret key:

```
d8 k -n argocd get secret/dex-client-argocd
```

Configure the ArgoCD object to use SSO in Deckhouse Platform:

```
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  rbac:
    scopes: "[groups, email]"
  sso:
    dex:
      config: |
        connectors:
          - type: oidc
            id: deckhouse
            name: deckhouse
            config:
              issuer: "https://dex.<CLUSTER_DOMAIN>/"
              clientID: "dex-client-argocd@argocd"
              clientSecret: "$dex-client-argocd:clientSecret"
              insecureEnableGroups: true
              scopes:
                - profile
                - email
                - openid
                - groups
    provider: dex
  server:
    host: <ARGOCD_DOMAIN>
    ingress:
      enabled: true
      ingressClassName: <INGRESS_CLASS_NAME>
      tls:
        - hosts:
           - <ARGOCD_DOMAIN>
          secretName: argocd-ingress-tls
    insecure: true
```

Restart the Argo CD server:

```
d8 k -n argocd rollout restart deploy/argocd-server
```

⚠ If you do not restart the Argo CD server, the sign-in attempt fails, and an error message appears in the Argo CD server log (issue argoproj/argo-cd#13526).

Example error message...

```
time="2024-10-16T14:12:59Z" level=warning msg="Failed to verify token: failed to verify token:
token verification failed for all audiences: error for aud \"argo-cd\": Failed to query provider
\"https://argocd.<ARGOCD_DOMAIN>/api/dex\": Get \"https://argocd.<ARGOCD_DOMAIN>/api/dex/.well-
known/openid-configuration\": tls: failed to verify certificate: x509: certificate is valid for
ingress.local, not argocd.<ARGOCD_DOMAIN>, error for aud \"argo-cd-cli\": Failed to query provider
\"https://argocd.<ARGOCD_DOMAIN>/api/dex\": Get \"https://argocd.<ARGOCD_DOMAIN>/api/dex/.well-
known/openid-configuration\": tls: failed to verify certificate: x509: certificate is valid for
ingress.local, not argocd.<ARGOCD_DOMAIN>"
```

Using a self-signed certificate

First obtain the self-signed certificate used by the Deckhouse Platform identity and access subsystem:

```
d8 k -n d8-user-authn get secret ingress-tls -o jsonpath='{.data.tls\.crt}' | base64 -d
```

Then add the obtained certificate to the OIDC connector configuration in the `rootCAs` section of ArgoCD:

```
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  sso:
    dex:
      config: |
        connectors:
          - type: oidc
            id: deckhouse
            name: deckhouse
            config:
              issuer: "https://dex.<CLUSTER_DOMAIN>/"
              rootCAs:
                - |
                  -----BEGIN CERTIFICATE-----
                  <Self-signed certificate obtained in the previous step>
                  -----END CERTIFICATE-----
              clientID: "dex-client-argocd@argocd"
              clientSecret: "$dex-client-argocd:clientSecret"
              insecureEnableGroups: true
              scopes:
                - profile
                - email
                - openid
                - groups
    provider: dex
  server:
    host: <ARGOCD_DOMAIN>
    ingress:
      enabled: true
      tls:
        - hosts:
            - <ARGOCD_DOMAIN>
          secretName: argocd-ingress-tls
    insecure: true
```

Creating a user token

Argo CD does not allow issuing permanent tokens for users authenticated with SSO. At the same time, such users can use the `argocd` CLI utility by specifying the `--sso` flag during authentication:

```
argocd login <ARGOCD_DOMAIN>:443 --sso
```

When this command runs on the administrator workstation, a web browser opens with the Deckhouse Platform authentication form.

> **i** To issue a permanent token, create a local Argo CD user and set the `apiKey` attribute for them. In this case, the user has access rights only to the Argo CD API. For details, see Creating additional local users.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring role-based access control

Argo CD uses its own role-based access control (RBAC) model, which is not based on the Kubernetes or Deckhouse Platform role model. The Argo CD role model lets you restrict access to resources and operations through its own policies and roles.

Before configuring role-based access control, complete authentication and authorization setup. After that, assign roles to users and groups and set permissions at the level of the entire Argo CD instance or individual projects with an AppProject object.

You can define role-based access control (RBAC) rules in two places:

- globally — in the ArgoCD object;
- at the project level — in the roles of an AppProject object.

Built-in roles

Argo CD has two predefined roles with a set of policies:

- `role:readonly` — read-only access (used by default for all authenticated users);
- `role:admin` — access with administrator privileges.

Full description of predefined role policies...

```
# Policies of the readonly role.
p, role:readonly, applications, get, */*, allow
p, role:readonly, applicationsets, get, */*, allow
p, role:readonly, certificates, get, *, allow
p, role:readonly, clusters, get, *, allow
p, role:readonly, repositories, get, *, allow
p, role:readonly, write-repositories, get, *, allow
p, role:readonly, projects, get, *, allow
p, role:readonly, accounts, get, *, allow
p, role:readonly, gpgkeys, get, *, allow
p, role:readonly, logs, get, */*, allow

# Policies of the admin role.
p, role:admin, applications, create, */*, allow
p, role:admin, applications, update, */*, allow
p, role:admin, applications, update/*, */*, allow
p, role:admin, applications, delete, */*, allow
p, role:admin, applications, delete/*, */*, allow
p, role:admin, applications, sync, */*, allow
p, role:admin, applications, override, */*, allow
p, role:admin, applications, action/*, */*, allow
p, role:admin, applicationsets, get, */*, allow
p, role:admin, applicationsets, create, */*, allow
p, role:admin, applicationsets, update, */*, allow
p, role:admin, applicationsets, delete, */*, allow
p, role:admin, certificates, create, *, allow
p, role:admin, certificates, update, *, allow
p, role:admin, certificates, delete, *, allow
p, role:admin, clusters, create, *, allow
p, role:admin, clusters, update, *, allow
p, role:admin, clusters, delete, *, allow
p, role:admin, repositories, create, *, allow
p, role:admin, repositories, update, *, allow
p, role:admin, repositories, delete, *, allow
p, role:admin, write-repositories, create, *, allow
p, role:admin, write-repositories, update, *, allow
p, role:admin, write-repositories, delete, *, allow
p, role:admin, projects, create, *, allow
p, role:admin, projects, update, *, allow
p, role:admin, projects, delete, *, allow
p, role:admin, accounts, update, *, allow
p, role:admin, gpgkeys, create, *, allow
p, role:admin, gpgkeys, delete, *, allow
p, role:admin, exec, create, */*, allow

# The admin role includes all privileges of the readonly role.
g, role:admin, role:readonly

# The local admin user is assigned the admin role.
g, admin, role:admin
```

Default policy for authenticated users

After successful authentication, the user receives the role specified in the `spec.rbac.defaultPolicy` parameter of ArgoCD (`role:readonly` by default).

> ⚠ All authenticated users receive at least the permissions defined in the `spec.rbac.defaultPolicy` parameter. These rights cannot be revoked with a `deny` effect rule.

Create a separate role, for example `role:authenticated`, grant it a minimal set of permissions, and use it in `spec.rbac.defaultPolicy`.

Example:

```
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  rbac:
    defaultPolicy: role:authenticated
    policy: |
      p, role:authenticated, applications, get, */*, allow
...
```

Anonymous access

If you enable anonymous access to an Argo CD instance, users can receive rights according to the policy specified in the `spec.rbac.defaultPolicy` parameter without authentication.

Anonymous access is enabled with the `spec.usersAnonymousEnabled` parameter of ArgoCD.

> ⚠ When enabling anonymous access, create a separate default role, for example `role:unauthenticated`, and assign it in `spec.rbac.defaultPolicy`.

Role-based access control structure

The Argo CD role-based access control syntax is based on the Casbin model and uses two types of records:

- binding a user or group to a role;
- assigning permissions to a role, user, or group.

Role binding

Syntax:

```
g, <user/group>, <role>
```

Where:

- `<user/group>` — a local user, SSO user, or group;
- `<role>` — an internal Argo CD role.

Example:

```
g, my-org:team-beta, role:admin
g, user@example.org, role:readonly
```

Access policy

Syntax:

```
p, <role/user/group>, <resource>, <action>, <object>, <effect>
```

Where:

- `<role/user/group>` — the subject to which the rule is assigned;
- `<resource>` — the resource type;
- `<action>` — the allowed operation;
- `<object>` — the object to which the rule applies;
- `<effect>` — the check result: `allow` or `deny`.

Example:

```
p, role:developer, applications, sync, dev-project/*, allow
p, role:developer, logs, get, dev-project/*, allow
```

> **i** To assign rules to a group, first bind the group to a role with a `g, <group>, <role>` record. After that, assign permissions to the role itself.

Resources and supported actions

The following are the main Argo CD resources and actions that you can use in RBAC policies.

Resource	get	create	update	delete	sync	action	override	invoke
`applications`	✓	✓	✓	✓	✓	✓	✓	✓
`applicationsets`	✓	✓	✓	✓	✓	✓	✓	✓
`clusters`	✓	✓	✓	✓	✓	✓	✓	✓
`projects`	✓	✓	✓	✓	✓	✓	✓	✓
`repositories`	✓	✓	✓	✓	✓	✓	✓	✓
`accounts`	✓	✓	✓	✓	✓	✓	✓	✓
`certificates`	✓	✓	✓	✓	✓	✓	✓	✓
`gpgkeys`	✓	✓	✓	✓	✓	✓	✓	✓
`logs`	✓	✓	✓	✓	✓	✓	✓	✓
`exec`	✓	✓	✓	✓	✓	✓	✓	✓
`extensions`	✓	✓	✓	✓	✓	✓	✓	✓

Application-bound policies

Some resources are bound to specific applications:

- `applications`;
- `applicationsets`;
- `logs`;
- `exec`.

For such resources, the `<object>` value usually has the `<APP_PROJECT>/<APP_NAME>` format.

Example:

```
p, example-user, applications, get, *, allow
p, example-user, logs, get, example-project/my-app, allow
```

If Argo CD has application placement in arbitrary namespaces enabled, the `<object>` format changes to `<APP_PROJECT>/<APP_NAMESPACE>/<APP_NAME>`.

Example:

```
p, example-user, applications, get, */app-namespace/*, allow
p, example-user, logs, get, example-project/app-namespace/my-app, allow
```

The `applications` resource

The `applications` resource supports both basic actions and more detailed rules.

Detailed permissions for `update` and `delete`

The `update` and `delete` permissions granted for an application allow changing or deleting the

application itself, but not its nested resources.

To allow an operation on application resources, use the format:

```
<action>/<group>/<kind>/<namespace>/<name>
```

For example, to allow a user to delete only Pods in the `prod-app` application:

```
p, example-user, applications, delete/*/Pod/*/*, default/prod-app, allow
```

To allow updating all application resources but not the application itself:

```
p, example-user, applications, update/*, default/prod-app, allow
```

To deny deleting the application but allow deleting Pods:

```
p, example-user, applications, delete, default/prod-app, deny
p, example-user, applications, delete/*/Pod/*/*, default/prod-app, allow
```

To allow updating the application but deny updating any subresources:

```
p, example-user, applications, update, default/prod-app, allow
p, example-user, applications, update/*, default/prod-app, deny
```

⚠ Argo CD does not use the `/` character as a separator when comparing glob patterns. Therefore, always specify the full resource path, that is, use patterns with four `/` characters.

The `action` action

The `action` action corresponds to built-in or custom actions on application resources.

Format of the `<action>` value:

```
action/<group>/<kind>/<action-name>
```

For example:

- `action/extensions/DaemonSet/restart` — an action for `DaemonSet`;
- `action//Pod/maintenance-off` — an action for `Pod` that has no API group.

Policy example:

```
p, example-user, applications, action//Pod/maintenance-off, default/*, allow
p, example-user, applications, action/extensions/DaemonSet/*, default/*, allow
```

To allow all actions on application resources:

```
p, example-user, applications, action/*, default/*, allow
```

The `override` action

The `override` permission allows passing arbitrary manifests or another revision when synchronizing an `Application`.

⚠ The `override` right lets a user effectively change the composition or state of deployed application resources. Grant it only to users who truly need it.

If the `application.sync.requireOverridePrivilegeForRevisionSync: 'true'` parameter is enabled in the `argocd-cm` ConfigMap, passing an arbitrary revision during synchronization also requires the `override` right.

Other resources

The `applicationsets` resource

The `applicationsets` resource also belongs to application-bound policies. The `create` permission for this resource effectively allows creating Application objects through an ApplicationSet object.

Example:

```
p, dev-group, applicationsets, *, dev-project/*, allow
```

With this rule, users from `dev-group` can create an ApplicationSet that manages applications only within the `dev-project` project.

The `logs` resource

The `get` permission for the `logs` resource allows viewing Pod logs of an application through the Argo CD web interface. In meaning, this is equivalent to `d8 k logs`.

The `exec` resource

The `create` permission for the `exec` resource allows opening an `exec` session in an application Pod through the Argo CD web interface. In meaning, this is similar to `d8 k exec`.

The `extensions` resource

The `extensions` resource is used to invoke proxy extensions. Checks for such rules work together with the `applications` resource: the user must have read access to the application from which the request is made.

Example:

```
p, example-user, applications, get, default/*, allow
p, example-user, extensions, invoke, httpbin, allow
```

The `deny` effect

If a policy with the `deny` effect matches a request, access is denied even if there are more specific rules with the `allow` effect.

The order of lines in `spec.rbac.defaultPolicy` does not affect the result.

Policy evaluation order and matching modes

Access checks are performed in two stages:

1. Rules from `spec.rbac.defaultPolicy` are checked.
2. If no decision is found, rules related to the user and their groups are checked.

If access is explicitly allowed or denied by the default policy, further checks are not performed.

Argo CD supports two matching modes for values set in `spec.rbac.policyMatcherMode`:

- `glob` — matching by glob patterns;
- `regex` — matching by regular expressions.

Matching in `glob` mode

In `glob` mode, tokens are treated as whole strings without special separators.

Policy example:

```
p, example-user, applications, action/extensions/*, default/*, allow
```

If the `example-user` user invokes the `extensions/DaemonSet/test` action, the following checks are performed:

1. `example-user` matches `example-user`.
2. `applications` matches `applications`.
3. `action/extensions/DaemonSet/test` matches `action/extensions/*`.
4. `default/my-app` matches `default/*`.

Using SSO users and groups

The `scopes` parameter defines which OIDC scopes Argo CD must analyze during RBAC checks in addition to `sub`. If the parameter is not set, the default value is `'[groups]'`.

Example of an ArgoCD object with scopes configured:

```
apiVersion: argoproj.io/v1beta1
kind: ArgoCD
metadata:
  name: argocd
  namespace: argocd
spec:
  rbac:
    policy: |
      p, my-org:team-alpha, applications, sync, my-project/*, allow
      g, my-org:team-beta, role:admin
      g, user@example.org, role:admin
      g, admin, role:admin
      g, role:admin, role:readonly
    defaultPolicy: role:readonly
    scopes: '[groups, email]'
```

In this example:

1. `g, admin, role:admin` explicitly binds the built-in `admin` user to the `role:admin` role.
2. `g, role:admin, role:readonly` sets role inheritance: everyone who has `role:admin` automatically also gets `role:readonly` rights.

You can combine this approach with roles at the AppProject level. For example, you can create the `team-beta-project` project and assign rights to users and groups:

```
apiVersion: argoproj.io/v1alpha1
kind: AppProject
metadata:
  name: team-beta-project
  namespace: argocd
spec:
  roles:
    - name: admin
      description: Administrator permissions for team-beta.
      policies:
        - p, proj:team-beta-project:admin, applications, *, team-beta-project/*, allow
      groups:
        - user@example.org
        - my-org:team-beta
```

Local users

You can grant access to local users in two ways:

- assign rules directly;
- bind the user to a role.

Example of assigning a rule directly:

```
p, my-local-user, applications, sync, my-project/*, allow
```

Example of binding to a role:

```
g, my-local-user, role:admin
```

⚠ If SSO and local users are used at the same time, ambiguity is possible. For example, if the local user `sally` is bound to `role:admin`, and one of the SSO scope values is also `sally`, that SSO user may also receive `role:admin` rights.

To avoid this situation, when using SSO and local users together, assign rules to local users directly rather than through roles.

Example:

```
p, my-local-user, *, *, *, allow
```

Testing RBAC policies

To verify RBAC rules, use the `argocd` CLI utility. To check whether a specific user, group, or role can perform a certain action, use the following command:

```
argocd admin settings rbac can
```

For example, run the command below to check whether the `admin@deckhouse.io` user has rights to create `applications` in the `default` project:

```
argocd admin settings rbac can admin@deckhouse.io create application 'default/*' --namespace argocd
```

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Marketplace

Marketplace is a package management system in Deckhouse Platform (DP). It lets administrators connect package repositories, discover available packages, and make them available to project users to install applications.

Marketplace is available in DP starting from version 1.76.

For the Marketplace architecture, including core concepts, application development and configuration, templates, Nelm annotations, hooks, and the application lifecycle, refer to “Architecture”.

To learn about installing and removing applications from Marketplace, as well as troubleshooting, refer to “Usage”.

Administrator tasks

A cluster administrator:

1. Connects a package repository by creating a PackageRepository resource.
2. Monitors the repository scanning operations by Marketplace, discovering available packages.
3. Grants users the permissions to create Application objects in their namespaces. Any authenticated user can view package versions.
4. If needed, chooses the packages available in projects.

Users interact with packages through the Application object.

Marketplace resources

The following resources are used for working with the Marketplace:

Resource	Short name	Scope	Description
PackageRepository	—	Cluster	Package repository and its scanning settings
PackageRepositoryOperation	`pro`	Cluster	A repository scanning operation
ApplicationPackageVersion	`apv`	Cluster	Discovered version of a package
ApplicationPackage	`ap`	Cluster	Package summary: the repositories it's available in, the versions the release channels point to, and the applications that use it
Application	—	Namespace	Installed application instance managed by a user

The Marketplace documentation includes the following sections:

- "Package repositories" describes how to connect a repository and check its status.
- "Scanning" describes how to monitor scanning operations and trigger a scanning manually.
- "Configuring package access" describes how to configure access to packages in projects.

Additional resources

- Using Marketplace
- Global custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Package repositories

To connect Deckhouse Platform (DP) to an application package repository, use the PackageRepository resource. Once the resource is created, DP scans the repository and creates an ApplicationPackageVersion object for each discovered package version.

Example of a PackageRepository manifest:

```
apiVersion: deckhouse.io/v1alpha1
kind: PackageRepository
metadata:
  name: my-registry
spec:
  registry:
    repo: registry.example.com/packages
    scheme: HTTPS
    dockerCfg: <BASE64_ENCODED_DOCKER_CONFIG>
```

Authentication and scan interval

Authentication

To authenticate to the package repository, use one of the following methods:

- `dockerCfg`: Docker configuration in the `~/.docker/config.json` format, Base64-encoded. It

must contain an `auths` entry for the repository host. DP uses the username and password from this entry.

- `login` and `password`: Explicit credentials. If both methods are specified, `login` and `password` take precedence.

```
spec:
  registry:
    repo: registry.example.com/packages
    scheme: HTTPS
    login: my-user
    password: my-password
```

If the repository uses a self-signed TLS certificate, specify the CA certificate in the `ca` parameter:

```
spec:
  registry:
    repo: registry.example.com/packages
    scheme: HTTPS
    dockerCfg: <BASE64_ENCODED_DOCKER_CONFIG>
    ca: |
      -----BEGIN CERTIFICATE-----
      ...
      -----END CERTIFICATE-----
```

Scan interval

By default, DP scans the repository **every 6 hours**. To change the interval, set the `scanInterval` parameter. The minimum interval is 3 minutes:

```
spec:
  registry:
    repo: registry.example.com/packages
  scanInterval: 1h30m
```

For details about starting a scanning or viewing results, refer to “Scanning”.

Checking repository status

The state of the repository is shown in the status of the PackageRepository object.

To display brief information about the status, use the following command:

```
d8 k get packagerepository <REPOSITORY_NAME>
```

Output columns:

Column	Description
`Phase`	Repository phase. Displayed as `Active` after the first successful scan
`Scan`	Time of the last successful scan
`Repository`	Repository address (`spec.registry.repo`)
`Packages`	Number of packages in the repository
`MSG`	Message of the `LastScanSucceeded` condition, for example, the error of the last scan

For detailed information about the status, use the following command:

```
d8 k get packagerepository <REPOSITORY_NAME> -o yaml
```

For status field descriptions, refer to the PackageRepository documentation.

To check the result of the last scan, view the `LastScanSucceeded` condition:

```
d8 k get packagerepository <REPOSITORY_NAME> \
  -o jsonpath='{.status.conditions[?(@.type=="LastScanSucceeded")]}'
```

If the last scan completed successfully, the condition status is set to `True`. Otherwise, it is `False`, and the error details are available in the status message.

Viewing discovered package versions

After a successful scan, ApplicationPackageVersion objects (or `apv` for short) are automatically created in the cluster.

To print out a list of all created ApplicationPackageVersion objects, run the following command:

```
d8 k get apv
```

Example output:

```
NAME                           PACKAGE    REPOSITORY    METADATALOADED   USEDBY
AGE
my-registry-redis-v7.2.0       redis      my-registry   True                      5m
my-registry-postgres-v15.0.0   postgres   my-registry   True                      5m
```

To filter the versions by package name, use the following command (the example shows the versions of the `redis` package):

```
d8 k get apv -l packages.deckhouse.io/package=redis
```

> i `MetadataLoaded=True` means that the package's OpenAPI schema, description, and requirements were successfully loaded from the repository. A package version with `MetadataLoaded=False` cannot be installed until the metadata is loaded.

Scanning

Deckhouse Platform (DP) uses PackageRepositoryOperation objects to configure package repository scanning. Each scan operation discovers new package versions and creates ApplicationPackageVersion objects for them. DP creates operations automatically, but you can also create them manually.

Viewing scan operations

To view a list of scan operations, use the following command (you can use `pro` instead of PackageRepositoryOperation):

```
d8 k get pro
```

DP keeps the 10 most recent operations of each repository and deletes operations if that threshold is exceeded, starting from the oldest ones.

Example output:

```
NAME                   COUNT   COMPLETED   MSG   COMPLETIONTIME
test-scan-1780052895   23      True              3h38m
test-scan-1780053890   23      True              3h22m
```

Output columns:

Column	Description
`Count`	Total number of packages found during the scan
`Completed`	Whether the operation has finished (`True` or `False`). A failed operation is considered completed too. The result is defined by the reason of the `Completed` condition: `ScanSucceeded` or `ScanFailed`
`MSG`	Message of the `Completed` condition, for example, the scan error
`CompletionTime`	Time when the operation completed

To filter operations by repository, use the following command:

```
d8 k get pro -l packages.deckhouse.io/repository=<REPOSITORY_NAME>
```

Inspecting a scan operation

For full scan results including per-package details, use the following command:

```
d8 k get pro <OPERATION_NAME> -o yaml
```

For status field descriptions, refer to the PackageRepositoryOperation documentation.

An example command for viewing packages with errors:

```
d8 k get pro <OPERATION_NAME> \
  -o jsonpath='{range .status.packages.failed[*]}{.name}: {range .errors[*]}
{.version} - {.message}{"\n"}{end}{end}'
```

Triggering a manual scan

DP starts a scan of a PackageRepository when the resource is created, when its specification is modified, when DP restarts, and then every `spec.scanInterval` (6 hours by default, at least 3 minutes). A scan is skipped if the previous operation of the repository hasn't completed yet.

To start the scanning immediately, create a PackageRepositoryOperation manually, for example:

```
apiVersion: deckhouse.io/v1alpha1
kind: PackageRepositoryOperation
metadata:
  generateName: my-registry-scan-manual-
spec:
  packageRepositoryName: my-registry
  type: Update
  update:
    fullScan: true
```

> **i** The `generateName` field gives every operation a unique name. It works only with `d8 k create`, but not with `d8 k apply`.

Alternatively, to create a scan operation, use the following command:

```
d8 system package scan <REPOSITORY_NAME>
```

This command creates a PackageRepositoryOperation with `spec.type: Update` and `spec.update.fullScan: true`.

Full scanning

To run a full scanning of a package repository, set the `spec.update.fullScan: true` parameter in a PackageRepositoryOperation. In this mode, all available package versions are scanned, not only the ones higher than discovered previously.

With `spec.update.fullScan: false` (by default), only the SemVer tags with a version higher than the package version already processed in the cluster are processed.

Automatic operations perform a full repository scan until the first successful scan. After that, automatic scans process only versions newer than the latest package version already processed.

Use the full scanning in the following cases:

- A package version was published after a newer version, for example, a patch for a previous minor version.
- ApplicationPackageVersion resources are missing from the cluster for versions available in the package repository.

Additional resources

- Global custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring package access

By default, a user who may create Application objects in a namespace can install applications from any package. If the `multitenancy-manager` module is enabled, the cluster administrator can restrict the packages available for installation in each project and each namespace of a project. A request to create an Application with unavailable package will be rejected.

To configure access to packages, Deckhouse Platform registers an ApplicationPackage as a cluster-wide resource named `applicationpackages`. The `multitenancy-manager` module checks the `spec.packageName` field value of Application objects in project namespaces. Package access in configured using the ClusterResourceGrantPolicy resource. A policy does not grant RBAC permissions: to install an application, a user still needs a role that allows creating Application objects in the corresponding namespace.

For details on the access management mechanism, refer to the `multitenancy-manager` module documentation.

Allowing packages in a project

To allow installing only the `postgres` and `redis` packages in the `my-project` project, create the following ClusterResourceGrantPolicy:

```
apiVersion: multitenancy.deckhouse.io/v1alpha2
kind: ClusterResourceGrantPolicy
metadata:
  name: my-project-packages
spec:
  projectSelector:
    matchLabels:
      projects.deckhouse.io/project: my-project
  resources:
    - resourceName: applicationpackages
      allowed:
        - postgres
        - redis
```

The names in `allowed` field are the names of ApplicationPackage objects corresponding to the respective `spec.packageName` field values of an Application. To list the available packages, run `d8 k get ap`.

The `multitenancy-manager` module automatically assigns the `projects.deckhouse.io/project: <PROJECT_NAME>` label to every Project, which makes the policy applied to every namespace in the respective namespace, including the additional namespaces created after the policy is created.

To apply a policy to several projects, use one of the labels:

- `projects.deckhouse.io/project-template: <PROJECT_TEMPLATE_NAME>` label, which selects all projects based on the template
- your own label on the Project objects, for example `team: payments`, which selects a custom group of projects.

Once a policy with `allowed` field applies to a project, the packages that are not listed in it become unavailable for installation. If several policies apply to a project, their `allowed` lists are combined.

Allowing packages in one namespace of a project

Using the `namespaceSelector` parameter, you can restrict a policy to selected namespaces of a project. The policy is applied only to namespaces whose labels match the selector. It does not restrict the other namespaces of the project. If no other policy restricts them, every package is available there.

For example, to allow installation of the `postgres` package only in the `my-project-db` namespace of the `my-project` project and deny installation of any packages in other namespaces of the project, create two policies:

```
apiVersion: multitenancy.deckhouse.io/v1alpha2
kind: ClusterResourceGrantPolicy
metadata:
  name: my-project-no-packages
spec:
  projectSelector:
    matchLabels:
      projects.deckhouse.io/project: my-project
  resources:
    - resourceName: applicationpackages
      availabilityDefault: None
---
apiVersion: multitenancy.deckhouse.io/v1alpha2
kind: ClusterResourceGrantPolicy
metadata:
  name: my-project-db-packages
spec:
  projectSelector:
    matchLabels:
      projects.deckhouse.io/project: my-project
  namespaceSelector:
    matchLabels:
      kubernetes.io/metadata.name: my-project-db
  resources:
    - resourceName: applicationpackages
      allowed:
        - postgres
```

The first policy (`my-project-no-packages`) makes every package unavailable for installation in all namespaces of the project. The second one (`my-project-db-packages`) allows the `postgres` packages in the `my-project-db` namespace. If a package is allowed at least by a single policy, it's available for installation, even if another policy sets `availabilityDefault: None`.

The `NewNamespacesCovered` condition in the status of the second policy is `False`, because a new additional namespace of the project does not match its `namespaceSelector`. However the first policy covers such namespaces, so no packages are available for installation in them.

Denying packages

To deny installation of specific packages while keeping the others available, list them in `denied`.

The following is an example policy that makes the `experimental-db` package unavailable in every project:

```
apiVersion: multitenancy.deckhouse.io/v1alpha2
kind: ClusterResourceGrantPolicy
metadata:
  name: deny-experimental-db
spec:
  projectSelector: {}
  resources:
    - resourceName: applicationpackages
      denied:
        - experimental-db
```

The empty `projectSelector` parameter selects every project. A package listed under `denied` is unavailable for installation even if another policy allows it.

Packages in a project template or in a project

Package access rules can be set in `spec.resources` of a project template, so that they apply to every project created from the template, or in `spec.grants.resources` of a single Project.

For example, to allow installation of only `postgres` and `redis` packages in the projects of a template,

add the following entry to the template:

```
spec:
  resources:
    - resourceName: applicationpackages
      allowed:
        - postgres
        - redis
```

For details, refer to “Granting cluster-wide resources through a project template” and “Granting cluster-wide resources to one project”.

Checking the available packages

The packages available for installation in a namespace are listed in the `applicationpackages` AvailableClusterResource of the corresponding namespace. That same list can be read by the project users.

To view the list, run the following command:

```
d8 k get available applicationpackages -n <NAMESPACE> -o yaml
```

Requests of the platform components and of members of the `system:masters` group are not checked against policies. To check on restrictions, use a project user account.

For example, to perform a server-side dry run of an Application manifest without creating the object, run the following:

```
d8 k apply -f application.yaml --dry-run=server --as <USER_NAME>
```

Applications installed before a restriction

Introducing policy restrictions does not remove installed applications. When an existing Application object is changed, the availability of its package is checked only if the package is modified. Therefore an application installed before its package became unavailable to the project keeps working.

Such applications are counted by the `d8 cluster_objects_grant_violated` metric, and the `ClusterResourceGrantPolicyViolation` alert fires. The alert stops when the package becomes available to the project again or the corresponding Application object is deleted.

Limitations

When configuring access to packages, consider the following limitations:

- Policies apply only in project namespaces. They do not apply to the namespaces of the virtual projects `default` and `deckhouse`, so any package can be installed there.
- A policy selects available packages by name. It does not restrict the repository an available package is installed from (`spec.packageRepositoryName`) or its version.
- A policy does not hide unavailable packages. Any authenticated user can read the ApplicationPackageVersion objects of all packages, including the ones unavailable to the project. The `status.usedBy` field of a version lists the applications installed from it and their namespaces in all projects.
- While the controller of the `multitenancy-manager` module is unavailable, Application objects cannot be created or changed in project namespaces. To keep the controller available, enable `highAvailability` in the `multitenancy-manager` settings.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Platform update

Deckhouse Platform (DP) includes a built-in update management mechanism for both the platform itself and Kubernetes cluster components. To roll out new versions consistently and safely, DP uses a five-channel update system ranging from the newest and unstable (Alpha) to the most thoroughly tested (Rock Solid). Each new version gradually moves through these channels, helping identify issues early and ensuring stability in production environments. For details on each channel, refer to the Architecture section.

> ⚠ DP does not support version downgrades. After a release is installed, rolling the platform back to an earlier minor or patch version is not possible.
>
> When switching to a more stable channel, the platform remains on the current release until a newer version becomes available on that channel.
>
> Rolling back by one minor version is possible only for the Kubernetes (control plane) version, not for the DP version.

You can configure the update process. Both automatic and manual modes are supported, as well as update windows and other parameters. See Update configuration for details.

An alerting system is used to track the update status and quickly report any issues. For more information, refer to Notification settings.

The following features are supported:

- Release notifications: DP can send release notifications via webhooks.
- Retrieving the changelog: Each DP release includes a changelog, available both in the cluster and as part of the release notification.
- Checking dependencies before update: Checks for component dependencies before proceeding with an update to prevent conflicts.

For more details on updating DP in air-gapped environment, see the “Updating DP in air-gapped environment” guide.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring updates

Deckhouse Platform (DP) supports a flexible update mechanism, allowing you to select release channels and configure the update mode. Release channels help you balance stability with the speed of receiving new features.

The update mode configuration lets you choose between automatic or manual updates and define update windows during which new versions can be installed. Together, these features help you avoid updates at inconvenient times and control migration to new releases.

> Up-to-date information about DP versions available on different release channels is available at releases.deckhouse.io.

Checking the current release channel

To check which release channel is used in your cluster, run the following command:

```
d8 k get mc deckhouse -o yaml | grep releaseChannel
```

Example output:

```
    releaseChannel: Stable
```

Switching release channels

To switch the release channel, specify the new channel in the `settings.releaseChannel` parameter of the `deckhouse` module.

Example configuration using the `Stable` channel:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  settings:
    releaseChannel: Stable
```

Update modes

DP supports two update modes that determine how new versions are applied:

- **Automatic mode** — the cluster updates as soon as a new version appears on the selected release channel. Two configuration options are available:
  - `AutoPatch` — only patch version updates within the current minor version are applied;
  - `Auto` — both patch and minor versions are applied automatically.
- **Manual mode (`Manual`)** — both patch and minor versions are applied only after manual approval.

For automatic mode, update windows settings are available — allowed updates are applied taking `update.windows` into account, if windows are configured. If no windows are set, the update is applied as soon as the version appears on the release channel.

> **i**
>
> The `update` settings of the `deckhouse` module (mode and windows) apply by default to both built-in and external modules.
>
> If a module has no dedicated update policy (ModuleUpdatePolicy) and its ModuleConfig does not specify the `updatePolicy` parameter, the module inherits `releaseChannel` and `update` from the `deckhouse` ModuleConfig.

Patch versions only within the current minor (AutoPatch)

To keep DP updates within the current minor version (apply patch versions only), use the `AutoPatch` mode.

For example, if version `v1.70.1` is installed, DP can automatically update to `v1.70.2`, but will not move to `v1.71.*` without manual approval.

This is the default value. To set the `AutoPatch` mode explicitly, run the following command:

```
d8 k patch mc deckhouse --type=merge -p='{"spec":{"settings":{"update":
{"mode":"AutoPatch"}}}}'
```

To approve a minor version update, run the following command, replacing `<DECKHOUSE-VERSION>` with the target DP version:

```
d8 k patch DeckhouseRelease <DECKHOUSE-VERSION> --type=merge -p='{"approved": true}'
```

Automatic updates for all versions (Auto)

In the `Auto` mode, DP automatically applies both patch and minor versions, taking update windows into account if they are configured.

To enable the `Auto` mode, the following command:

```
d8 k patch mc deckhouse --type=merge -p='{"spec":{"settings":{"update":{"mode":"Auto"}}}}'
```

Manual mode (Manual)

In the `Manual` mode, DP receives information about new versions in the cluster, but applying both patch and minor versions requires manual approval.

To enable the `Manual` mode, the following command:

```
d8 k patch mc deckhouse --type=merge -p='{"spec":{"settings":{"update":
{"mode":"Manual"}}}}'
```

Checking the current update mode

To determine the current update mode used in the cluster, inspect the configuration of the `deckhouse` module with the following command:

```
d8 k get mc deckhouse -o yaml
```

Example output:

```
spec:
  settings:
    releaseChannel: Stable
    update:
      mode: AutoPatch
      windows:
      - days:
        - Mon
        from: "19:00"
        to: "20:00"
```

How automatic updates are applied

Automatic update mode is enabled when the `releaseChannel` parameter is specified in the `deckhouse` module configuration. When this condition is met:

1. DP checks the release channel every minute for new releases.
2. When a new release appears, DP downloads it into the cluster and creates a DeckhouseRelease custom resource.
3. Once the DeckhouseRelease resource appears in the cluster, DP applies the corresponding update according to the configured update settings (by default — automatically, at any time).

To view the list and status of all releases in the cluster, run the following command:

```
d8 k get deckhousereleases
```

⚠ Starting from DP 1.70, patch version updates (for example, an update to version `1.70.2` when version `1.70.1` is installed) are applied taking update windows into account. Prior to DP 1.70, patch version updates are applied without regard to the update mode and windows.

Release pinning

Release pinning refers to fully or partially disabling automatic updates.

There are three ways to restrict automatic updates in Deckhouse:

- Enable manual update approval mode.

  In this mode, DP will receive updates into the cluster, but applying patch and minor versions will require manual approval.

  To enable manual update approval mode, set the `settings.update.mode` parameter to `Manual` in the `deckhouse` module configuration using the following command:

  ```
  d8 k patch mc deckhouse --type=merge -p='{"spec":{"settings":{"update":
  {"mode":"Manual"}}}}'
  ```

  To approve an update, run the following command, replacing `<DECKHOUSE-VERSION>` with the target DP version:

  ```
  d8 k patch DeckhouseRelease <DECKHOUSE-VERSION> --type=merge -p='{"approved": true}'
  ```

- Enable automatic updates for patch versions only.

  In this mode, DP will receive updates into the cluster, but applying minor versions will require manual approval. Patch versions within the current minor version will be applied automatically, taking update windows into account if they are configured.

  For example, if you have DP version `v1.70.1` installed, after enabling this mode, Deckhouse can automatically update to `v1.70.2`, but it will not update to `v1.71.*` without manual approval.

  To enable automatic updates for patch versions only, set the `settings.update.mode` parameter to `AutoPatch` in the `deckhouse` module configuration using the following command:

  ```
  d8 k patch mc deckhouse --type=merge -p='{"spec":{"settings":{"update":
  {"mode":"AutoPatch"}}}}'
  ```

  To approve a minor version update, run the following command, replacing `<DECKHOUSE-VERSION>` with the target DP version:

  ```
  d8 k patch DeckhouseRelease <DECKHOUSE-VERSION> --type=merge -p='{"approved": true}'
  ```

- Manually set the target DP version tag for the `deckhouse` Deployment and remove the `releaseChannel` parameter from the `deckhouse` module configuration.

In this case, DP will remain at the specified version, and no information about newer available versions (DeckhouseRelease objects) will appear in the cluster.

> **i** **Important**. This mode blocks the installation of patch releases, which may include critical security or bug fixes. If you need to receive patches within the current minor version, use the `AutoPatch` mode instead of hard pinning.

Example of pinning version `v1.66.3` for DP EE and removing the `releaseChannel` parameter from the `deckhouse` module configuration:

```
d8 k -ti -n d8-system exec svc/deckhouse-leader -c deckhouse -- kubectl set image
deployment/deckhouse deckhouse=registry.deckhouse.io/deckhouse/ee:v1.66.3
```

```
d8 k patch mc deckhouse --type=json -p='[{"op": "remove", "path":
"/spec/settings/releaseChannel"}]'
```

Manual update approval

Manual approval of DP updates is required in the following cases:

- The DP update confirmation mode is enabled.

  This means the `settings.update.mode` parameter of the `deckhouse` module is set to either `Manual` (confirmation required for both patch and minor updates) or `AutoPatch` (confirmation required only for minor updates).

To approve an update, run the following command, replacing `<DECKHOUSE-VERSION>` with the target version:

```
d8 k patch DeckhouseRelease <DECKHOUSE-VERSION> --type=merge -p='{"approved": true}'
```

- Automatic update approval is disabled for a NodeGroup, for updates that might cause temporary downtime of system components.

  This means the `spec.disruptions.approvalMode` parameter of the corresponding NodeGroup resource is set to `Manual`.

  To apply the update, set the `update.node.deckhouse.io/disruption-approved=` annotation on each node in the group:

  Example:

  ```
  d8 k annotate node ${NODE_1} update.node.deckhouse.io/disruption-approved=
  ```

Update windows

DP allows you to define *update windows*, which are specific time intervals during which automatic updates are allowed. Using update windows ensures that updates won't be installed at inconvenient times or during periods of high cluster load.

Applying updates when update windows are configured

- If update windows are configured, DP installs new versions only during the specified windows.
- If no update windows are configured, the update is applied as soon as a new version appears on the configured release channel.

Configuring update windows

You can manage DP update windows in the following ways:

- **To control general updates**, use the `update.windows` parameter in the `deckhouse` module configuration;
- **To control updates that may lead to short-term downtime of system components**, use the `disruptions.automatic.windows` and `disruptions.rollingUpdate.windows` parameters in the NodeGroup resource.

Configuration examples

- Two daily update windows: from 08:00 to 10:00 and from 20:00 to 22:00 (UTC):

  ```
  apiVersion: deckhouse.io/v1alpha1
  kind: ModuleConfig
  metadata:
    name: deckhouse
  spec:
    version: 1
    settings:
      releaseChannel: EarlyAccess
      update:
        windows:
          - from: "8:00"
            to: "10:00"
          - from: "20:00"
            to: "22:00"
  ```

- Update windows on Tuesdays and Saturdays from 18:00 to 19:30 (UTC):

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  settings:
    releaseChannel: Stable
    update:
      windows:
        - from: "18:00"
          to: "19:30"
          days:
            - Tue
            - Sat
```

Updating virtualization

If virtualization is enabled in the cluster, its components fall into two categories that are updated differently:

- the components that manage virtualization resources (the control layer);
- the components that run virtual machines (the “firmware”).

Updating the control layer doesn’t affect the virtual machines that are already running, but it drops open VNC and serial console connections while the component restarts.

Updating the “firmware” may require migrating virtual machines to the new version. DKP migrates a machine once, and if the migration fails, the machine owner has to move or restart it manually. To pick a suitable time for such an update, use update windows and the manual mode.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Configuring notifications on new releases

Deckhouse Platform (DP) generates alerts in the monitoring system and can automatically send notifications about upcoming minor updates to external systems. This helps you plan updates and prepare for them in advance.

Conditions for sending notifications to external systems:

- DP is operating in automatic update mode.
- A minor version update is planned (notifications are not sent for patch versions).
- A webhook for notifications is configured.

Alerts in the monitoring system

If an update requires making changes to the cluster (for example, updating the Kubernetes or OS version), DP generates designated alerts. These alerts include:

- `D8NodeHasDeprecatedOSVersion`: Nodes with an unsupported OS version have been detected in the cluster.
- `HelmReleasesHasResourcesWithDeprecatedVersions`: Some Helm releases use deprecated resources.
- `D8KubernetesVersionIsDeprecated`: The installed Kubernetes version is no longer supported.

If any of these alerts appear, make sure to resolve them before updating. This helps avoid disruptions and ensures the cluster remains stable after the update.

Configuring notifications

In the `Auto` update mode, you can configure a webhook call to receive a notification about an upcoming minor DP version update.

Additionally, notifications are generated not only for Deckhouse updates but also for updates of any modules, including individual ones.
In some cases, the system may initiate multiple notifications simultaneously (10–20 notifications) at approximately 15-second intervals.

> **i** Notifications are available only in the `Auto` update mode; they are not generated in the `Manual` mode.

> **i** Specifying a webhook is optional: if the `update.notification.webhook` parameter is not set but the `update.notification.minimalNotificationTime` parameter is specified, the update will still be postponed for the defined duration. In this case, the appearance of the DeckhouseRelease resource in the cluster, named after the new version, can be considered the notification.

After a new minor DP version appears in the selected update channel but before it is applied in the cluster, a POST request will be sent to the configured webhook address.

The minimalNotificationTime parameter allows postponing the update installation for a defined period, providing time to react to the notification while respecting update windows.
If the webhook is unavailable, each failed attempt to send the notification will postpone the update by the same amount, which may lead to the update being indefinitely deferred.

> **⚠** If your webhook returns any status code out of 2xx range, DP retries sending the notification up to five times with exponential backoff. If all attempts fail, the release is blocked until the webhook becomes available again.

For easier error handling and debugging, when returning error codes the webhook should return a JSON response with the following structure:

- `code` — optional internal error code for programmatic handling;
- `message` — a human-readable description of what went wrong.

If the webhook returns a successful HTTP status (2xx), DP treats the notification as successful regardless of the response body.

Minimal Go webhook example...

```
package main
import (
  "encoding/json"
  "fmt"
  "log"
  "net/http"
)
// Payload structure Deckhouse sends in POST body.
type WebhookData struct {
  Subject      string          `json:"subject"`
  ModuleName   string          `json:"moduleName,omitempty"`
  Version      string          `json:"version"`
  Requirements  map[string]string `json:"requirements,omitempty"`
  ChangelogLink string          `json:"changelogLink,omitempty"`
  ApplyTime    string          `json:"applyTime,omitempty"`
  Message      string          `json:"message"`
}

// Response structure that Deckhouse expects from webhook on error
type ResponseError struct {
```

```
  Code    string `json:"code,omitempty"`
  Message string `json:"message"`
}

func handler(w http.ResponseWriter, r *http.Request) {
  if r.Method != http.MethodPost {
    w.WriteHeader(http.StatusMethodNotAllowed)
    return
  }
  defer r.Body.Close()

  var data WebhookData
  if err := json.NewDecoder(r.Body).Decode(&data); err != nil {
    log.Printf("failed to decode payload: %v", err)
    w.WriteHeader(http.StatusInternalServerError)
    return
  }

  // Print payload fields
  log.Printf("subject=%s version=%s applyTime=%s changelog=%s requirements=%v",
    data.Subject, data.Version, data.ApplyTime, data.ChangelogLink, data.Requirements)
  log.Printf("message=%s", data.Message)

  // Example conditional logic: fail intentionally for testing
  if data.Version == "v0.0.0-fail" {
    // Return structured error response with error status code
    errorResp := ResponseError{
      Code:    "TEST_FAILURE",
      Message: "intentional failure for testing",
    }

    w.WriteHeader(http.StatusBadRequest)
    json.NewEncoder(w).Encode(errorResp)
    return
  }

  // Return success response with 2xx status code
  w.WriteHeader(http.StatusOK)
  w.Write([]byte("Notification processed successfully"))
}

func main() {
  mux := http.NewServeMux()
  mux.HandleFunc("/webhook", handler)

  addr := ":8080"
  fmt.Printf("listening on %s, POST to http://localhost%s/webhook\n", addr, addr)
  if err := http.ListenAndServe(addr, mux); err != nil {
    log.Fatal(err)
  }
}
```

Supported notifications parameters

- `update.notification.webhook`: URL for sending notifications. A POST request with update information is sent as soon as a new minor version appears on the selected release channel, but before the update is installed in the cluster.
- `update.notification.auth`: Authentication parameters for calling the webhook. If this parameter is not set, authentication is not used.
  - `update.notification.auth.basic`: Basic authentication. The username and password are passed in the `Authorization` header as `Basic <base64(username:password)>`.
    - `update.notification.auth.basic.username`: Username.
    - `update.notification.auth.basic.password`: Password.
  - `update.notification.auth.bearerToken`: Token-based authentication. The token is passed in the `Authorization` header as `Bearer <token>`.

- `update.notification.minimalNotificationTime`: Minimum interval between the appearance of a new minor version on the selected release channel and the start of the update. Specified in hours and minutes: `30m`, `1h`, `2h30m`, `24h`. If an update window is configured, the update will be applied only after the `minimalNotificationTime` has elapsed and within the defined window.
- `update.notification.tlsSkipVerify`: Disables TLS certificate verification when calling the webhook (for example, if a self-signed certificate is used). Set to `false` by default.

Example `update.notification` configuration using basic authentication:

```
update:
  notification:
    webhook: https://release-webhook.mydomain.com
    minimalNotificationTime: 4h
    auth:
      basic:
        username: myusername
        password: mypassword
    tlsSkipVerify: true
```

Example `update.notification` configuration without authentication:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  settings:
    update:
      releaseChannel: Stable
      mode: Auto
      notification:
        webhook: https://release-webhook.mydomain.com
        minimalNotificationTime: 8h
```

Notification format

When the conditions for sending notifications are met, DP sends a POST request to the specified webhook with the header `Content-Type: application/json`.

Example request body for Deckhouse release:

```
{
  "subject": "Deckhouse",
  "version": "1.68",
  "requirements":  {"k8s": "1.29.0"},
  "changelogLink":
"https://github.com/deckhouse/deckhouse/blob/main/CHANGELOG/CHANGELOG-v1.68.md",
  "applyTime": "2025-02-01T14:30:00Z00:00",
  "message": "New Deckhouse Release 1.68 is available. Release will be applied at:
Wednesday, 05-Feb-25 14:30:00 UTC"
}
```

Example request body for module release:

```
{
  "subject": "Module",
  "moduleName": "test",
  "version": "0.7.14",
  "requirements": {"deckhouse": ">= 1.69"},
  "changelogLink":
"https://github.com/deckhouse/modules/blob/main/CHANGELOG/CHANGELOG-test-
v0.7.14.md",
  "applyTime": "2025-12-17T12:32:24Z",
  "message": "New test Release 0.7.14 is available. Release will be applied at:
Wednesday, 17-Dec-25 12:32:24 UTC"
}
```

Field descriptions:

- `subject`: Release subject (“Deckhouse” for Deckhouse releases or “Module” for module releases).
- `moduleName`: Module name (present only for module releases).
- `version`: Minor version number (a string).
- `requirements`: Object with requirements for the new version (for example, the minimum Kubernetes version).
- `changelogLink`: Link to the changelog describing changes in the new minor version.
- `applyTime`: Scheduled update date and time in RFC3339 format with the configured update windows considered.
- `message`: A short text notification about the available minor version and its scheduled installation time.

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Updating Kubernetes and versioning

Updating and version management

The control plane update process in DP is fully automated.

- DP supports the latest five Kubernetes versions.
- You can roll back the control plane one minor version and upgrade forward several minor versions — one at a time.
- Patch versions (e.g., `1.35.3` → `1.35.5`) are updated automatically with Deckhouse and cannot be managed manually.
- Minor versions are set manually using the `kubernetesVersion` parameter in the `control-plane-manager` ModuleConfig.

Changing the Kubernetes version

You can downgrade only one minor version from the highest version ever used in the cluster. Upgrades proceed one minor version at a time.

1. Open the `control-plane-manager` ModuleConfig editor:

   ```
   d8 k edit mc control-plane-manager
   ```

2. Set the target Kubernetes version using the `settings.kubernetesVersion` parameter:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: control-plane-manager
spec:
  version: 3
  enabled: true
  settings:
    kubernetesVersion: "1.35"
```

> **i** The kubernetesVersion field in ClusterConfiguration, previously used to select the Kubernetes version, has been deprecated. Until the `settings.kubernetesVersion` parameter of the `control-plane-manager` module is set, this field determines the cluster's Kubernetes version. Once the parameter is set, its value is used instead. Do not change the Kubernetes version via ClusterConfiguration.

3. Save the changes.
4. Wait for the update to complete. You can track the update progress with the `d8 k get no` command. The update can be considered complete when the updated version appears in the `VERSION` column of each cluster node in the command output.

Monitoring Kubernetes update progress

The `control-plane-manager` module includes the `update-observer` component, which provides up-to-date information about the Kubernetes version update process in the cluster.

`update-observer` component:

- reads cluster configuration from the `d8-cluster-configuration` Secret
- tracks kubelet versions on all nodes via `nodeInfo.kubeletVersion`
- collects versions from all control plane instances via the `control-plane-manager.deckhouse.io/kubernetes-version` annotation
- creates and maintains the **`d8-cluster-kubernetes`** ConfigMap in the `kube-system` namespace with detailed update status.

The `d8-cluster-kubernetes` ConfigMap displays:

- **Component status**: Versions of control plane components (kube-apiserver, kube-scheduler, kube-controller-manager) on each master node.
- **Node progress**: How many nodes have been updated and the total count.
- **Target and current version**: The desired version from configuration and the actual state during the update.
- **Version mismatch**: If any components are running a version different from the target (including newer than desired).
- **Version lists**:
  - `supportedVersions`: Lists minor Kubernetes versions supported in the current DP release.
  - `availableVersions`: Lists versions that can be selected for upgrade or downgrade in the *current* cluster. The set is limited by the highest minor version ever installed on the cluster and by the rule that downgrade proceeds one minor at a time.
- **`maxUsedKubernetesVersion`**: The highest minor version the cluster has ever converged onto. It only ever rises, and it is what limits how far the version can be rolled back.
- **`automaticVersion`**: Minor version that will be used when the update mode is `Automatic`. It describes the installed DP build rather than the state of the cluster.

During `ControlPlaneUpdating`, `status.progress` reflects overall upgrade progress across intermediate minor versions. For a multi-hop upgrade (for example, 1.33 → 1.35), the percentage increases as each hop completes, not only when every control plane component reaches the final target.

Minor versions in the ConfigMap (`spec`, `status`, and metadata labels such as `k8s-version` and `max-k8s-version`) use the same string format as the `kubernetesVersion` parameter, meaning without a `v` prefix (for example, `"1.33"`).

You can see in real time which components are being updated, at what stage the process is, and whether the update has "stuck" on any node or component.

To view the update status, run the command:

```
d8 k get configmap d8-cluster-kubernetes -n kube-system -o yaml
```

ConfigMap content examples

The `data.spec` and `data.status` fields store YAML with the `spec` field (target version and update mode) and the `status` field (current state). Below are examples of the content for various situations.

Cluster up to date (3 master nodes, 3 worker nodes)

```

  uid: ba981996-f737-469c-9ce1-53aa46135994
```

Intermediate step of a multi-hop upgrade (e.g. 1.33 → 1.35)

In the configuration, the target Kubernetes version may be several minor versions ahead of the current cluster version. In this case, the upgrade is performed step by step through intermediate minor versions.

The `status.currentVersion` field reflects the current upgrade step (the active minor version the cluster is being brought to at the moment). Within a single step, individual control plane components may temporarily run different minor versions.

The `progress` field reflects the entire upgrade path, including intermediate versions. Therefore, its value can be significantly greater than 0% even before all components reach the target version.

```
apiVersion: v1
data:
  spec: |
    desiredVersion: "1.35"
    updateMode: Manual
    automaticVersion: "1.33"
  status: |
    currentVersion: "1.34"
    supportedVersions:
    - "1.31"
    - "1.32"

Additional resources

- Global custom resources
- Module `control-plane-manager` documentation

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Switching between DP editions

This guide describes the steps required to switch the Deckhouse Platform edition in a running cluster.

Follow the sections in order.

The switching process differs depending on how you work with the image registry. Choose the method that applies to your cluster and follow the instructions.

A valid license key is required when switching to DP BE/SE/SE+/EE. It is not required when switching to DP CE.

> ⚠ This guide assumes the use of a public container image registry (`registry.deckhouse.io`). If you use a different registry address, adjust the commands or refer to the guide for switching Deckhouse to a third-party container image registry.
>
> Execute all commands on the master node of the existing cluster as the `root` user.

Pre-switch preparation

Before switching between revisions, follow these steps:

1. Make sure that the DP queues are empty.
2. Determine the current DP revision and version.
3. Verify that you can switch from the current version to the desired one.

Queue check

Make sure the DP queues are empty and there are no running tasks that could interfere with the switch:

```
d8 system queue list
```

Example output (queues are empty)...

```
Summary:
- 'main' queue: empty.
- 88 other queues (0 active, 88 empty): 0 tasks.
- no tasks to handle.
```

Determining the current edition and version

To ensure the correctness of further steps, determine the current DP edition used in the cluster. This helps avoid errors during the switch and confirms that the required modules and features are supported in the new edition.

You can find the edition and version currently used in the cluster on the main page of the DP web interface, or by using CLI commands:

- edition:

  ```
  d8 k -n d8-system exec -it svc/deckhouse-leader -c deckhouse -- deckhouse-controller global values -o yaml | yq '.deckhouseEdition'
  ```

- version:

  ```
  d8 k -n d8-system get deploy deckhouse -ojson | jq -r '.spec.template.spec.containers[] | select(.name == "deckhouse") | .image' | awk -F: '{print $NF}'
  ```

Checking whether switching to the desired edition is possible

Different DP editions support different sets of modules, Kubernetes versions, and features. It is important to understand what functional changes will occur during the switch and which capabilities will become unavailable. This will help you prepare for the switching process.

A comparison of DP editions by module set can be found in the documentation on the Edition comparison page.

What to consider before switching:

- To DP CE

- To DP BE
- To DP SE
- To DP SE+
- To DP EE

1. Determine the list of internal modules used in the cluster that are not supported in DP new edition. To do this, follow these steps:

   1. Get the list of internal modules not supported in DP ce:

      ```
      (set -e
      trap 'echo "Execution error"' ERR

      echo

      echo "Modules not supported in the desired edition (edition code - ce,
      version - $DECKHOUSE_VERSION):"
      echo MODULES_TO_DISABLE=\"$MODULES_TO_DISABLE\"
      )

      echo
      echo "Deleting the deckhouse pod of the new edition"
      d8 k delete pod/ce-image secret/ce-image-pull-secret --wait=true --ignore-not-
      found=true
      ```

   2. Disable the modules from the list if acceptable (the module functionality is not used, or you are ready to give it up). Otherwise, **abort the switching process.**

      You can disable the modules from the list in the DP web interface under System → System Management → Deckhouse → Modules, or by running the following command:

      ```
      echo $MODULES_TO_DISABLE | tr ' ' '\n' | awk {'print "d8 platform module
      disable",$1'} | bash
      ```

2. Determine the list of external modules launched via `moduleSource/deckhouse` that are not supported in DP new edition. To do this, follow these steps:

   1. Get the list of external modules launched via `moduleSource/deckhouse` with the result of checking their availability in DP new edition:

```
(set -e
trap 'echo "Execution error"' ERR
d8-crane() {
   if command -v d8 &>/dev/null && d8 cr &>/dev/null 2>&1; then
       d8 cr "$@"
   else
       crane "$@"
   fi
}

check_external_modules() {
   local repo="$1"

   local modules=$(d8 k get modulerelease -o json | jq -r '.items[] |
select(.metadata.ownerReferences[] | select(.kind=="ModuleSource" and
.name=="deckhouse")) | "\(.spec.moduleName) \(.spec.version)"')
   [[ -z "$modules" ]] && return 0
   local registry_modules=$(d8-crane ls "$repo" 2>/dev/null)

   echo "Module | In registry"
   echo "-------|------------"

   echo "$modules" | while read module version; do
       grep -qx "$module" <<< "$registry_modules" && list="" || list=""
     echo "$module | $list"
   done
}

d8-crane --help > /dev/null 2>&1 || { echo "ERROR: crane not found"; exit 1; }
check_external_modules "registry.deckhouse.io/deckhouse/ce/modules"
)
```

2. Disable the modules that were not found in the new edition if acceptable. Otherwise, **abort the switching process.**

3. Make sure all tasks in the DP queue are complete before continuing the switching process:

   ```
   d8 system queue list
   ```

   Example output (queues are empty)...

   ```
   Summary:
   - 'main' queue: empty.
   - 88 other queues (0 active, 88 empty): 0 tasks.
   - no tasks to handle.
   ```

1. Determine the list of internal modules used in the cluster that are not supported in DP new edition. To do this, follow these steps:

   1. Set the environment variable with the license key for the edition you plan to switch to:

      ```
      LICENSE_TOKEN=<LICENSE_KEY>
      ```

   2. Get the list of internal modules not supported in DP be:

```
(set -e
trap 'echo "Execution error"' ERR

echo
echo "Running the deckhouse pod of the new edition with the command 'sleep
-- infinity'"

DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image'
| awk -F: '{print $NF}')
d8 k create secret docker-registry be-image-pull-secret --docker-
server=registry.deckhouse.io --docker-username=license-token --docker-
password=${LICENSE_TOKEN}
d8 k run be-image --image=registry.deckhouse.io/deckhouse/be/install:$DECKHOUSE_VERSION
\
--overrides="{\"spec\": {\"imagePullSecrets\":[{\"name\": \"be-image-pull-
secret\"}]}}" \
--command sleep -- infinity
d8 k wait --for=condition=ready pod/be-image --timeout=300s

echo
echo "Getting information about internal modules from the current and new
edition"
echo "Comparing internal modules of the current and new edition"
NEW_MODULES=$(d8 k exec be-image -- ls -l deckhouse/modules/ |  grep -oE "\d.*-\w*"
| awk {'print $9'} | cut -c5-)

)
```

3. Disable the modules that were not found in the new edition if acceptable. Otherwise, **abort the switching process.**

3. Make sure all tasks in the DP queue are complete before continuing the switching process:

   ```
   d8 system queue list
   ```

   Example output (queues are empty)...

   ```
   Summary:
   - 'main' queue: empty.
   - 88 other queues (0 active, 88 empty): 0 tasks.
   - no tasks to handle.
   ```

Switching the edition

Selecting a switching method

When selecting a switching method, consider how the DP container image repository is configured within the cluster.

There are two ways to work with the DP container image registry:

- Using the `registry` module — **(recommended)** — the configuration for working with the DP registry is specified in the `registry` section of the `deckhouse` module parameters (ModuleConfig `deckhouse`). This method provides a smoother transition process and automatic verification that the required images are present. If your cluster uses this method for working with the DP container registry, use the section “Switching Using the registry Module” to switch editions.
- Without using the `registry` module — the configuration for working with the DP registry is set during cluster installation in `InitConfiguration`, and the `registry.mode` of the `deckhouse` module (ModuleConfig `deckhouse`) is set to `Unmanaged`, and the `registry.unmanaged` parameter of the `deckhouse` module is not specified.

  This method is the only one available for managed Kubernetes clusters where the control plane is managed by a cloud provider rather than DP (e.g. Amazon EKS, Azure AKS, Google GKE, etc.).

  If your cluster uses this method for managing the DP container image repository, refer to the section “Switching without using the registry module” to switch versions.

Switching using the registry module

⚠
- Before proceeding, complete the preparatory steps described in the Pre-switch preparation section.
- This switching method must be performed only in `Unmanaged` mode. Make sure that the cluster uses the `registry` module. ModuleConfig `deckhouse` must contain the registry parameters of the previous DP edition in `Unmanaged` mode. If this is not the case, use the “Switching without the registry module” section: DP 1.78 and later no longer contain the v1 implementation of the `registry` module, so a cluster cannot be moved to it.
- This method is not applicable for managed Kubernetes (EKS, AKS, GKE).

1. In ModuleConfig `deckhouse`, set `imagesRepo` to the target edition and `checkMode: Relax`:

   Run the command to edit ModuleConfig `deckhouse`:

   ```
   d8 k edit moduleconfig deckhouse
   ```

   Choose the example for your target edition:

   - DP CE
   - DP BE
   - DP SE
   - DP SE+
   - DP EE

   ```
   apiVersion: deckhouse.io/v1alpha1
   kind: ModuleConfig
   metadata:
     name: deckhouse
   spec:
     version: 1
     enabled: true
     settings:
       registry:
         mode: Unmanaged
         unmanaged:
           checkMode: Relax
           imagesRepo: registry.deckhouse.io/deckhouse/ce
           scheme: HTTPS
   ```

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Unmanaged
      unmanaged:
        license: <LICENSE_KEY>
        checkMode: Relax
        imagesRepo: registry.deckhouse.io/deckhouse/be
        scheme: HTTPS
```

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Unmanaged
      unmanaged:
        license: <LICENSE_KEY>
        checkMode: Relax
        imagesRepo: registry.deckhouse.io/deckhouse/se
        scheme: HTTPS
```

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Unmanaged
      unmanaged:
        license: <LICENSE_KEY>
        checkMode: Relax
        imagesRepo: registry.deckhouse.io/deckhouse/se-plus
        scheme: HTTPS
```

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    registry:
      mode: Unmanaged
      unmanaged:
        license: <LICENSE_KEY>
        checkMode: Relax
        imagesRepo: registry.deckhouse.io/deckhouse/ee
        scheme: HTTPS
```

2. Make sure that `deckhouse` pods has started after the registry change:
   1. To do this, run the command:

      ```
      d8 k -n d8-system get pods -l "app=deckhouse"
      ```

   2. If Deckhouse is in ImagePullBackoff with an error downloading sidecar containers, specify the actual images:

      Get the actual digests of the sidecar images:

      ```
      DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
      '.spec.template.spec.containers[] | select(.name == "deckhouse") | .image'
      | awk -F':' '{print $1}')
      DKP_TAG=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
      '.spec.template.spec.containers[] | select(.name == "deckhouse") | .image'
      | awk -F':' '{print $2}')

      d8 k run dkp-image --image=$DECKHOUSE_VERSION/install:$DKP_TAG --command sleep --
      infinity
      d8 k wait --for=condition=ready pod/dkp-image --timeout=300s

      DECKHOUSE_KUBE_RBAC_PROXY=$(d8 k exec dkp-image -- cat
      /deckhouse/candi/images_digests.json | jq -r ".common.kubeRbacProxy")
      DECKHOUSE_INIT=$(d8 k exec dkp-image -- cat /deckhouse/candi/images_digests.json | jq -
      r ".deckhouse.init")

      d8 k delete pod dkp-image
      ```

      Apply images:

      ```
      d8 k -n d8-system set image deployment/deckhouse \
      kube-rbac-proxy=$DECKHOUSE_VERSION@$DECKHOUSE_KUBE_RBAC_PROXY \
      init-downloaded-modules=$DECKHOUSE_VERSION@$DECKHOUSE_INIT
      ```

   3. Make sure there is no image download error:

      ```
      d8 k -n d8-system get pods -l "app=deckhouse"
      ```

3. Wait for the switch to complete.

   Check the status:

```
d8 k -n d8-system -o yaml get secret registry-state | yq -C -P '.data | del .state |
map_values(@base64d) | .conditions = (.conditions | from_yaml) | {"conditions":
[.conditions[] | select(.type == "Ready" or .type ==
"RegistryContainsRequiredImages")]}'
```

Example of a successful output:

```
conditions:
  - lastTransitionTime: "2026-05-05T13:53:23Z"
    message: |-
      Mode: Default
      registry.deckhouse.io: all 1 items are checked
    reason: Ready
    status: "True"
    type: RegistryContainsRequiredImages
  - lastTransitionTime: "2026-05-05T13:54:49Z"
    message: ""
    reason: ""
    status: "True"
    type: Ready
```

4. Set `checkMode` back to `Default`:

```
d8 k patch moduleconfig deckhouse --type=json -p='[{"op": "replace", "path":
"/spec/settings/registry/unmanaged/checkMode", "value": "Default"}]'
```

5. Check the switch status again.

   Check the status:

```
d8 k -n d8-system -o yaml get secret registry-state | yq -C -P '.data | del .state |
map_values(@base64d) | .conditions = (.conditions | from_yaml) | {"conditions":
[.conditions[] | select(.type == "Ready" or .type ==
"RegistryContainsRequiredImages")]}'
```

   Example of a successful output:

```
conditions:
  - lastTransitionTime: "2026-05-05T13:53:23Z"
    message: |-
      Mode: Default
      registry.deckhouse.io: all 182 items are checked
    reason: Ready
    status: "True"
    type: RegistryContainsRequiredImages
  - lastTransitionTime: "2026-05-05T13:54:49Z"
    message: ""
    reason: ""
    status: "True"
    type: Ready
```

6. Check for pods with image pull errors:

```
d8 k get pods -A | awk 'NR==1 || /^d8-/' | grep -E 'ImagePullBackOff|ErrImagePull'
```

   For each problematic module, run the following commands **on all master nodes**, specifying the module name:

```
rm -rf /var/lib/deckhouse/downloaded/<MODULE_NAME>/
d8 k rollout restart deploy -n d8-system deckhouse
```

7. Check for pods using the old registry:

```
d8 k get pods -A -o json | jq -r '.items[] | select(.spec.containers[] |
select(.image | contains("deckhouse.io/deckhouse/<PREVIOUS_EDITION_CODE>"))) |
.metadata.namespace + "\t" + .metadata.name' | sort | uniq
```

Switching without the registry module

⚠

- Before proceeding, complete the preparatory steps described in the Pre-switch preparation section.
- Before applying, make sure that the `registry` module is not used in the cluster. ModuleConfig `deckhouse` must not contain registry parameters. The `registry` module must be disabled. If this is not the case, perform the migration to the deprecated registry management format (without the registry module).

Choose the target edition:

- DP CE/BE/SE/SE+/EE

1. Run the command to set the authentication credentials for the image registry:

   - DP CE
   - DP BE
   - DP SE
   - DP SE+
   - DP EE

   Not required for DP CE.

   i If you need to add configuration for an additional registry in containerd, refer to the How to add configuration for an additional registry in containerd section.

   For ContainerdV1:

```
AUTH_STRING="$(echo -n license-token:${LICENSE_TOKEN} | base64 )"
d8 k --as=system:sudouser apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerdv1-be-config.sh
spec:
  nodeGroups:
  - '*'
  bundles:
  - '*'
  weight: 1
  content: |
    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/be-registry.toml - << "EOF"
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry.configs]
          [plugins."io.containerd.grpc.v1.cri".registry.mirrors]

[plugins."io.containerd.grpc.v1.cri".registry.mirrors."registry.deckhouse.io"]
              endpoint = ["https://registry.deckhouse.io"]

[plugins."io.containerd.grpc.v1.cri".registry.configs."registry.deckhouse.io".a
uth]
            auth = "$AUTH_STRING"
    EOF
EOF
```

For ContainerdV2:

```
d8 k --as=system:sudouser apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerdv2-be-config.sh
spec:
  nodeGroups:
  - '*'
  bundles:
  - '*'
  weight: 31
  content: |
    mkdir -p /etc/containerd/registry.d/registry.deckhouse.io
    bb-sync-file "/etc/containerd/registry.d/registry.deckhouse.io/hosts.toml"
- << "EOF"
    [host]

      [host."https://registry.deckhouse.io"]
         capabilities = ["pull", "resolve"]
         [host."https://registry.deckhouse.io".auth]
            username = "license-token"
            password = "${LICENSE_TOKEN}"
    EOF
EOF
```

Wait for the bashible service to synchronize (the `UPTODATE` column value for a NodeGroup must match `NODES`):

```
d8 k get ng -o custom-
columns=NAME:.metadata.name,NODES:.status.nodes,READY:.status.ready,UPTODATE:.status.upToDate
```

The bashible log should contain `Configuration is in sync, nothing to do`:

```
journalctl -u bashible -n 5
```

> **i** If you need to add configuration for an additional registry in containerd, refer to the How to add configuration for an additional registry in containerd section.

For ContainerdV1:

```
AUTH_STRING="$(echo -n license-token:${LICENSE_TOKEN} | base64 )"
d8 k --as=system:sudouser apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerdv1-se-config.sh
spec:
  nodeGroups:
  - '*'
  bundles:
  - '*'
  weight: 1
  content: |
    mkdir -p /etc/containerd/conf.d
    bb-sync-file /etc/containerd/conf.d/se-registry.toml - << "EOF"
    [plugins]
      [plugins."io.containerd.grpc.v1.cri"]
        [plugins."io.containerd.grpc.v1.cri".registry.configs]
          [plugins."io.containerd.grpc.v1.cri".registry.mirrors]

[plugins."io.containerd.grpc.v1.cri".registry.mirrors."registry.deckhouse.io"]
              endpoint = ["https://registry.deckhouse.io"]

[plugins."io.containerd.grpc.v1.cri".registry.configs."registry.deckhouse.io".a
uth]
            auth = "$AUTH_STRING"
    EOF
EOF
```

For ContainerdV2:

```
d8 k --as=system:sudouser apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: NodeGroupConfiguration
metadata:
  name: containerdv2-se-config.sh
spec:
  nodeGroups:
  - '*'
  bundles:

            username = "license-token"
            password = "${LICENSE_TOKEN}"
    EOF
EOF
```

Wait for the bashible service to synchronize (the `UPTODATE` column value for a NodeGroup must match `NODES`):

```
d8 k get ng -o custom-
columns=NAME:.metadata.name,NODES:.status.nodes,READY:.status.ready,UPTODATE:.status.upToDate
```

The bashible log should contain `Configuration is in sync, nothing to do`:

```
journalctl -u bashible -n 5
```

2. Switch the container image registry:

   - DP CE
   - DP BE
   - DP SE
   - DP SE+
   - DP EE

```
DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image' | awk
-F: '{print $NF}')

d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry \
--new-deckhouse-tag=$DECKHOUSE_VERSION \
registry.deckhouse.io/deckhouse/ce
```

```
DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image' | awk
-F: '{print $NF}')

AUTH_STRING="$(echo -n license-token:${LICENSE_TOKEN} | base64 )"
DOCKER_CONFIG_JSON=$(echo -n "{\"auths\": {\"registry.deckhouse.io\":
{\"username\": \"license-token\", \"password\": \"${LICENSE_TOKEN}\", \"auth\":
\"${AUTH_STRING}\"}}}" | base64 -w 0)

d8 k --as system:sudouser -n d8-cloud-instance-manager patch secret deckhouse-registry \
--type merge \
--patch="{\"data\":{\".dockerconfigjson\":\"$DOCKER_CONFIG_JSON\"}}"

d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry \
--user=license-token \
--password=$LICENSE_TOKEN \
--new-deckhouse-tag=$DECKHOUSE_VERSION \
registry.deckhouse.io/deckhouse/be
```

```
DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image' | awk
-F: '{print $NF}')

AUTH_STRING="$(echo -n license-token:${LICENSE_TOKEN} | base64 )"
DOCKER_CONFIG_JSON=$(echo -n "{\"auths\": {\"registry.deckhouse.io\":
{\"username\": \"license-token\", \"password\": \"${LICENSE_TOKEN}\", \"auth\":
\"${AUTH_STRING}\"}}}" | base64 -w 0)

d8 k --as system:sudouser -n d8-cloud-instance-manager patch secret deckhouse-registry \
--type merge \
--patch="{\"data\":{\".dockerconfigjson\":\"$DOCKER_CONFIG_JSON\"}}"

d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry \
--user=license-token \
--password=$LICENSE_TOKEN \
--new-deckhouse-tag=$DECKHOUSE_VERSION \
registry.deckhouse.io/deckhouse/se
```

```
DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image' | awk
-F: '{print $NF}')

AUTH_STRING="$(echo -n license-token:${LICENSE_TOKEN} | base64 )"
DOCKER_CONFIG_JSON=$(echo -n "{\"auths\": {\"registry.deckhouse.io\":
{\"username\": \"license-token\", \"password\": \"${LICENSE_TOKEN}\", \"auth\":
\"${AUTH_STRING}\"}}}" | base64 -w 0)

d8 k --as system:sudouser -n d8-cloud-instance-manager patch secret deckhouse-registry \
--type merge \
--patch="{\"data\":{\".dockerconfigjson\":\"$DOCKER_CONFIG_JSON\"}}"

d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry \
--user=license-token \
--password=$LICENSE_TOKEN \
--new-deckhouse-tag=$DECKHOUSE_VERSION \
registry.deckhouse.io/deckhouse/se-plus
```

```
DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image' | awk
-F: '{print $NF}')

AUTH_STRING="$(echo -n license-token:${LICENSE_TOKEN} | base64 )"
DOCKER_CONFIG_JSON=$(echo -n "{\"auths\": {\"registry.deckhouse.io\":
{\"username\": \"license-token\", \"password\": \"${LICENSE_TOKEN}\", \"auth\":
\"${AUTH_STRING}\"}}}" | base64 -w 0)

d8 k --as system:sudouser -n d8-cloud-instance-manager patch secret deckhouse-registry \
--type merge \
--patch="{\"data\":{\".dockerconfigjson\":\"$DOCKER_CONFIG_JSON\"}}"

d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller helper
change-registry \
--user=license-token \
--password=$LICENSE_TOKEN \
--new-deckhouse-tag=$DECKHOUSE_VERSION \
registry.deckhouse.io/deckhouse/ee
```

3. Make sure that `deckhouse` pods has started after the registry change:
   1. To do this, run the command:

      ```
      d8 k -n d8-system get pods -l "app=deckhouse"
      ```

   2. If Deckhouse is in ImagePullBackoff with an error downloading sidecar containers, specify the actual images:

      Get the actual digests of the sidecar images:

```
DECKHOUSE_VERSION=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image'
| awk -F':' '{print $1}')
DKP_TAG=$(d8 k -n d8-system get deploy deckhouse -ojson | jq -r
'.spec.template.spec.containers[] | select(.name == "deckhouse") | .image'
| awk -F':' '{print $2}')

d8 k run dkp-image --image=$DECKHOUSE_VERSION/install:$DKP_TAG --command sleep --
infinity
d8 k wait --for=condition=ready pod/dkp-image --timeout=300s

DECKHOUSE_KUBE_RBAC_PROXY=$(d8 k exec dkp-image -- cat
/deckhouse/candi/images_digests.json | jq -r ".common.kubeRbacProxy")
DECKHOUSE_INIT=$(d8 k exec dkp-image -- cat /deckhouse/candi/images_digests.json | jq -
r ".deckhouse.init")

d8 k delete pod dkp-image
```

Apply images:

```
d8 k -n d8-system set image deployment/deckhouse \
kube-rbac-proxy=$DECKHOUSE_VERSION@$DECKHOUSE_KUBE_RBAC_PROXY \
init-downloaded-modules=$DECKHOUSE_VERSION@$DECKHOUSE_INIT
```

3. Make sure there is no image download error:

```
d8 k -n d8-system get pods -l "app=deckhouse"
```

4. Wait for DP to be ready:

```
d8 system queue list
```

Example output (queues are empty)...

```
Summary:
- 'main' queue: empty.
- 88 other queues (0 active, 88 empty): 0 tasks.
- no tasks to handle.
```

5. Check for pods with image pull errors:

```
d8 k get pods -A | awk 'NR==1 || /^d8-/' | grep -E 'ImagePullBackOff|ErrImagePull'
```

For each problematic module, run the following commands **on all master nodes**, specifying the module name:

```
rm -rf /var/lib/deckhouse/downloaded/<MODULE_NAME>/
d8 k rollout restart deploy -n d8-system deckhouse
```

6. Check for pods using the old registry:

```
d8 k get pods -A -o json | jq -r '.items[] | select(.spec.containers[] |
select(.image | contains("deckhouse.io/deckhouse/<PREVIOUS_EDITION_CODE>"))) |
.metadata.namespace + "\t" + .metadata.name' | sort | uniq
```

7. Perform cleanup:

   - DP CE
   - DP BE
   - DP SE
   - DP SE+
   - DP EE

Not required for DP CE.

For ContainerdV1

```
d8 k --as=system:sudouser delete ngc containerdv1-be-config.sh
d8 k --as=system:sudouser apply -f - <<EOF

Uninstallation

Deleting a cluster deployed with a cloud provider

Perform the following steps to delete a cluster deployed with a cloud provider

1. Find out the release channel set in the cluster. To do this, run the command:

```
kubectl get mc deckhouse  -o jsonpath='{.spec.settings.releaseChannel}'
```

2. Run the Deckhouse installer:

```
docker run --pull=always -it [<MOUNT_OPTIONS>] \
  registry.deckhouse.io/deckhouse/<DECKHOUSE_REVISION>/install:<RELEASE_CHANNEL> bash
```

where:

- `<MOUNT_OPTIONS>` — parameters for mounting files in the installer container, such as SSH access keys;
- `<DECKHOUSE_REVISION>` — the Deckhouse edition (e. g., `ee` — for the Enterprise Edition, `ce` — for the Community Edition, etc.)
- `<RELEASE CHANNEL>` — the Deckhouse release channel in kebab-case:
  - `alpha` — for the *Alpha* release channel;
  - `beta` — for the *Beta* release channel;
  - `early-access` — for the *Early Access* release channel;
  - `stable` — for the *Stable* release channel;
  - `rock-solid` — for the *Rock Solid* release channel.

Below is an example command to run the Deckhouse CE installer container:

```
docker run -it --pull=always \
  -v "$PWD/dhctl-tmp:/tmp/dhctl" \
  -v "$HOME/.ssh/:/tmp/.ssh/" registry.deckhouse.io/deckhouse/ce/install:stable bash
```

3. In the container you have started, run the following command:

```
dhctl destroy --ssh-user=<USER> \
  --ssh-agent-private-keys=/tmp/.ssh/<SSH_PRIVATE_KEY_FILE> \
  --yes-i-am-sane-and-i-understand-what-i-am-doing \
  --ssh-host=<MASTER_IP>
```

where:

- `<USER>` — the user of the remote machine that ran the installation. If `<USER>` needs to perform actions via `sudo`, add the `--ask-become-pass` flag;
- `<MASTER_IP>` — the IP address of the cluster's master node.

The installer will then connect to the cluster, retrieve the necessary data, and delete all the resources and objects in the cloud that were created during the DP installation and operation.

Deleting a hybrid cluster

Follow these steps to delete a hybrid cluster consisting of the nodes that were automatically deployed in the cloud as well as the static nodes that were manually plugged in:

1. First, delete all the extra nodes (CloudStatic and Static) that were manually plugged in.
2. Find out the release channel set in the cluster. To do this, run the command:

```
kubectl get mc deckhouse  -o jsonpath='{.spec.settings.releaseChannel}'
```

3. Run the Deckhouse installer:

```
docker run --pull=always -it [<MOUNT_OPTIONS>] \
  registry.deckhouse.io/deckhouse/<DECKHOUSE_REVISION>/install:<RELEASE_CHANNEL> bash
```

where:

- `<MOUNT_OPTIONS>` — parameters for mounting files in the installer container, such as SSH access keys;
- `<DECKHOUSE_REVISION>` — the Deckhouse edition (e. g., `ee` — for the Enterprise Edition, `ce` — for the Community Edition, etc.)
- `<RELEASE CHANNEL>` — the Deckhouse release channel in kebab-case:
  - `alpha` — for the *Alpha* release channel;
  - `beta` — for the *Beta* release channel;
  - `early-access` — for the *Early Access* release channel;
  - `stable` — for the *Stable* release channel;
  - `rock-solid` — for the *Rock Solid* release channel.

Below is an example command to run the Deckhouse CE installer container:

```
docker run -it --pull=always \
  -v "$PWD/dhctl-tmp:/tmp/dhctl" \
  -v "$HOME/.ssh/:/tmp/.ssh/" registry.deckhouse.io/deckhouse/ce/install:stable bash
```

4. In the container you have started, run the following command:

   ```
   dhctl destroy --ssh-user=<USER> \
     --ssh-agent-private-keys=/tmp/.ssh/<SSH_PRIVATE_KEY_FILE> \
     --yes-i-am-sane-and-i-understand-what-i-am-doing \
     --ssh-host=<MASTER_IP>
   ```

   where:

   - `<USER>` — the user of the remote machine that ran the installation. If `<USER>` needs to perform actions via `sudo`, add the `--ask-become-pass` flag;
   - `<MASTER IP>` — the IP address of the cluster's master node;
   - `<SSH_PRIVATE KEY_FILE>`: Name of private key. For example, for a key with RSA encryption it can be `id_rsa`, and for a key with ED25519 encryption it can be `id_ed25519`.

The installer will then connect to the cluster, retrieve the necessary data, and delete all the resources and objects in the cloud that were created during the DP installation and operation.

Deleting a static cluster

Follow the steps below to delete a cluster that has been manually installed (e.g., on bare metal):

1. Delete all the extra nodes from the cluster.
2. Find out the release channel set in the cluster. To do this, run the command:

   ```
   kubectl get mc deckhouse  -o jsonpath='{.spec.settings.releaseChannel}'
   ```

3. Run the Deckhouse installer:

   ```
   docker run --pull=always -it [<MOUNT_OPTIONS>] \
     registry.deckhouse.io/deckhouse/<DECKHOUSE_REVISION>/install:<RELEASE_CHANNEL> bash
   ```

   where:

   - `<MOUNT_OPTIONS>` — parameters for mounting files in the installer container, such as SSH access keys;
   - `<DECKHOUSE_REVISION>` — the Deckhouse edition (e.g., `ee` — for the Enterprise Edition, `ce` — for the Community Edition, etc.)
   - `<RELEASE CHANNEL>` — the Deckhouse release channel in kebab-case:
     - `alpha` — for the *Alpha* release channel;
     - `beta` — for the *Beta* release channel;
     - `early-access` — for the *Early Access* release channel;
     - `stable` — for the *Stable* release channel;
     - `rock-solid` — for the *Rock Solid* release channel.

   Below is an example command to run the Deckhouse CE installer container:

   ```
   docker run -it --pull=always \
     -v "$PWD/dhctl-tmp:/tmp/dhctl" \
     -v "$HOME/.ssh/:/tmp/.ssh/" registry.deckhouse.io/deckhouse/ce/install:stable bash
   ```

4. Run the command below to delete the cluster:

   ```
   dhctl destroy --ssh-user=<USER> \
     --ssh-agent-private-keys=/tmp/.ssh/<SSH_PRIVATE_KEY_FILE> \
     --yes-i-am-sane-and-i-understand-what-i-am-doing \
     --ssh-host=<MASTER_IP>
   ```

   where:

   - `<USER>` — the user of the remote machine that ran the installation. If `<USER>` needs to

perform actions via `sudo`, add the `--ask-become-pass` flag;
- `<MASTER IP>` — the IP address of the cluster's master node;
- `<SSH_PRIVATE KEY_FILE>`: Name of private key. For example, for a key with RSA encryption it can be `id_rsa`, and for a key with ED25519 encryption it can be `id_ed25519`.

The installer will then connect to the master node and delete all Deckhouse and Kubernetes cluster components on it.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Going to production

The following recommendations may be of less importance for a test or development cluster, but they may be critical for a production one.

Release channel and update mode

> Use the `EarlyAccess` or `Stable` release channel. Configure auto-update window or select manual mode.

Select the release channel and update mode that suit your needs. The more stable the release channel is, the later you will have the chance to use the new features.

If possible, use different release channels for clusters. Use a less stable update channel for a development cluster than for a testing cluster or stage (pre-production) cluster.

Use the `EarlyAccess` or `Stable` release channel for production clusters.

If you have more than one cluster in a production environment, make sure that the clusters update at different times. In this case, a new version is installed in one cluster first, and you have time to check it before the other clusters update. To spread the updates over time, set non-overlapping update windows for the clusters or connect them to different release channels. For example, if one cluster gets updates from the `EarlyAccess` channel and another one from the `Stable` channel, a new version reaches the second cluster later.

> ⚠ Even in very busy and critical clusters, it is not a good idea to disable the use of the release channel. The best strategy is a scheduled update. If you are using a Deckhouse Platform release in your cluster that has not received an update in over six months, you will have a hard time getting help quickly should a problem arise.

The update windows management allows you to schedule automatic platform release updates when your cluster is not experiencing peak load.

Kubernetes version

> Use the automatic Kubernetes version selection or set the version explicitly.

In most cases, opt for the automatic selection of the Kubernetes version. In Deckhouse Platform, this behavior is set by default, but it can be changed with the `kubernetesVersion` parameter. Upgrading the Kubernetes version in the cluster has no effect on applications and is done in a consistent and secure fashion.

If the automatic Kubernetes version selection is enabled, the platform can upgrade the Kubernetes version in the cluster together with the platform update (when upgrading a minor version). If the

Kubernetes version in the `kubernetesVersion` parameter is set explicitly, the platform may not upgrade to a newer version at some point if the Kubernetes version used in the cluster is no longer supported.

You must decide for yourself whether to use automatic version selection or set a specific version and update it manually every now and then.

If your application uses outdated versions of resources or depends on a particular version of Kubernetes for some other reason, check whether it is supported and set it explicitly.

Resource requirements

> **i** For production, use a cluster with three master nodes or a cluster with role separation. Choose node resources according to the resource requirements for the selected deployment option and workload type.

The resource requirements for each deployment option are listed on the “System requirements” page. The values in the tables cover only the load of Deckhouse Platform components.

When preparing a production cluster, consider the following:

- Do not use a single-node cluster or a single-master cluster: they are not fault-tolerant.
- For master nodes and monitoring nodes, use fast disks with performance of at least 400 IOPS.
- Set up a dedicated StorageClass on fast disks for Deckhouse Platform components.
- Add resources for the user workload to the resources of worker nodes.
- Run load tests of your applications and adjust node resources based on the results.

For details on choosing resources depending on the load, see the Picking resources for a bare metal cluster guide.

Things to consider when configuring

Master nodes

> **i** Three master nodes with fast 400+ IOPS disks are highly recommended for a cluster.

Use three master nodes in all cases, as they are sufficient for fault tolerance. Also, with three nodes, you can safely update the cluster’s control plane as well as the master nodes. Extra master nodes are not needed, while 2 nodes (or any even number) do not make a quorum.

The master node configuration for cloud clusters can be configured using the masterNodeGroup parameter.

Reference:

- How do I add a master node to a cluster...
- Working with static nodes...

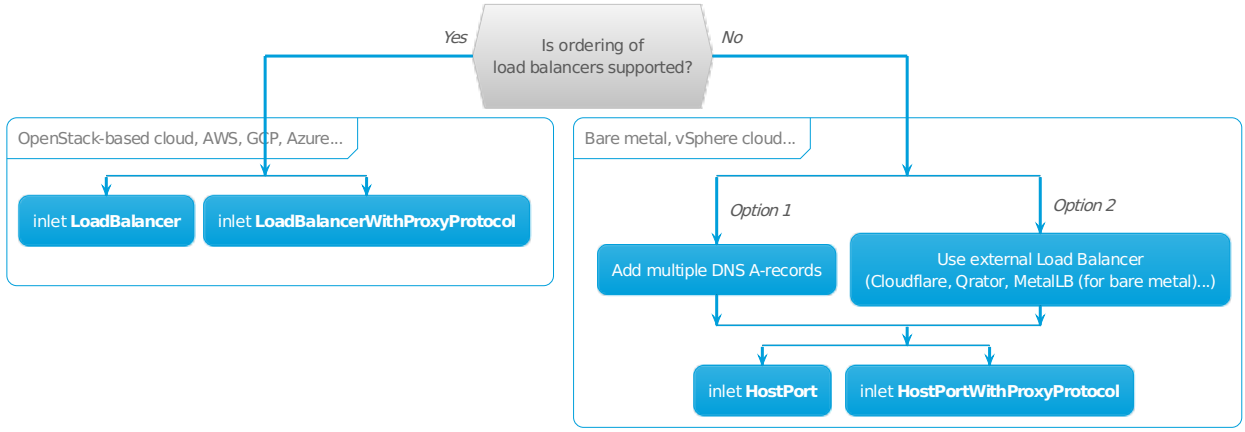
Frontend nodes

> **i** Use two or more frontend nodes.
>
> Use inlet `LoadBalancer` for OpenStack-based clouds and cloud services where automatic balancer ordering is not supported (AWS, GCP, Azure, etc.). Use inlet `HostPort` with an external load balancer for bare metal or vSphere.

Frontend nodes are used for balancing incoming traffic. Such nodes are allocated for Ingress controllers. The NodeGroup of the frontend nodes has a `node-role.deckhouse.io/frontend` label. Read more about allocating nodes for specific load types...

Use more than one frontend node. Frontend nodes must be able to still handle traffic even if one of the frontend nodes fails.

For example, if the cluster has two frontend nodes, each frontend node must be able to handle the entire cluster load in case the second frontend node fails. If the cluster has three frontend nodes, each frontend node must be able to handle a load that is at least one and a half times higher.



Select the inlet type (it defines the way the traffic comes in).

When deploying the platform in a cloud infrastructure where provisioning of load balancers is supported (e.g., OpenStack-based clouds, AWS, GCP, Azure, etc.), use the `LoadBalancer` or `LoadBalancerWithProxyProtocol` inlet.

In environments where automatic load balancer provisioning is not supported (bare metal clusters, vSphere, custom OpenStack solutions), use the `HostPort` or `HostPortWithProxyProtocol` inlet. In this case, you can either add some A-records to DNS for the corresponding domain or use an external load-balancing service (e.g., Cloudflare, Qrator solutions, or configure metallb).

⚠ The `HostWithFailover` inlet is suitable for clusters with a single frontend node. It reduces the time that the Ingress controller is unavailable during updates. This type of inlet is suitable for important development environments, but **not recommended for production**.

The algorithm for choosing an inlet:

Monitoring nodes

ℹ For high-load clusters, use two monitoring nodes equipped with fast disks.

Monitoring nodes are used to run Grafana, Prometheus, and other monitoring components. The NodeGroup for monitoring nodes has the `node-role.deckhouse.io/monitoring` label attached.

In high-load clusters, where many alerts are generated and many metrics are collected, allocate dedicated nodes for monitoring. If not, monitoring components will be deployed to system nodes.

When allocating monitoring nodes, it is important to allocate fast disks to them. You can do so by providing a dedicated `storageClass` on fast disks for all platform components (global parameter storageClass) or allocate a dedicated `storageClass` to monitoring components only storageClass and longtermStorageClass parameters of the `prometheus` module.

If the cluster is initially created with nodes allocated for a specific type of workload (system nodes, nodes for monitoring, etc.), explicitly specify the corresponding `nodeSelector` parameter in the module configuration for modules that use persistent storage volumes (for example, for the `prometheus` module). For the `prometheus` module, this parameter is nodeSelector.

System nodes

ℹ Dedicate two system nodes.

System nodes are used to run platform modules. Their NodeGroup has the `node-role.deckhouse.io/system` label.

Set two nodes to be system nodes. This way, platform modules will run on them without interfering with user applications in the cluster. Read more about allocating nodes to specific load types….

Provide the platform components with fast disks (the storageClass global parameter).

Cluster subnets

> **i** Plan the cluster subnets before installation, because you cannot change them afterwards.

You set the pod subnet (`podSubnetCIDR`), the service subnet (`serviceSubnetCIDR`), and the node subnet size (`podSubnetNodeCIDRPrefix`) when you install the cluster. Select the pod and service subnets so that they do not overlap with each other or with the node network. Changing these parameters in a running cluster can break it, so the platform blocks such changes. If you need other subnets, recreate the cluster.

The node subnet size defines how many pods fit on a node. By default, the pod limit per node, the `kubelet.maxPods` parameter of the node group, is calculated from this size. The mapping between the subnet size and the pod limit is listed in the Pod limit per node section.

Storage

> **i** Use replicated storage for production data and set a default StorageClass.

Workloads keep persistent data in PersistentVolume volumes, so connect at least one of the supported storage types to the cluster. For production, use storage with data replication between nodes, for example, replicated storage based on DRBD, so the data stays available if a node fails. If you use software-defined storage (SDS), add dedicated disks for data to its nodes.

Set the default StorageClass in the `defaultClusterStorageClass` global parameter. Volumes that do not specify a storage class explicitly get this class.

Virtualization

If virtual machines (VMs) will run in the cluster, follow the recommendations in this section together with the other recommendations of this guide.

Node requirements for VMs

A cluster with VMs must meet the following requirements:

- VMs run on physical servers (bare metal).
- CPUs of nodes for VMs support Intel-VT (VMX) or AMD-V (SVM) instructions, and hardware virtualization is enabled in BIOS or UEFI settings.
- All cluster nodes run the same Linux kernel version.

The same kernel version is necessary for stable VM live migration, because system calls and resource handling differ between kernel versions.

> **⚠** Use virtual machines instead of physical servers as nodes only for demonstration purposes. In this case, enable nested virtualization.

Number of VMs per node

The number of VMs per node is limited by the pod limit, which VMs, containers, and system components share. A running VM with disks usually occupies two pods, because besides the VM pod, a service pod runs on the node and attaches the VM disks and images. It serves disks added with the VirtualMachineBlockDeviceAttachment resource and all disks of a VM with paravirtualization enabled (the `.spec.enableParavirtualization` parameter, enabled by default). During live migration, the same pods start on the target node, so take them into account when you select the node subnet size.

VM subnets

VMs get IP addresses in the main cluster network from the subnets listed in the `virtualMachineCIDRs` parameter of the `virtualization` module. Select these subnets so that they do not overlap with the node network or the cluster subnets, otherwise address conflicts occur.

Specify a subnet by its start address aligned to the mask, for example, `192.168.1.192/27`, not `192.168.1.190/27`. You can specify several subnets and add new ones later, but you cannot delete a subnet while VirtualMachineIPAddress resources hold addresses from it.

The `virtualMachineCIDRs` parameter is optional. Without it, VMs cannot work in the main cluster network or get addresses with the VirtualMachineIPAddress resource, so you can connect them only to

additional networks. VM network configuration is described in the Virtual machine networking section.

Live migration network

By default, live migration traffic goes through the main node network, competes with workloads for bandwidth, and is limited to 640 MiB/s per migration. To keep migrations from affecting workloads and to make them faster, send them to a dedicated network in the `liveMigration.network` parameter of the `virtualization` module, where the platform does not limit the speed by default. This requires the `sdn` module to be enabled and the SystemNetwork resource to be in the `Ready` state. The configuration is described in the Dedicated migration network section.

Running VMs on master nodes

You need to run VMs on master nodes if the cluster has no separate nodes for workloads, for example, in a single-node cluster. To run VMs on master nodes, remove the taints from the `master` node group in the `nodeTemplate.taints` parameter or set tolerations for the selected VMs. Set tolerations in a VM with the `.spec.tolerations` parameter or in a VM class with the `.spec.tolerations` parameter. Removing the taints lets any workload run on master nodes, and tolerations let only the VMs that have them run there.

Storage for VM disks

VM disks and images are stored in PersistentVolume volumes, so select storage for them according to the recommendations in the Storage section. If VM disks will be stored in software-defined storage, take their size into account when you add disks to the nodes of this storage.

Live migration of VMs with local disks is available only in commercial Deckhouse Platform editions, where the disks move together with the VM. In Deckhouse Platform Open, a VM with a local disk cannot move to another node, so you have to stop it during node maintenance.

Image storage

The platform stores VM images in the internal image storage (DVCR), which runs as a single instance on one persistent volume. The storage class and size of this volume are set in the `dvcr.storage` parameter of the `virtualization` module. After the volume is created, you can only increase its size, and you cannot change its storage class, so select the class in advance. Use replicated storage for DVCR so that the images stay available if a node fails.

VM classes

Create your own VM classes (the VirtualMachineClass resource) and do not use the `generic` class for production workloads. The platform creates the `generic` class during installation with the Nehalem CPU model. This model supports the smallest instruction set, so VMs of the `generic` class start on any node but do not get the instructions of modern CPUs.

Mark your main class with the `virtualmachineclass.virtualization.deckhouse.io/is-default-class` annotation set to `true`, and the platform will set it for VMs that do not specify a class. Do not set this annotation on the `generic` class, because it can be lost when the module is updated.

The CPU type of a class is set by the `.spec.cpu.type` parameter and defines the nodes between which VMs can migrate. You cannot change it after you create the class, so select the type in advance:

- `Host` gives a VM an instruction set close to the node CPU. VMs migrate only between nodes with similar CPUs. Migration between Intel and AMD CPUs or between different CPU generations is not possible.
- `HostPassthrough` passes the node CPU to a VM without changes. VMs migrate only to nodes with exactly the same CPU.
- `Discovery` builds a common instruction set for the selected nodes and suits a cluster with different CPUs. The set is fixed when the class is created and does not change when nodes are added to the cluster.

The other CPU types are described in the Virtual processor of virtual machines section.

The `.spec.sizingPolicies` parameter sets the sizing policies of a class. The policies limit the number of cores, the memory size, and the core fraction for VMs of this class. The core fraction is the part of physical core CPU time that the platform guarantees to a VM. The allowed fraction values in the `coreFractions` parameter define how strong CPU oversubscription can be. Oversubscription configuration is described in the CPU oversubscription for virtual machines section.

Access control

> **i** Configure user authentication and grant permissions with the granular role-based model. Create projects for teams.

You can create users and groups in the cluster with the User and Group resources of the `user-authn` module or get them from external authentication providers. The platform supports providers that use OIDC, SAML, and LDAP, as well as GitHub, GitLab, Atlassian Crowd, and Bitbucket Cloud. You can connect several providers to the cluster at the same time. Provider configuration is described in the Integration with external authentication providers section, and creating users in the cluster is described in the Local authentication section.

To isolate team workloads from each other, create projects for the teams (the Project resource of the `multitenancy-manager` module). A project is created from a template that sets resource limits, network isolation, and a security profile. Project management is described in the Project management section.

Grant permissions with the granular role-based model of the `user-authz` module. The model uses standard Kubernetes RBAC resources and the roles that the module creates. Each role acts in one of four scopes:

- **Namespace.** The `d8:namespace:<LEVEL>` roles grant permissions to application users in one namespace and are assigned with a RoleBinding resource.
- **Project.** The `d8:project:<LEVEL>` roles grant permissions to teams in all namespaces of a project at once and are assigned with a ProjectRoleBinding resource.
- **Subsystem.** The `d8:subsystem:<SUBSYSTEM>:<LEVEL>` roles grant permissions to administrators of a part of the platform, for example, the network, and are assigned with a ClusterRoleBinding resource.
- **Entire platform.** The `d8:system:<LEVEL>` roles grant permissions to platform administrators and are assigned with a ClusterRoleBinding resource.

Here, `<LEVEL>` is the access level, for example, `viewer` or `manager`, and `<SUBSYSTEM>` is the subsystem name.

The basic role-based model, built on the ClusterAuthorizationRule and AuthorizationRule resources, still works, but its support will be discontinued in future releases.

Configuring alerts

> **i** You can send alerts using the internal Alertmanager or connect the external one.

Monitoring will work once the platform is installed, however, it is not enough for production clusters. Configure the Alertmanager built in the platform or connect your own Alertmanager to receive incident notifications.

Using the CustomAlertmanager custom resource, you can configure sending alerts to an e-mail, Slack, Telegram, via the webhook, or by other means.

For the list of all available alerts in the Deckhouse Platform monitoring system, refer to the corresponding documentation page.

Collecting logs

> **i** Configure centralized log collection.

Set up centralized log collection from system and user applications using the log-shipper module.

All you have to do is to create a custom resource specifying *what to collect*: ClusterLoggingConfig or PodLoggingConfig; and create a custom resource that specifies where to *send* the collected logs: ClusterLogDestination.

Reference:

- Grafana Loki example
- Logstash example
- Splunk example

Backups

> **i** Set up etcd backups. Have a backup plan ready at all times.

At a minimum, set up etcd backups. This will be your last chance to restore the cluster should things go awry. Keep these backups as *away* from your cluster as possible.

The backups won't help if they don't work or if you don't know how to use them to recover the cluster. Compile a Disaster Recovery Plan (DRP) with specific steps and commands to restore the cluster from a backup. The restore procedures are described in the Backup and restore section.

This plan should be periodically updated and tested in drills.

Community

> **i** Follow the project channel on Telegram for news and updates.

Join the community to keep up with important news and developments. This will help you to share experiences with people who are doing the same thing as you are and avoid typical problems.

Running production in Kubernetes takes effort. Share your experience with Deckhouse Platform in the community to help others switch to Kubernetes.

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Picking resources for a bare metal cluster

Before deploying a cluster running Deckhouse Platform, you have to plan the configuration of the future cluster and decide on the parameters of its nodes (e.g., RAM, CPU, etc.).

Installation planning

Before deploying a cluster, you need to plan for the resources that you might need to run the cluster. The following questions will help you plan ahead:

- What is the expected load?
- Does your cluster require a high load mode?
- Does your cluster require a high availability mode?
- Which Deckhouse Platform modules do you intend to use?

The answers to these questions can help you estimate the number of nodes recommended for your cluster deployment. See the Deployment options section of the "System requirements" page to learn more.

> **i** The information below applies to a Deckhouse Platform installation running the Default module set.

Deployment scenarios

Cluster deployment options (single-node cluster, cluster with one master node, cluster with three master nodes or cluster with role separation) and node types are described in the Deployment options

section of the “System requirements” page.

> **i** Starting with version 1.74, Deckhouse Platform has a module integrity control mechanism that protects modules from being replaced or modified. This mechanism is enabled automatically when the operating system on the nodes where Deckhouse Platform is installed supports the `erofs` kernel module. If this kernel module is not present, Deckhouse Platform will continue to operate without the module integrity control mechanism, but an alert will be displayed indicating that this functionality is not working.

Deciding on the amount of resources needed for nodes

Resource requirements depend on the deployment option (single-node cluster, cluster with one master node, cluster with three master nodes or cluster with role separation) and on the workload type (running containers, virtual machines, or both containers and virtual machines).

The tables with node resources for every deployment option and workload type are given in the Resource requirements section of the “System requirements” page. The same section describes what the values in the tables include and which resources to reserve on nodes in addition.

Single-node cluster

> ⚠ Such clusters lack fault tolerance. Do not use this kind of clusters in production environments.

In some cases, a cluster can consist of a single node that performs all the node roles described above. This configuration may be used, for example, to familiarize yourself with the technology or to run workloads with low resource requirements.

The Getting Started guide contains instructions for deploying a single-node cluster. Once you un-taint the node, it will run all cluster components included in the selected module bundle (bundle: Default by default). The resources for such a node are given in the “Single-node cluster” row of the tables in the Resource requirements section for the required workload type: containers, virtual machines or combined workloads.

Such a configuration would allow some workloads to be run.

In a single-node cluster for running containers with the resources from the table, a load of 2500 RPS on a typical web application (e.g., a static Nginx page) consisting of 30 pods, and incoming traffic of 24 Mbps will result in approximately the following resource consumption figures:

- CPU load will increase to ~60% in total;
- RAM and disk resource consumption figures will remain largely unchanged. In the end, however, it comes down to the number of metrics collected and the nature of the workload being run.

> **i** Run load testing of the application and adjust the server capacity according to its results.

Configuration examples

The example below is a cluster with role separation without fault tolerance: one node of each type, without dedicated monitoring nodes. The node resources are taken from the For containers table for the cluster with role separation.

To deploy Deckhouse Platform for running containers in the Ultimate/Enterprise Edition with the Default module set, the following node configuration is required:

- **master nodes** — 1 node, 6 CPU, 12 GB RAM, 60 GB of disk space;
- **frontend nodes** — 1 node, 2 CPU, 4 GB RAM, 60 GB of disk space;
- **system nodes** — 1 node, 6 CPU, 12 GB RAM, 300 GB of disk space (the system node hosts the monitoring components and system PVCs);
- **worker nodes** — 1 node, 2 CPU, 4 GB RAM, 60 GB of disk space plus the resources for the user workload.

> **i** If needed, you can also run Deckhouse Platform in the same configuration on a single node. Its resources are given in the “Single-node cluster” row of the same table: 12 CPU, 24 GB RAM and 350 GB of disk space.

Node and network requirements

The requirements for node hardware, the operating system and the network between nodes are given in the Node requirements and Network requirements sections of the “System requirements” page.

Community

> **i** Join our Telegram channel to stay up to date.

Join the Deckhouse community for updates on important developments and news. There, you will be able to chat with others and learn from their experiences. This way, you can avoid many common mistakes.

Setting up and running a production Kubernetes cluster takes effort. Share your experience with Deckhouse Platform in the community to help others move to Kubernetes.

Additional resources

- Module `deckhouse` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

Updating DP in air-gapped environment

> **i** This guide is intended for DP Enterprise Edition, but the mechanism is the same for other editions.
>
> To run the commands given in the guide, you need to authenticate in the container registry `registry.deckhouse.io`. Use `license-token` as the username and your license token as the password for authentication.
>
> The guide uses the third-party utility crane to analyze the container registry. Install it first following the official instructions.

Platform update mechanism using release channels

Deckhouse Platform (DP) updates are based on release channels. You can check which release channel is configured for your DP installation in the `deckhouse` ModuleConfig by running the following command:

```
d8 k get mc deckhouse -o jsonpath='{.spec.settings.releaseChannel}'
```

Example output:

```
Stable
```

Technically, a DP update works as follows: the registry contains an image with the name `release-channel` and a tag corresponding to the release channel. This tag points to an image of a specific DP version (when a new version is released, the tag is updated to point to the new image).

The example below examines the contents of a DP Enterprise Edition image with the Alpha release channel.

To do that, run the following command:

```
crane export registry.deckhouse.io/deckhouse/ee/release-channel:alpha | tar -tf -
```

The output contains a list of files and directories in the image:

```
changelog.yaml
version.json
.werf
.werf/stapel
.werf/tmp
.werf/tmp/ssh-auth-sock
```

The image contains two key files:

- `changelog.yaml`: Describes changes.
- `version.json`: Contains data about the release canary deployment (`canary`), requirements (`requirements`), disruptions (`disruptions`) (deprecated field), and the release version itself in the `version` field.

  To view the contents of `version.json`, run the following command:

  ```
  crane export registry.deckhouse.io/deckhouse/ee/release-channel:alpha | tar -xOf - version.json | jq
  ```

  Example contents of `version.json`:

```
{
  "canary": {
    "alpha": {
      "enabled": true,
      "waves": 2,
      "interval": "5m"
    },
    "beta": {
      "enabled": false,
      "waves": 1,
      "interval": "1m"
    },
    "early-access": {
      "enabled": true,
      "waves": 6,
      "interval": "30m"
    },
    "stable": {
      "enabled": true,
      "waves": 6,
      "interval": "30m"
    },
    "rock-solid": {
      "enabled": false,
      "waves": 5,
      "interval": "5m"
    }
  },
  "requirements": {
    "k8s": "1.29",
    "disabledModules": "delivery,l2-load-balancer,ceph-csi",
    "migratedModules": "",
    "autoK8sVersion": "1.31",
    "ingressNginx": "1.9",
    "nodesMinimalOSVersionUbuntu": "18.04",
    "nodesMinimalOSVersionDebian": "10",
    "istioMinimalVersion": "1.21",
    "metallbHasStandardConfiguration": "true",
    "unmetCloudConditions": "true",
    "nodesMinimalLinuxKernelVersion": "5.8.0"
  },
  "disruptions": {
    "1.36": [
      "ingressNginx"
    ]
  },
  "version": "v1.71.5"
}
```

When the `version` field changes in `version.json` in the registry, DP applies a new release in the cluster: a `deckhouserelease` object is created and the update process begins.

> **i** If the `deckhouse` module is set to manual update mode (via the `settings.update.mode` field), you need to manually approve the new version before it is applied.

If there is a gap between the minor version running in the cluster and the one in the `release-channel` image, DP will automatically attempt to reconstruct intermediate `deckhouserelease` objects to perform a sequential update.

⚠ Note that DP can’t be updated non-sequentially by skipping minor releases (patch releases are not affected). Minor releases often include migrations that must be applied in order. These migrations may be removed over time. Skipping minor releases may result in:

- Leftover “garbage”
- Cluster malfunction due to missed migrations

Module from source update mechanism

Modules from source have a similar update mechanism, but their release cycle is decoupled from the platform and fully independent.

The cluster contains ModuleSource resources tracked by DP, which determine the list of available modules.

To see from which repository modules will be installed, run the following command:

```
d8 k get ms deckhouse -o jsonpath='{.spec.registry.repo}'
```

Example output:

```
registry.deckhouse.io/deckhouse/ee/modules
```

You can view repository contents with the following command:

```
crane ls registry.deckhouse.io/deckhouse/ee/modules
```

Example output:

```
commander-agent
console
csi-ceph
csi-nfs
observability
operator-postgres
pod-reloader
prompp
sds-local-volume
sds-node-configurator
sds-replicated-volume
secrets-store-integration
snapshot-controller
stronghold
virtualization
```

As an example, let’s look at the contents of the `console` module image. The registry contains an image with the fixed name `release` and a tag for the channel, pointing to a specific version of the `console` module (when a new module version is released, this tag is updated).

To view the contents of this image, use the following command:

```
crane export registry.deckhouse.io/deckhouse/ee/modules/console/release:alpha | tar -tf -
```

Example output:

```
changelog.yaml
version.json
```

Similarly to the DP image, the module image contains the `changelog.yaml` and `version.json` files.

To view the contents of `version.json`, run the following command:

```
crane export registry.deckhouse.io/deckhouse/ee/modules/console/release:alpha | tar -xOf -
version.json | jq
```

Example contents of `version.json`:

```
{
  "version": "v1.39.4"
}
```

The `version` field contains the module version. When it changes, DP applies a new release (a `modulerelease` object is created and the update process begins).

⚠ Note that modules can't be updated non-sequentially by skipping minor releases (patch releases are not affected). Minor releases often include migrations that must be applied in order. These migrations may be removed over time. Skipping minor releases may result in:

- Leftover "garbage"
- Cluster malfunction due to missed migrations

If required minor versions are missing, DP will report an error that may look as follows: `minor version is greater than deployed $version by one`.

If there is a gap between the minor version running in the cluster and the one in the `release` image, DP will automatically attempt to reconstruct intermediate `modulerelease` objects to perform a sequential update.

Vulnerability scanner database update mechanism

⚠ Available in DP EE and DP Ultimate.

Vulnerability databases are updated every 6 hours. The `operator-trivy` module in the cluster downloads them from the registry once during this period.

Vulnerability database images in DP EE have fixed names and tags and are available at:

```
registry.deckhouse.io/deckhouse/ee/security/trivy-db:2
registry.deckhouse.io/deckhouse/ee/security/trivy-java-db:1
registry.deckhouse.io/deckhouse/ee/security/trivy-checks:0
registry.deckhouse.io/deckhouse/ee/security/trivy-bdu:1
```

To configure periodic updates of vulnerability database images, run the command in the following format:

```
d8 mirror pull --source='registry.deckhouse.io/deckhouse/ee' --
license='<LICENSE_TOKEN>' --no-platform --no-modules $(pwd)/d8-bundle-security-db && d8
mirror push $(pwd)/d8-bundle-security-db <PRIVATE_REGISTRY_HOSTNAME>:5050/dkp/ee --registry-
login='<REGISTRY_LOGIN>' --registry-password='<REGISTRY_PASSWORD>' --tls-skip-verify
```

Here:

- `<LICENSE_TOKEN>`: DP license token.
- `<PRIVATE_REGISTRY_HOSTNAME>`: Address of the private container registry.
- `<REGISTRY_LOGIN>` and `<REGISTRY_PASSWORD>`: Credentials for the private container registry.

Example workflow for updating the platform, modules, and vulnerability databases

To update DP, its modules, and vulnerability databases to the latest versions in an air-gapped environment, download the latest patch releases of all required platform minor versions and modules, then upload them to your registry.

Running `d8 mirror pull --source='registry.deckhouse.io/deckhouse/ee' --license='<LICENSE_TOKEN>' $(pwd)/d8-bundle` downloads all release channel images and all modules (over 30 in DP EE). This results in a very large `d8-bundle` (at the time of writing, the volume

of the `d8-bundle` directory is more than 50 GB).

To avoid this, download only the images relevant to your version following these guidelines:

1. Get the DP version in your cluster using the following command:

   ```
   d8 k -n d8-system get deployment deckhouse -o json | jq -r '.metadata.annotations |
   {"core.deckhouse.io/edition","core.deckhouse.io/version"}'
   ```

   Example output:

   ```
   {
     "core.deckhouse.io/edition": "EE",
     "core.deckhouse.io/version": "v1.68.13"
   }
   ```

2. Get the list of modules deployed in the cluster:

   ```
   d8 k get mr | grep Deployed
   ```

   Example output:

   ```
   commander-agent-v1.2.4             Deployed                    13d
   console-v1.35.1                    Deployed                    7d4h
   ```

   Add this list to the `d8 mirror pull` command as flags: `--include-module='commander-agent@1.2.4' --include-module='console@1.35.1'`

   Alternatively, use a one-liner:

   ```
   d8 k get mr -o json | jq -r '.items[] | select(.status.phase == "Deployed") | "--
   include-module='\''\(.spec.moduleName)@\(.spec.version)'\''"' | paste -sd " " -
   ```

3. Create the final command for pulling images with the obtained parameters:

   ```
   d8 mirror pull --source='registry.deckhouse.io/deckhouse/ee' --
   license='<LICENSE_TOKEN>' --since-version='v1.68.13' --include-
   module='commander-agent@1.2.4' --include-module='console@1.35.1' $(pwd)/d8-bundle
   ```

   > **i** If you have already set up periodic downloading and pushing of vulnerability databases to your registry, you can add the flag `--no-security-db` to skip them during this process.

   This will download the latest patch releases of all required platform minor versions and modules, starting from the latest patch versions up to the current ones on release channels.

4. Push the artifacts to your registry using the following command:

   ```
   d8 mirror push $(pwd)/d8-bundle <PRIVATE_REGISTRY_HOSTNAME>:5050/dkp/ee --registry-
   login='<REGISTRY_LOGIN>' --registry-password='<REGISTRY_PASSWORD>' --tls-skip-
   verify
   ```

5. Check the update status in the cluster by running the following commands:

   ```
   d8 k get deckhousereleases.deckhouse.io
   d8 k get modulereleases.deckhouse.io
   d8 system queue list
   ```

Possible issues

Release is suspended

When trying to download platform images with `d8 mirror pull d8-bundle/ --license='<LICENSE_KEY>'`, you may encounter the following error:

```
Sep  9 00:10:57.145 INFO  ╔ Pull Deckhouse Platform
Sep  9 00:11:01.532 ERROR Pull Deckhouse Platform failed error="Find tags to mirror:
Find versions to mirror: get stable release version from registry: Cannot mirror
Deckhouse: source registry contains suspended release channel \"stable\", try again
later"
Error: pull failed, see the log for details
```

This means that release deployment on a channel has been suspended. This happens when a new version is pushed to the release channel but then something happened that paused its rollout. The channel image is patched with a `suspend` flag.

Nevertheless, you can still download the platform version by specifying the `--deckhouse-tag` flag in `d8 mirror pull`. For example:

```
d8 mirror pull d8-bundle/ --license='<LICENSE_KEY>' --deckhouse-tag='v1.71.3'
```

Example output:

```
Sep 16 12:56:25.074 INFO  ╔ Pull Deckhouse Platform
Sep 16 12:56:25.713 INFO  ╠ Skipped releases lookup as tag "v1.71.3" is specifically

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Disk layout and size

In the Resource requirements section for various types of Deckhouse Platform nodes, the disk volumes that must be allocated for successful installation and operation of Deckhouse Platform are specified. But you should also pay attention to the correct configuration of the file system so that the disk space does not suddenly “run out” despite the correctly selected volume at the installation stage.

> **i** Problems may arise not through the fault of the administrator, but due to the peculiarities of the installer of the selected Linux distribution. For example, during installation, Astra Linux may allocate 15 GB for the root file system (`/`), 15 GB for the user's home directory (`/home`), and leave the rest unallocated, despite the connected disk having a total capacity of 60 GB, as recommended in the guide. With this configuration, the Deckhouse Platform installation will not fail with an error about insufficient disk space.

To avoid problems in the future, before installing, make sure that the file system partitions of the disk allocated for the machine meet the Deckhouse Platform volume requirements.

Where and what does Deckhouse Platform store

Deckhouse Platform stores various types of data in specific file system directories. The main ones are:

- `/etc/kubernetes/`, `/etc/containerd`, etc. — directories with Kubernetes component configuration;
- `/var/lib/containerd` — layers of images of Deckhouse Platform components and other containers running on the node. The more Deckhouse Platform components are installed on a node or user load containers are launched on it, the more free space in this directory will be required.
- `/var/lib/kubelet` — two types of information are stored in this directory:
  - data about the pods running in the cluster;
  - ephemeral-storage data — for example, if 7 GB of ephemeral-storage is requested on the master node, and there is not enough space in this directory, pods will not be scheduled for this node.
- `/var/lib/etcd` — the etcd database, which stores the information necessary for the operation of the Kubernetes cluster;
- `/var/lib/deckhouse/downloaded/` — repository of release configurations for Deckhouse Platform modules (ModuleRelease);
- `/var/lib/deckhouse/stronghold/` — data storage for Stronghold (if the corresponding module is enabled);
- `/var/log/pods/` — storage of pod logs;
- `/opt/deckhouse/` — Deckhouse Platform service components such as kubelet, containerd, static utilities (e.g. lsblk), etc.;
- `/opt/deckhouse/registry/` (`/var/lib/deckhouse/registry/` when the master NodeGroup has `systemType: DeckhouseEngine`) — the store of the `registry` module, on master nodes only. It holds the in-cluster cache (`storage.cache`) or, in the v1 implementation (Deckhouse Platform up to and including 1.77), the data of the `Proxy` and `Local` modes. When the cache is turned off, the data is kept on purpose (see how to remove leftover cache data). See below for how much space the store needs;
- `/opt/local-path-provisioner/` — directory for storing data when using local storage Local Path Provisioner. The directory is set in the required `spec.path` parameter of LocalPathProvisioner, and the configuration examples use `/opt/local-path-provisioner`.

Disk space recommendations

The sections below show the disk volumes occupied by the various cluster components.

> **i** The total amount of space specified in the tables may exceed the minimum recommended disk size for a cluster node specified in the "Quick Start" or in the Resource requirements section. This is due to the fact that the table shows the maximum required values for the components, and the minimum requirements for the node indicate the average value.

Master nodes

The table below shows the recommended amounts of space for the directories used by Deckhouse Platform on the cluster's master nodes.

Directory	Disk size, GB
`/mnt/vector-data`	1
`/opt` Not counting the `registry` module store: the in-cluster cache or the `Proxy` and `Local` modes of the v1 implementation (details...).	1

Directory	Disk size, GB
`/tmp`	1
`/var/lib` [Show details...]	75
`/var/log/kube-audit`	2
`/var/log/pods`	18 (details...)

Worker nodes

The table below shows the recommended amounts of space for the directories used by Deckhouse Platform on the worker nodes of the cluster.

Directory	Disk size, GB
`/mnt/vector-data`	1
`/opt`	1
`/opt/local-path-provisioner` Depends on the storage settings set by the user. It is recommended to put it on a separate section.	100
`/tmp`	1
`/var/lib` [Show details...]	55
`/var/log/pods`	5 (details...)

System nodes

The system nodes are the nodes on which the Deckhouse Platform components are running. When adding such nodes to the cluster, keep in mind that they host the monitoring load, including:

- Prometheus;
- loki;
- upmeter and other Deckhouse Platform components.

If monitoring data is stored locally on the nodes, it is recommended to additionally allocate ≥ 100 GB of free disk space for each system node.

> **i** If you use a cluster configuration without dedicated system nodes, the above load will be distributed to other nodes, and you need to take into account the recommended amount of disk storage when choosing their configuration.

Pod log storage

Pod logs are stored in the `/var/log/pods/` directory. The amount of logs used depends on the number of containers and Deckhouse Platform settings. On average, about 90 containers are running on the master node when using the Default module set, By default, up to 4 log files of up to 50 MB each are stored for each container, that is, up to 200 MB per container. That is, there should be a minimum of `90 * 200 MB = 18 GB` space available in the directory `/var/log/pods/`.

The log storage parameters can be redefined in the `spec.kubelet.containerLogMaxSize` and `spec.kubelet.containerLogMaxFiles` parameters of the NodeGroup (see node customization). Default values:

```
spec:
  kubelet:
    containerLogMaxSize: 50Mi
    containerLogMaxFiles: 4
```

Trivy vulnerability database repository

Deckhouse Platform has a built-in vulnerability image scanning system based on Trivy, which scans all

container images used in the cluster's pods. Both public vulnerability databases and enriched data from Astra Linux, ALT Linux and RED OS are used for scanning. The total amount of disk space occupied by databases is 5 GB, so it must be taken into account when choosing the disk partition configuration.

Databases are stored on the cluster's system nodes, and if there are no such nodes in the cluster, the databases will be located on the worker node.

Registry store on master nodes

The master node table above does not include the store of the in-cluster cache of the `registry` module. If the cache is enabled (`storage.cache`), every master node keeps its own copy of the store in `/opt/deckhouse/registry` (`/var/lib/deckhouse/registry` when the master NodeGroup has `systemType: DeckhouseEngine`), and the file system that holds this directory needs extra space:

- for the store budget set in `storage.size`: plan for three releases of the image set the cluster uses (the deployed one, the previous one and the next one) together with its modules and the module catalog;
- for the reserve that the store always leaves free for the node on that file system. Because of the reserve, the file system must be noticeably larger than `storage.size`, including when the store has a disk of its own.

It is recommended to mount a separate disk at the store directory: if the store shares a disk with etcd, etcd slows down while the cache is being filled. Without a separate disk, reserve the space on the file system that holds the store directory (with a DeckhouseEngine master NodeGroup, the one that holds `/var/lib/deckhouse`). If `/opt` is a separate partition sized by the table above (1 GB), the store does not fit there.

The `Proxy` and `Local` modes of the v1 implementation also keep their data in `/opt/deckhouse/registry`.

For sizing details, see "Requirements for using the module" in the `registry` module documentation.

If resource limits are configured

If resource limits in terms of disk space are configured for cluster entities, then the necessary free disk space on the node must be available in any case, otherwise the load will be displaced from these nodes.

LVM-based local storage

In a Deckhouse Platform cluster, you can configure local storage on nodes, using LVM.

Requirements and placement procedure:

- Free block devices (disk partitions) should be available on the node.
- These devices will be used by the sds-local-volume module to create a StorageClass.
- The amount of free space on the block device must correspond to the amount that is planned to be provided through the created StorageClass.

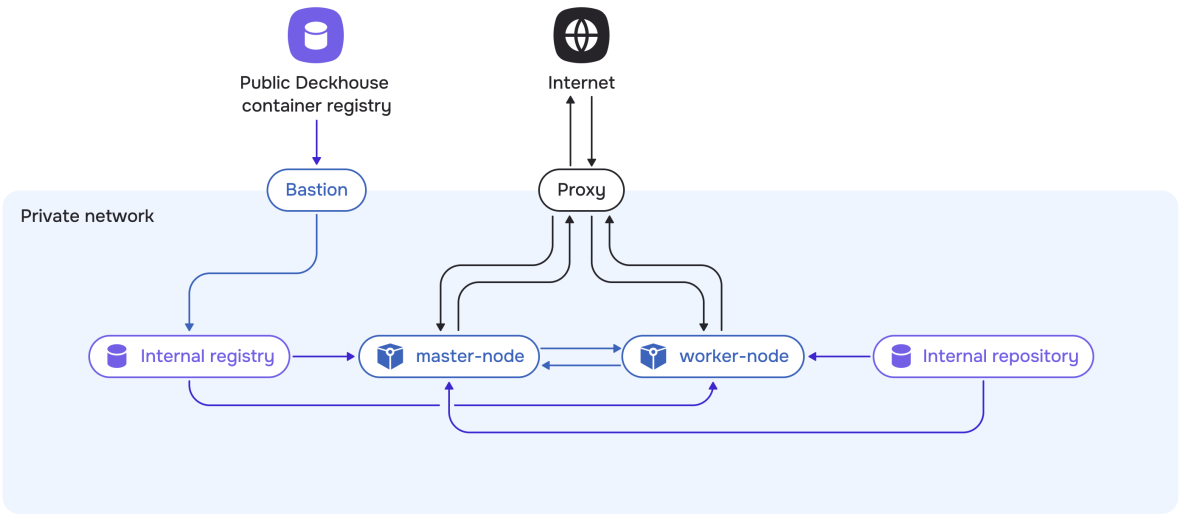
Installing Deckhouse Platform in a private environment

This guide describes how to deploy a Deckhouse Platform cluster in a private environment with no direct access to the Deckhouse Platform container image registry (`registry.deckhouse.io`) and to external deb/rpm package repositories used on nodes running supported operating systems.

Private environment specifics

Deploying in a private environment is almost the same as deploying on bare metal.



Key specifics:

- Proxy server parameters set in the cluster configuration during installation are automatically propagated to the `HTTP_PROXY`, `HTTPS_PROXY`, and `NO_PROXY` environment variables for **cluster nodes and Deckhouse Platform components**. User applications (pods) do not receive these variables from the cluster configuration automatically. To give them Internet access via a proxy, you must set the environment variables (`HTTP_PROXY`, `HTTPS_PROXY`, and, if needed, `NO_PROXY`) explicitly in manifests. Depending on corporate policy, application access may be arranged in other ways—for example, by allowing direct egress from nodes.
- A container registry with Deckhouse Platform images is deployed separately with access from inside the perimeter, and the cluster is configured to use it with the required permissions.

Cluster nodes are usually accessed through a dedicated physical server or virtual machine called a bastion host. A proxy for access to external resources from the internal network is deployed according to your network policy and infrastructure architecture; depending on requirements, it may run on the bastion host or on a separate machine. A private container registry should preferably run on a separate VM or server in the internal network. Colocating the registry on the bastion host is not recommended for production. An exception may be lab or simplified stand-alone setups for limited use cases.

> **i** Depending on your organization’s security policies, access to external resources may be fully disabled. In that case, no proxy is used for outbound access to external networks. Required external artifacts (for example, an archive of Deckhouse Platform container images) are brought into the perimeter onto the target VM by any permitted means—for example, removable media.

Overall private environment diagram:

> **i** The diagram also shows an internal OS package repository. It is used to install packages on nodes when access to official repositories is not available even through a proxy. Many private environments already run internal OS package mirrors, and installation uses them—in that case, a proxy for package traffic is not required. A proxy server is used for other kinds of traffic:
>
> - pulling container images from the public Deckhouse Platform registry to the bastion host
> - Deckhouse Platform components and nodes calling external resources (if allowed by policy)
> - optionally, pod applications accessing external services.

Infrastructure selection

This guide describes deploying a cluster in a private environment consisting of one master node and one worker node.

You will need:

- a personal computer from which you run operations
- a dedicated physical server or virtual machine for the bastion host
- a dedicated physical server or virtual machine for the container registry
- optionally, a physical server or virtual machine for the proxy server
- two physical servers or two virtual machines for the cluster nodes.

Server requirements:

- **Bastion**: at least 4 CPU cores, 8 GB RAM, and 150 GB on fast storage. That much disk space is needed because the bastion host temporarily holds all Deckhouse Platform images used for installation. Images are downloaded from the public Deckhouse Platform registry to the bastion host before being pushed to the private container registry and packed into archives; these steps require substantial free space.
- **VM for the private registry**: at least 4 CPU cores, 8 GB RAM, and at least 150 GB on fast storage for Deckhouse Platform images. Plan disk capacity with a margin, using the bundle size after `d8 mirror push` as a guide.
- **Cluster nodes**: choose resources for future cluster nodes based on expected workload. For example, the minimum recommended configuration is 4 CPU cores (*8 CPU cores recommended*), 8 GB RAM (*16 GB RAM recommended*), and 60 GB on fast storage (400+ IOPS) per node. If you plan to enable the in-cluster cache of the `registry` module, the master nodes also need disk space for the cache store (see “Disk layout and size”).

Preparing a private container registry

> ⚠ Deckhouse Platform supports Basic and Bearer token authentication schemes for container registries (Basic is tried first; if it fails, Bearer is used).
>
> If a reverse proxy is placed in front of the registry, it must correctly forward the Registry API v2 header `Docker-Distribution-API-Version: registry/2.0`. Otherwise the Basic check may fail, and the subsequent Bearer attempt may fail with the error `couldn't find bearer realm parameter`.

You may use any supported private container registry. Compatibility has been tested and is guaranteed for the following: Nexus, Harbor, Artifactory, Docker Registry, and Quay.

The instructions below cover two private container registry options — Docker Registry and Harbor. Choose the matching tab.

Installing a container registry

- Docker Registry
- Harbor

Install Docker Registry from your distribution’s repositories. For example, on a RHEL-based OS:

```
dnf install registry httpd-tools
```

Create a user and password with htpasswd. For example, to create user `deckhouse` with password `<PASSWORD>`:

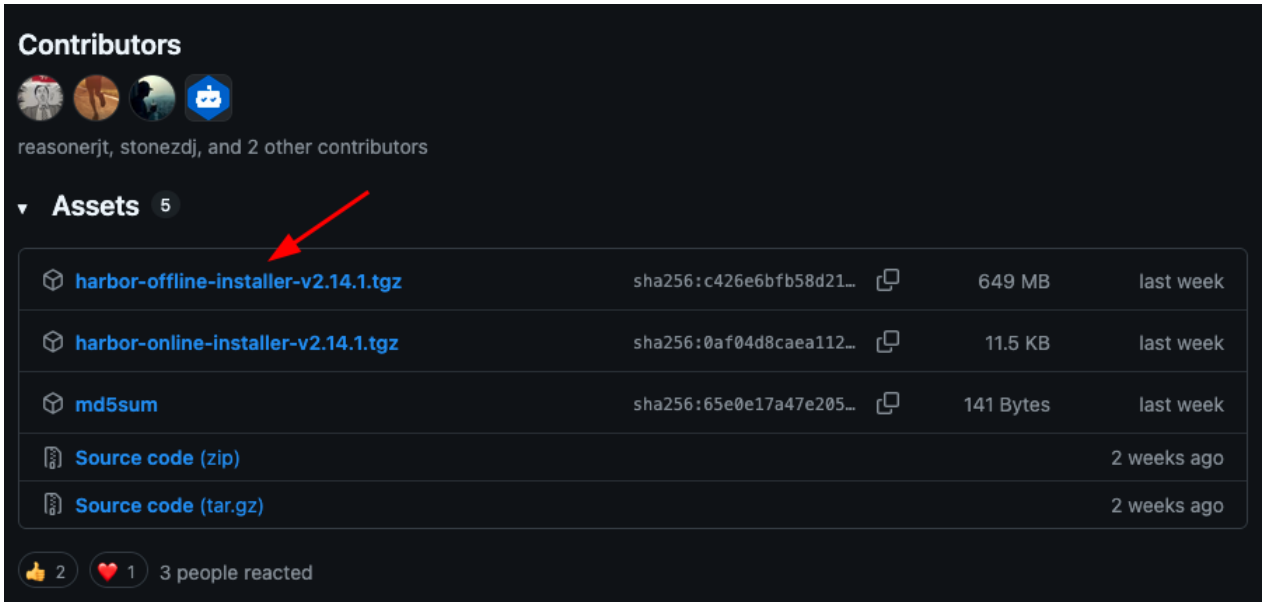
```
htpasswd -bcB /etc/registry/htpasswd deckhouse <PASSWORD>
```

Generate a self-signed certificate for the registry:

```
openssl req -x509 -newkey ec -pkeyopt ec_paramgen_curve:prime256v1 -keyout
/etc/registry/private.key -out /etc/registry/public.crt -days 3650 -nodes -subj
"/C=US/ST=California/L=SanFrancisco/O=example/OU=IT/CN=registry.local" -addext
"subjectAltName=DNS:registry.local"
```

Replace `registry.local` with the address that will be used for the image registry in your network.

Update the registry configuration with the certificates you created. Edit `/etc/registry/config.yml`:



```
version: 0.1
log:
  fields:
    service: registry
storage:
  cache:
    blobdescriptor: inmemory
  filesystem:
    rootdirectory: /var/lib/registry
  delete:
    enabled: true
http:
  addr: :443
  tls:
    certificate: /etc/registry/public.crt
    key: /etc/registry/private.key
  headers:
    X-Content-Type-Options: [nosniff]
auth:
  htpasswd:
    realm: basic-realm
    path: /etc/registry/htpasswd
health:
  storagedriver:
    enabled: true
    interval: 10s
    threshold: 3
```

Enable the service at boot and confirm it is running:

```
systemctl enable --now registry.service
systemctl status registry.service
```

Later sections of this guide use Harbor as the example. It supports policy configuration and role-based access control (RBAC), vulnerability scanning, and marking trusted artifacts. Harbor is a CNCF project.

Install the latest Harbor release from the project's GitHub releases page. Download the installer archive from the desired release, selecting the asset with `harbor-offline-installer` in its name.

Copy the download URL. For example, for `harbor-offline-installer-v2.14.1.tgz` it will look like this: `https://github.com/goharbor/harbor/releases/download/v2.14.1/harbor-offline-installer-v2.14.1.tgz`.

Connect via SSH to the **virtual machine where Harbor will run** and download the archive using any convenient method. If that VM has no direct Internet access, download the archive on your workstation

or on the bastion host, then copy it to the Harbor VM.

How to download the archive with wget...

Run the command (use the current URL):

```
wget https://github.com/goharbor/harbor/releases/download/v2.14.1/harbor-offline-installer-v2.14.1.tgz
```

How to download the archive with curl...

Run the command (use the current URL):

```
curl -O https://github.com/goharbor/harbor/releases/download/v2.14.1/harbor-offline-installer-v2.14.1.tgz
```

Extract the downloaded archive (specify the archive name):

```
tar -zxf ./harbor-offline-installer-v2.14.1.tgz
```

The extracted `harbor` directory contains the files required for installation.

On **the same VM**, install Docker and the Docker Compose plugin. You will need them to configure TLS access to the registry and to run the Harbor installer.

Before deploying the registry, generate a self-signed TLS certificate.

> **i** Due to access restrictions in a private environment, it is not possible to obtain certificates from services such as Let's Encrypt, since the service will not be able to perform the validation required to issue a certificate.
>
> There are several ways to generate certificates. This guide describes one of them. If needed, use any other suitable approach or provide an existing certificate.

Create the `certs` directory inside the `harbor` directory:

```
cd harbor/
mkdir certs
cd certs
```

Generate a self-signed certificate for Harbor:

```
openssl req -x509 -newkey ec -pkeyopt ec_paramgen_curve:prime256v1 -keyout registry.local.key -out registry.local.crt -sha256 -days 3650 -nodes -subj "/C=US/ST=California/L=SanFrancisco/O=example/OU=IT/CN=registry.local" -addext "subjectAltName=DNS:registry.local"
```

Replace `registry.local` with the address that will be used for the image registry in your network.

Verify that the certificates were created successfully:

```
ls -la
```

Example command output...

```
$ ls -la
total 12
drwxrwxr-x 2 ubuntu ubuntu 4096 Dec  5 14:58 .
drwxrwxr-x 3 ubuntu ubuntu 4096 Dec  4 12:53 ..
-rw-rw-r-- 1 ubuntu ubuntu  909 Dec  5 14:58 registry.local.crt
-rw------- 1 ubuntu ubuntu  292 Dec  5 14:57 registry.local.key
```

Next, configure Docker to work with the private container registry over TLS. Create the `registry.local` directory under `/etc/docker/certs.d/`:

```
sudo mkdir -p /etc/docker/certs.d/registry.local
```

> **i** The `-p` option tells `mkdir` to create parent directories if they do not exist (in this case, the `certs.d` directory).

Copy the certificate into it as the root CA (for a self-signed certificate this is the same file):

```
cp registry.local.crt /etc/docker/certs.d/registry.local/ca.crt
```

This certificate will be used when accessing the registry via the `registry.local` domain name.

Return to the `harbor` directory (installer root):

```
cd ..
```

Copy the configuration file template that comes with the installer:

```
cp harbor.yml.tmpl harbor.yml
```

Update the following parameters in `harbor.yml`:

- `hostname`: set to `registry.local` (the certificates were generated for this name)
- `certificate`: specify the path to the generated certificate in the `certs` directory (for example, `/home/ubuntu/harbor/certs/registry.local.crt`)
- `private_key`: specify the path to the private key (for example, `/home/ubuntu/harbor/certs/registry.local.key`)
- `harbor_admin_password`: set a password for accessing the web UI.

Save the file.

Example configuration file...

```
# Configuration file of Harbor

# The IP address or hostname to access admin UI and registry service.
# DO NOT use localhost or 127.0.0.1, because Harbor needs to be accessed by external
clients.
hostname: registry.local

# http related config
http:
  # port for http, default is 80. If https enabled, this port will redirect to https
port
  port: 80

# https related config
https:
  # https port for harbor, default is 443
  port: 443
  # The path of cert and key files for nginx
  certificate: /home/ubuntu/harbor/certs/registry.local.crt
  private_key: /home/ubuntu/harbor/certs/registry.local.key
  # enable strong ssl ciphers (default: false)
  # strong_ssl_ciphers: false

# # Harbor will set ipv4 enabled only by default if this block is not configured
# # Otherwise, please uncomment this block to configure your own ip_family stacks
# ip_family:
#   # ipv6Enabled set to true if ipv6 is enabled in docker network, currently it
affected the nginx related component
#   ipv6:
#     enabled: false
#   # ipv4Enabled set to true by default, currently it affected the nginx related
```

```
component
#   ipv4:
#     enabled: true

# # Uncomment following will enable tls communication between all harbor components
# internal_tls:
#   # set enabled to true means internal tls is enabled
#   enabled: true
#   # put your cert and key files on dir
#   dir: /etc/harbor/tls/internal

# Uncomment external_url if you want to enable external proxy
# And when it enabled the hostname will no longer used
# external_url: https://reg.mydomain.com:8433

# The initial password of Harbor admin
# It only works in first time to install harbor
# Remember Change the admin password from UI after launching Harbor.
harbor_admin_password: <PASSWORD>

# Harbor DB configuration
database:
  # The password for the user('postgres' by default) of Harbor DB. Change this
before any production use.
  password: <PASSWORD>
  # The maximum number of connections in the idle connection pool. If it <=0, no
idle connections are retained.
  max_idle_conns: 100
  # The maximum number of open connections to the database. If it <= 0, then there
is no limit on the number of open connections.
  # Note: the default number of connections is 1024 for postgres of harbor.
  max_open_conns: 900
  # The maximum amount of time a connection may be reused. Expired connections may
be closed lazily before reuse. If it <= 0, connections are not closed due to a
connection's age.
  # The value is a duration string. A duration string is a possibly signed sequence
of decimal numbers, each with optional fraction and a unit suffix, such as "300ms",
"-1.5h" or "2h45m". Valid time units are "ns", "us" (or "µs"), "ms", "s", "m", "h".
  conn_max_lifetime: 5m
  # The maximum amount of time a connection may be idle. Expired connections may be
closed lazily before reuse. If it <= 0, connections are not closed due to a
connection's idle time.
  # The value is a duration string. A duration string is a possibly signed sequence
of decimal numbers, each with optional fraction and a unit suffix, such as "300ms",
"-1.5h" or "2h45m". Valid time units are "ns", "us" (or "µs"), "ms", "s", "m", "h".
  conn_max_idle_time: 0

# The default data volume
data_volume: /data

# Harbor Storage settings by default is using /data dir on local filesystem
# Uncomment storage_service setting If you want to using external storage
# storage_service:
#   # ca_bundle is the path to the custom root ca certificate, which will be
injected into the truststore
#   # of registry's containers.  This is usually needed when the user hosts a
internal storage with self signed certificate.
#   ca_bundle:

#   # storage backend, default is filesystem, options include filesystem, azure,
gcs, s3, swift and oss
#   # for more info about this configuration please refer
https://distribution.github.io/distribution/about/configuration/
```

```
#   # and https://distribution.github.io/distribution/storage-drivers/
#   filesystem:
#     maxthreads: 100
#   # set disable to true when you want to disable registry redirect
#   redirect:
#     disable: false

# Trivy configuration
#
# Trivy DB contains vulnerability information from NVD, Red Hat, and many other
upstream vulnerability databases.
# It is downloaded by Trivy from the GitHub release page
https://github.com/aquasecurity/trivy-db/releases and cached
# in the local file system. In addition, the database contains the update timestamp
so Trivy can detect whether it
# should download a newer version from the Internet or use the cached one.
Currently, the database is updated every
# 12 hours and published as a new release to GitHub.
trivy:
  # ignoreUnfixed The flag to display only fixed vulnerabilities
  ignore_unfixed: false
  # skipUpdate The flag to enable or disable Trivy DB downloads from GitHub
  #
  # You might want to enable this flag in test or CI/CD environments to avoid GitHub
rate limiting issues.
  # If the flag is enabled you have to download the `trivy-offline.tar.gz` archive
manually, extract `trivy.db` and
  # `metadata.json` files and mount them in the `/home/scanner/.cache/trivy/db`
path.
  skip_update: false
  #
  # skipJavaDBUpdate If the flag is enabled you have to manually download the
`trivy-java.db` file and mount it in the
  # `/home/scanner/.cache/trivy/java-db/trivy-java.db` path
  skip_java_db_update: false
  #
  # The offline_scan option prevents Trivy from sending API requests to identify
dependencies.
  # Scanning JAR files and pom.xml may require Internet access for better detection,
but this option tries to avoid it.
  # For example, the offline mode will not try to resolve transitive dependencies in
pom.xml when the dependency doesn't
  # exist in the local repositories. It means a number of detected vulnerabilities
might be fewer in offline mode.
  # It would work if all the dependencies are in local.
  # This option doesn't affect DB download. You need to specify "skip-update" as
well as "offline-scan" in an air-gapped environment.
  offline_scan: false
  #
  # Comma-separated list of what security issues to detect. Possible values are
`vuln`, `config` and `secret`. Defaults to `vuln`.
  security_check: vuln
  #
  # insecure The flag to skip verifying registry certificate
  insecure: false
  #
  # timeout The duration to wait for scan completion.
  # There is upper bound of 30 minutes defined in scan job. So if this `timeout` is
larger than 30m0s, it will also timeout at 30m0s.
  timeout: 5m0s
  #
  # github_token The GitHub access token to download Trivy DB
```

```
  #
  # Anonymous downloads from GitHub are subject to the limit of 60 requests per
hour. Normally such rate limit is enough
  # for production operations. If, for any reason, it's not enough, you could
increase the rate limit to 5000
  # requests per hour by specifying the GitHub access token. For more details on
GitHub rate limiting please consult
  # https://docs.github.com/rest/overview/resources-in-the-rest-api#rate-limiting
  #
  # You can create a GitHub token by following the instructions in
  # https://help.github.com/en/github/authenticating-to-github/creating-a-personal-
access-token-for-the-command-line
  #
  # github_token: xxx

jobservice:

harbor-log
```

On the Harbor VM, add an entry to `/etc/hosts` that maps the `registry.local` domain name to `localhost` so you can open Harbor by that name from the same machine:

```
127.0.0.1 localhost registry.local
```

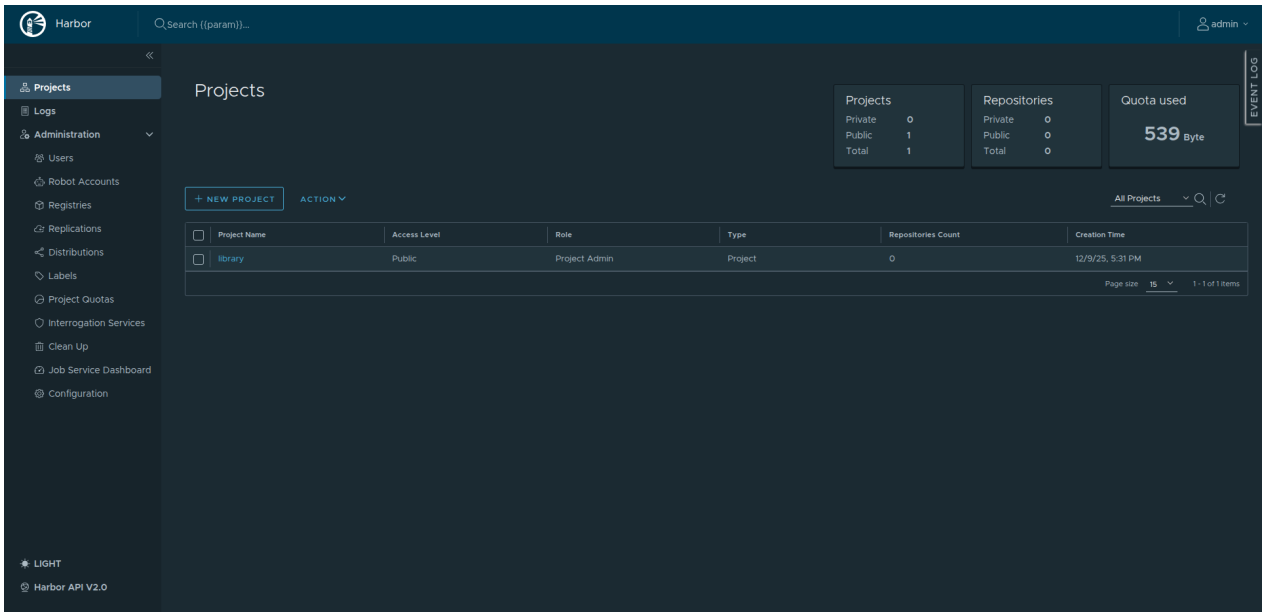
⚠ In some cloud providers (for example, Yandex Cloud), changes to `/etc/hosts` may be reverted after a virtual machine reboot. A note about this is typically shown at the beginning of the `/etc/hosts` file.

```
# Your system has configured 'manage_etc_hosts' as True.
# As a result, if you wish for changes to this file to persist
# then you will need to either
# a.) make changes to the master file in /etc/cloud/templates/hosts.debian.tmpl
# b.) change or remove the value of 'manage_etc_hosts' in
#     /etc/cloud/cloud.cfg or cloud-config from user-data
```

If your provider uses the same mechanism, apply the corresponding changes to the template file referenced in the comment so that the settings persist after reboot.

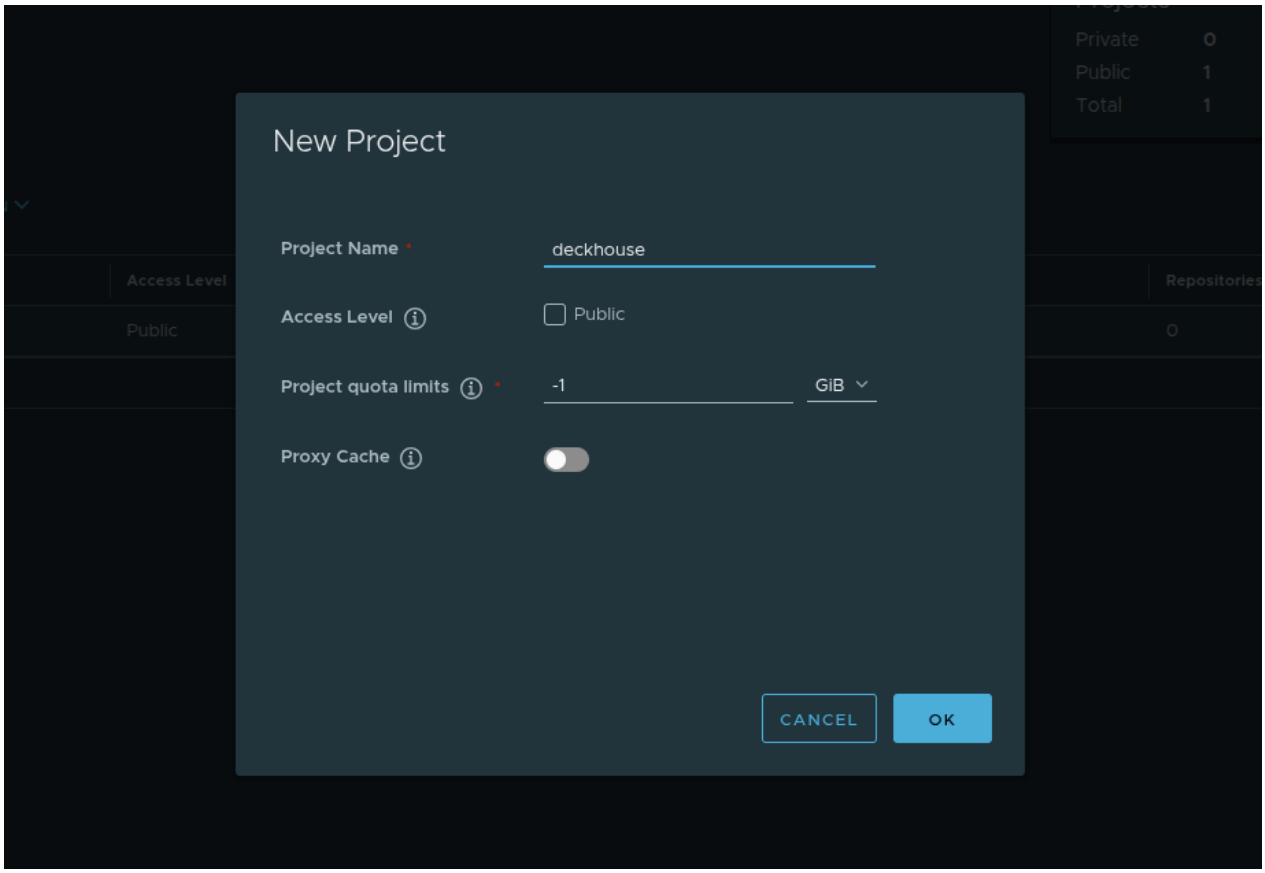
Harbor installation is now complete.

Configuring Harbor



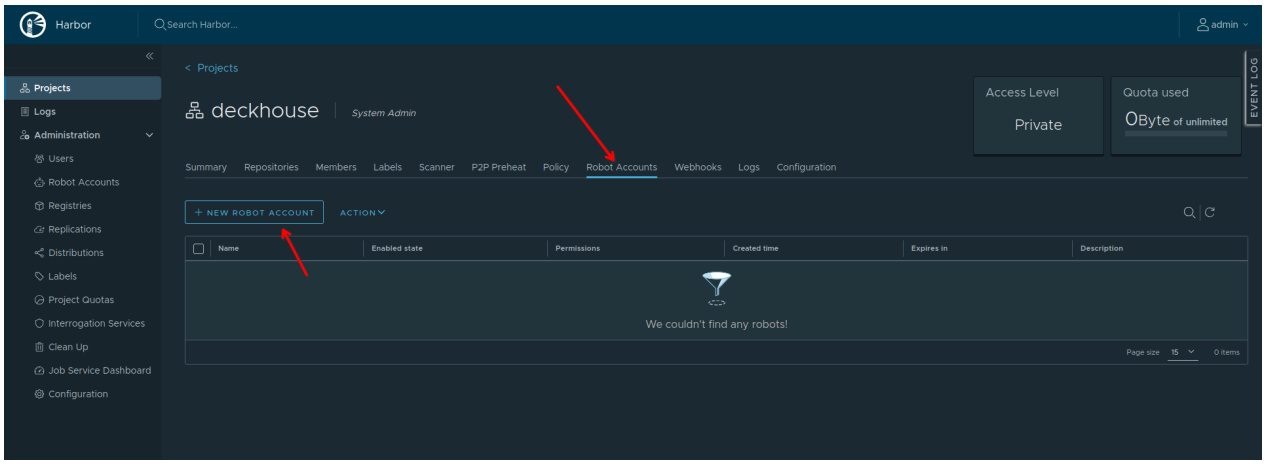
Create a project and credentials used to work with it.

Open the Harbor web UI at `registry.local`. Access to this UI from the public Internet is intentionally blocked; connect only from a host that has access to the internal network.



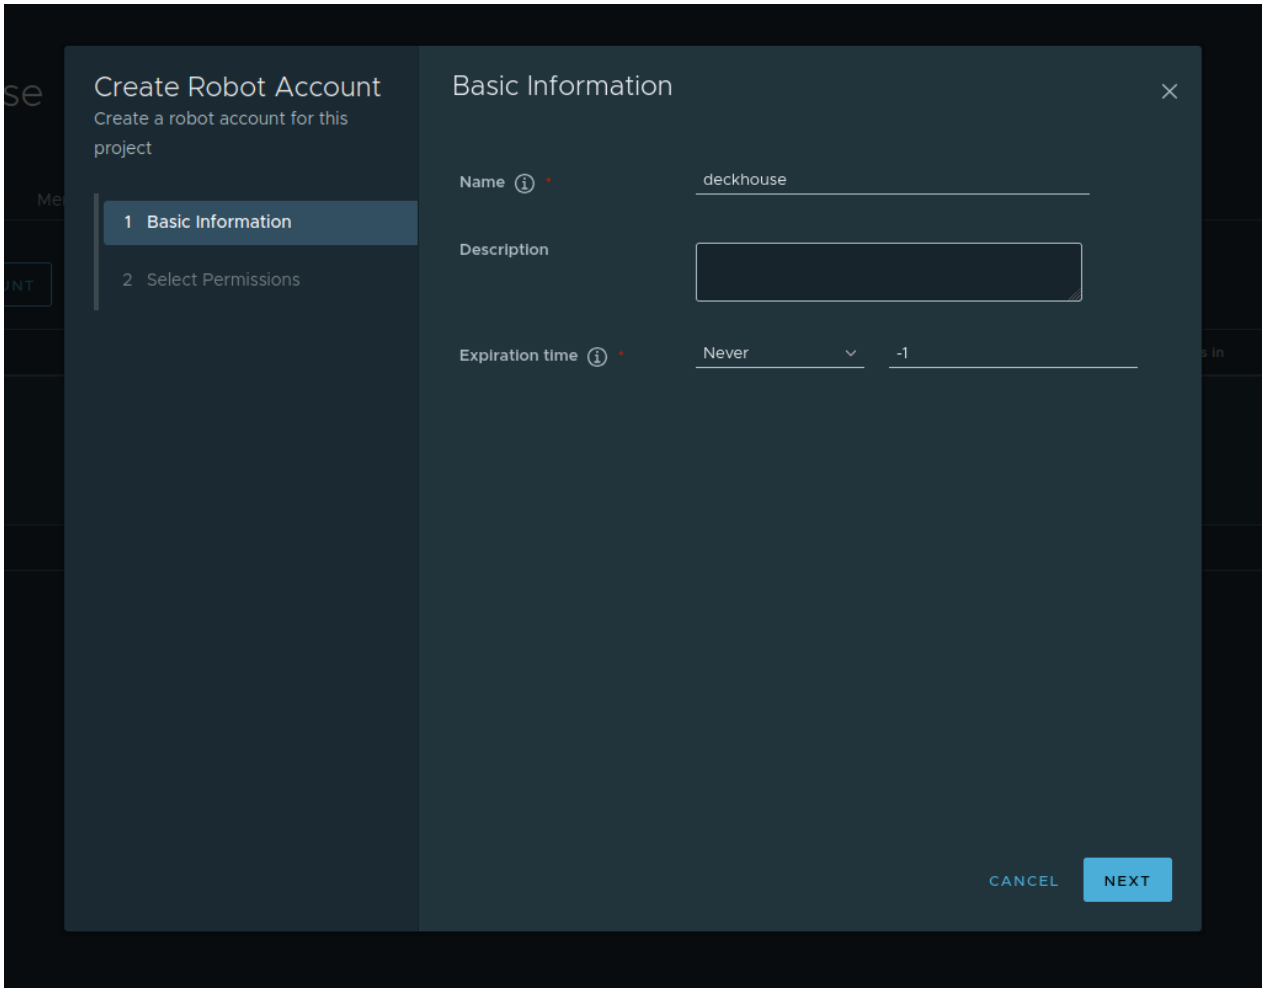
ℹ To open Harbor by the `registry.local` domain name from your workstation, add a matching entry to `/etc/hosts` pointing to the Harbor VM's internal IP address.

Sign in with the username and password from `harbor.yml`.

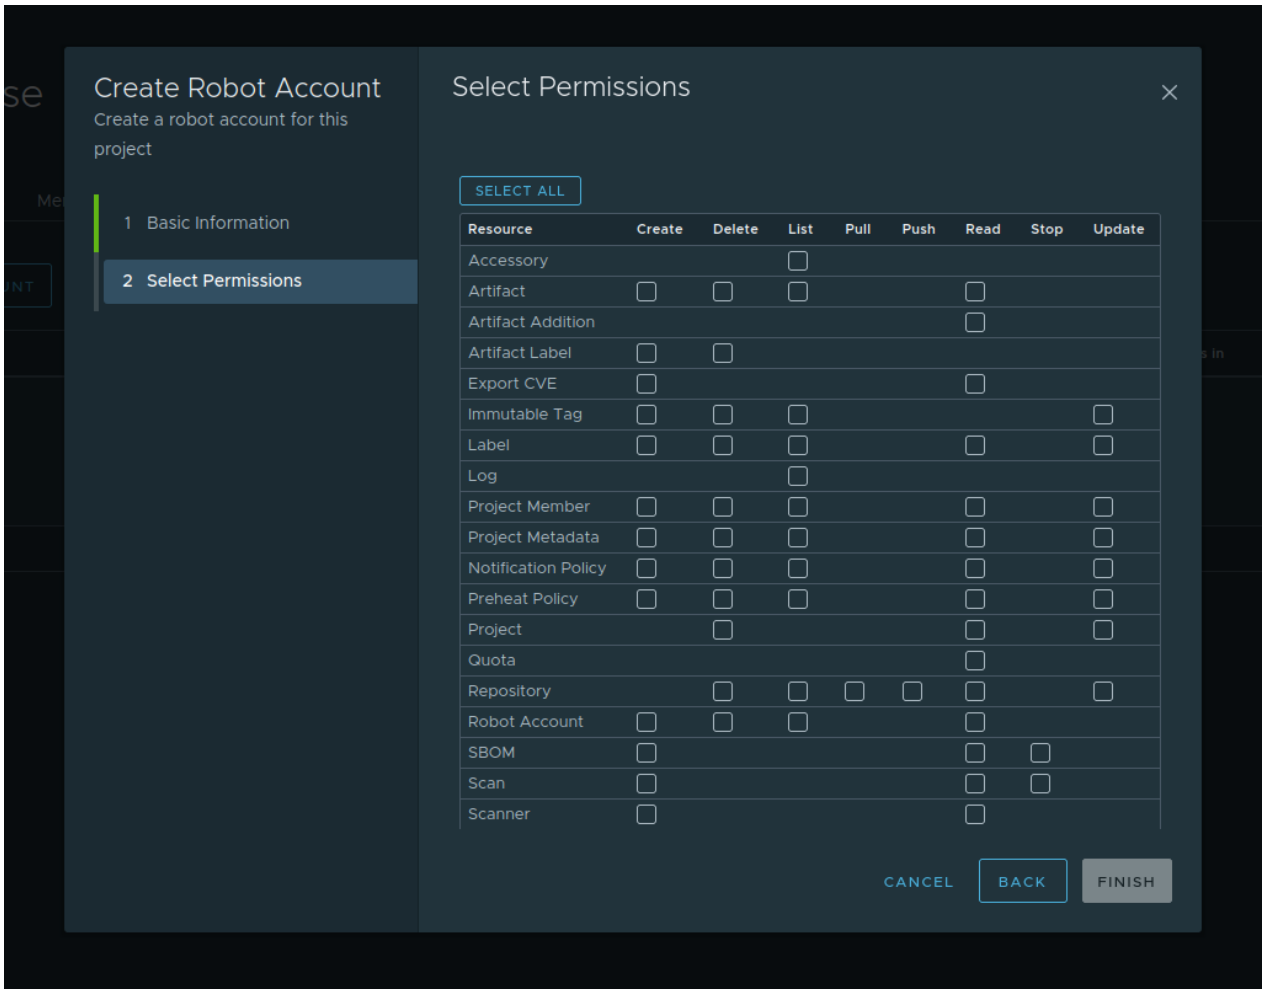


> **i** Your browser may warn about the self-signed certificate and mark the connection as “not secure”. In a private environment this is expected and acceptable. If needed, add the certificate to your browser or OS trust store to suppress the warning.

Create a new project: click **New Project**, set the name to `deckhouse`, and leave the other settings unchanged.

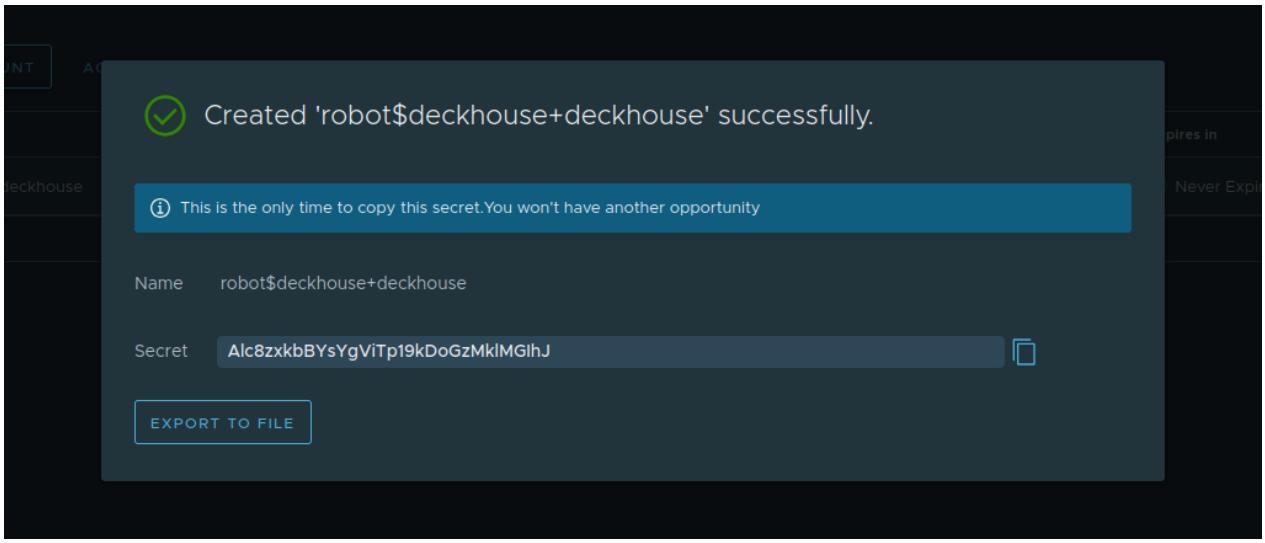


Create a robot account for this project. Robot accounts are tied to a project and meant for automation. They cannot use the web UI and are intended for Docker CLI or Helm CLI only.



Open the `deckhouse` project and go to the **Robot Accounts** tab. Click **New Robot Account**:

Set the account name, optional description, and expiration (days or never expire):



For correct operation, grant full access under **Repository**. Adjust other permissions as needed or per your security policy.

After creation, Harbor shows the robot account secret (token).

⚠ Save the secret immediately. Harbor will not show it again, and it cannot be retrieved later.

Harbor configuration is now complete.

Copying Deckhouse Platform images to a private container registry

The next step is to copy Deckhouse Platform component images from the public Deckhouse Platform registry to Harbor.

> **i** The steps in this section require the Deckhouse CLI. Install it on the host from which you will mirror images to the private registry — in this guide, the bastion host. For installation instructions, see the Deckhouse CLI documentation.

> ⚠ Downloading images takes a significant amount of time. To avoid losing progress if the SSH connection is interrupted, run the commands in a `tmux` or `screen` session. If the connection drops, you can reattach to the session and continue without starting over. Both utilities are typically available in Linux distribution repositories and can be installed using the package manager.
>
> How to use tmux...
>
> - Start a session with `tmux`.
> - Detach from the session by pressing `Ctrl + b`, then `d`. The session will keep running, and the processes started in it will continue to run. To exit the session, use `Ctrl + d`.
> - List running sessions with `tmux ls`:
>
>   ```
>   $ tmux ls
>   0: 1 windows (created Thu Dec 11 13:52:41 2025)
>   ```
>
> - Reattach to a running session: `tmux attach -t <SESSION_ID>`. In the example above, the `<SESSION_ID>` is `0`.
>
> How to use screen...
>
> - Start a session with `screen`.
> - Detach from the session by pressing `Ctrl + a`, then `d` (while holding `Ctrl`). The session will keep running, and the processes started in it will continue to run. To exit the session, use `Ctrl + d`.
> - List running sessions with `screen -r`:
>
>   ```
>   $ screen -r
>   There are several suitable screens on:
>           1166154.pts-0.guide-bastion     (12/11/25 14:00:26)     (Detached)
>           1165806.pts-0.guide-bastion     (12/11/25 13:59:35)     (Detached)
>           1165731.pts-0.guide-bastion     (12/11/25 13:59:24)     (Detached)
>           1165253.pts-0.guide-bastion     (12/11/25 13:58:16)     (Detached)
>   Type "screen [-d] -r [pid.]tty.host" to resume one of them.
>   ```
>
> - Reattach to a running session: `screen -r <SESSION_ID>`. In the example above, the `<SESSION_ID>` is `166154.pts-0.guide-bastion`.

Download Deckhouse Platform images into a dedicated directory using `d8 mirror pull`.

By default, `d8 mirror pull` downloads current Deckhouse Platform releases, vulnerability scanner databases (if included in your edition), and officially shipped modules.

Run the following command to download current image versions. Replace the placeholders with your values: `<EDITION>`, `<LICENSE_KEY>`, and optionally the target directory path:

```
d8 mirror pull --source='registry.deckhouse.io/deckhouse/<EDITION>' --
license='<LICENSE_KEY>' /home/ubuntu/d8-bundle
```

where:

- `--source` — Deckhouse Platform image registry address
- `<EDITION>` — Deckhouse Platform edition code (for example, `ee`, `se`, `se-plus`). The default is `ee` (Enterprise Edition), so `--source` may be omitted
- `--license` — Deckhouse Platform license key for authentication to the official registry
- `<LICENSE_KEY>` — your license key
- `/home/ubuntu/d8-bundle` — directory for downloaded image bundles (created automatically if missing).

If the download is interrupted, run the command again to resume, as long as no more than 24 hours have passed since it stopped.

Depending on your Internet connection, the process may take 30 to 40 minutes.

Example of a successful image download completion...

```

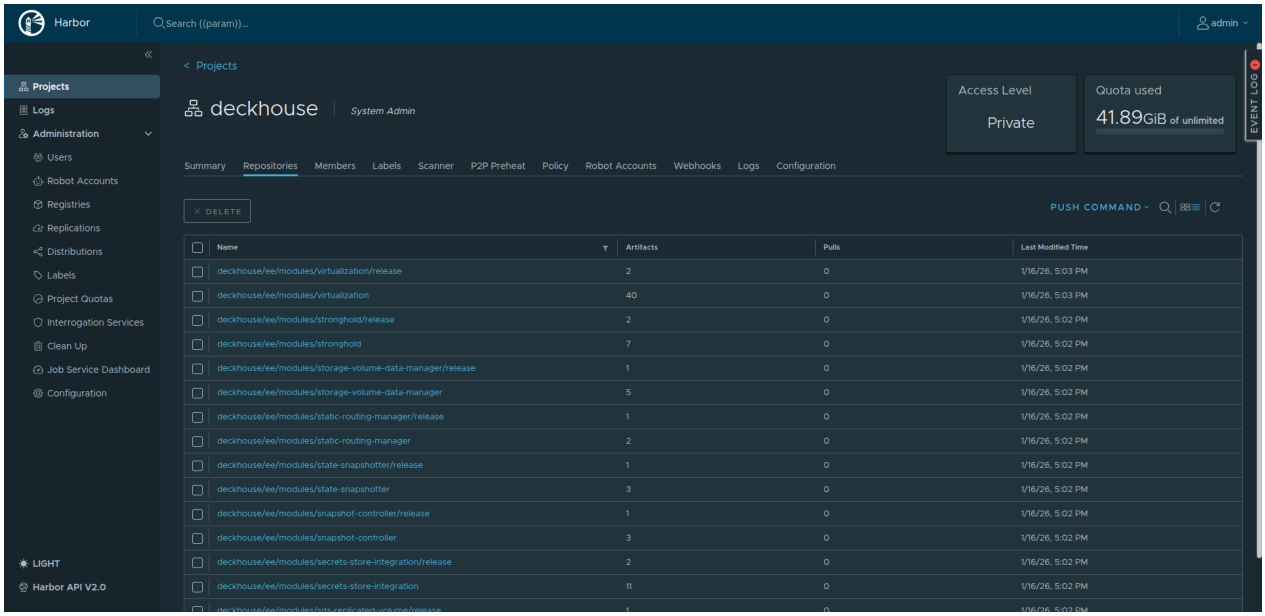
Verify that the bundles were created (you should see `platform.tar`, `security.tar`, `deckhousereleases.yaml`, and multiple `module-*.tar` files):

```
$ ls -lh /home/ubuntu/d8-bundle
total 51G
-rw-rw-r-- 1 user user 4.8K Feb 26 17:19 deckhousereleases.yaml
-rw-rw-r-- 1 user user 4.9G Feb 26 18:30 module-code.tar
-rw-rw-r-- 1 user user  26G Feb 26 17:50 platform.tar
-rw-rw-r-- 1 user user 1.3G Feb 26 17:51 security.tar
```

Push the downloaded images to the private registry. Substitute the Deckhouse Platform edition and Harbor robot account credentials:

- `<ROBOT_ACCOUNT_NAME>` — robot account name
- `<PASSWORD>` — token issued when the robot account was created.

```
d8 mirror push $(pwd)/d8-bundle 'registry.local:443/deckhouse/<EDITION>' --registry-
login='robot$<ROBOT_ACCOUNT_NAME>' --registry-password='<PASSWORD>' --tls-skip-
verify
```



> **i** The `--tls-skip-verify` flag tells the CLI to trust the registry certificate and skip verification.

Images are read from the local bundles and pushed to the registry. This step is usually faster than download and often takes about 15 minutes.

Example of a successful image push completion...

```
Dec 11 18:25:32.350 INFO  ╟ Pushing registry.local:443/deckhouse/ee/modules/virtualization/release

```

To verify the push, open the `deckhouse` project in the Harbor web UI.

The images are now available in the private container registry.

Signing in to the registry to run the installer

Use the host from which you will run the installer (in this guide, the bastion host). On that host, `registry.local` must resolve to the Harbor VM (via `/etc/hosts` or DNS). Configure Docker to trust the TLS registry the same way as on the Harbor host: create `/etc/docker/certs.d/registry.local/` and place the required certificates there (copy them from the Harbor VM or generate again).

Sign in to Harbor so Docker can pull the dhctl installer image:

```
docker login registry.local
```

Example of a successful command execution...

```
$ docker login registry.local
Username: deckhouse
Password:

WARNING! Your credentials are stored unencrypted in '/home/ubuntu/.docker/config.json'.
Configure a credential helper to remove this warning. See
https://docs.docker.com/go/credential-store/

Login Succeeded
```

Preparing VMs for the future nodes

VM requirements

⚠ The example configuration in this guide sets the `ContainerdV2` container runtime (`defaultCRI: ContainerdV2`). To use it, the nodes must meet the following requirements:

- `CgroupsV2` support;
- systemd version `244` or newer;
- Linux kernel version `5.8` or newer, except for versions 6.12.0–6.12.28 and 6.14.0–6.14.6;
- support for the `erofs` kernel module.

Some distributions (for example, Astra Linux 1.7.4) do not meet these requirements. Bring the node OS into compliance before installing Deckhouse Platform. For details, see the defaultCRI parameter description.

Servers intended for future cluster nodes must meet the following requirements:

- at least 4 CPU cores;
- at least 8 GB RAM;
- at least 60 GB of disk space on fast storage (400+ IOPS);
- a supported OS;
- Linux kernel version `5.8` or later;
- a **unique hostname** across all cluster servers (physical servers and virtual machines);
- one of the package managers available (`apt`/`apt-get`, `yum`, or `rpm`).
- Python installed;
- access to the proxying registry or to the private container registry that holds Deckhouse Platform images;
- access to the standard OS package repositories for your distribution (via a proxy or an internal package mirror);
- SSH access from the bastion host using a key;
- network access from the bastion host on port `22/TCP`;
- no container runtime packages installed on the node (for example, no containerd or Docker).

⚠ For proper resource sizing, read the production preparation guide and the system requirements for deployment options, node types, and sizing based on workload and operations.

Mapping registry.local to the Harbor VM

On the servers where the master and worker nodes will run, make the `registry.local` hostname resolve to the Harbor VM’s internal IP address in the private network.

Connect to each server in turn and add a line to `/etc/hosts` (and, if your cloud provider manages the file, update the cloud template as well).

How to connect to a server without external access...

To connect via SSH to a server without external access, you can use the Bastion host as a jump host.

There are two ways to connect:

1. *Connect via a jump host.* Run the command:

   ```
   ssh -J ubuntu@<BASTION_IP> ubuntu@<NODE_IP>
   ```

   In this mode, you first connect to the Bastion host, and then connect through it to the target server using the same SSH key.

2. *Connect with agent forwarding.* Connect to the Bastion host using:

   ```
   ssh -A ubuntu@<BASTION_IP>
   ```

   > **i** Note: for this to work, you may need to start ssh-agent and add your key with `ssh-add` on the workstation from which you run the command.

   Then connect to the target servers:

   ```
   ssh ubuntu@<NODE_IP>
   ```

```
<INTERNAL_IP_ADDRESS> registry.local proxy.local
```

> **i** Replace `<INTERNAL_IP_ADDRESS>` with the Harbor VM's actual internal IP address.

Configuring SSH access to the master node

To install Deckhouse Platform, add the public part of your SSH key to `.ssh/authorized_keys` for the user on the future master node that will be used to install the platform.

Run the commands as `root` (substitute the public part of your SSH key):

```
mkdir /home/<USER>/.ssh
export KEY='ssh-rsa AAAAB3NzaC1yc2EAAAADA...'
echo $KEY >> /home/<USER>/.ssh/authorized_keys
chmod 700 /home/<USER>/.ssh
chmod 600 /home/<USER>/.ssh/authorized_keys
echo '<USER> ALL=(ALL) NOPASSWD: ALL' | sudo EDITOR='tee -a' visudo
```

Here `<USER>` is the username on the master node.

How to obtain the public part of the key...

Run `cat ~/.ssh/id_rsa.pub` to print the public key (or use the path to your key's `.pub` file).

These commands add the public SSH key so you can log in to the server as `<USER>`, and configure passwordless privilege escalation for this user.

Verify that you can connect as the user:

```
ssh -J ubuntu@<BASTION_IP> <USER>@<NODE_IP>
```

Creating a user for the worker node

> **i** The following prepares the node for Cluster API Provider Static (CAPS). If you prefer to add static nodes manually with the bootstrap script, you can skip this subsection and the later CAPS steps: create a `Static` NodeGroup, take the script from the Secret, and run it on the server as described in the documentation (manual method).

On the **master node**, generate an SSH key with an empty passphrase:

```
ssh-keygen -t rsa -f /dev/shm/caps-id -C "" -N ""
```

On the worker node server, create the `caps` user. Run the following commands and set the public key from the previous step:

```
# Set the user’s public SSH key.
export KEY='<SSH_PUBLIC_KEY>'
useradd -m -s /bin/bash caps
usermod -aG sudo caps
echo 'caps ALL=(ALL) NOPASSWD: ALL' | sudo EDITOR='tee -a' visudo
mkdir /home/caps/.ssh
echo $KEY >> /home/caps/.ssh/authorized_keys
chown -R caps:caps /home/caps
chmod 700 /home/caps/.ssh
chmod 600 /home/caps/.ssh/authorized_keys
```

If you are using CentOS, Rocky Linux, ALT Linux, ROSA Server, RED OS, or MOS OS...

On RHEL-based operating systems, add the `caps` user to the `wheel` group. Run the following commands and set the public key from the previous step:

```
# Set the user’s public SSH key.
export KEY='<SSH_PUBLIC_KEY>'
useradd -m -s /bin/bash caps
usermod -aG wheel caps
echo 'caps ALL=(ALL) NOPASSWD: ALL' | sudo EDITOR='tee -a' visudo
mkdir /home/caps/.ssh
echo $KEY >> /home/caps/.ssh/authorized_keys
chown -R caps:caps /home/caps
chmod 700 /home/caps/.ssh
chmod 600 /home/caps/.ssh/authorized_keys
```

If you are using an Astra Linux family OS...

On Astra Linux systems that use the Parsec mandatory integrity control module, set the maximum integrity level for the `caps` user:

```
pdpl-user -i 63 caps
```

Preparing the configuration file

The configuration file for a private environment differs from bare metal in several ways. Take `config.yml` from step 4 of the bare metal guide and apply the changes below.

If cluster nodes need outbound access via a proxy, deploy the proxy ahead of time—preferably on a dedicated machine with Internet access.

Example: Squid proxy in a container...

A proxy may be required for traffic such as pulling images from the public Deckhouse Platform registry to the bastion, or for Deckhouse Platform components and nodes to reach external URLs when policy allows. OS packages on nodes can still come from internal mirrors, in which case the proxy is not used for package traffic.

Deploy a proxy on a separate machine if your environment allows external access.

You may use any suitable proxy. This example uses Squid:

```
docker run -d --name squid -p 3128:3128 ubuntu/squid
```

Example of a successful start:

```
$ docker run -d --name squid -p 3128:3128 ubuntu/squid
Unable to find image 'ubuntu/squid:latest' locally
latest: Pulling from ubuntu/squid
1678e6c91c57: Pull complete
040467b888ae: Pull complete
18b9e99f4452: Pull complete
Digest: sha256:6a097f68bae708cedbabd6188d68c7e2e7a38cedd05a176e1cc0ba29e3bbe029
Status: Downloaded newer image for ubuntu/squid:latest
059b21fddbd2aba33500920f3f6f0712fa7b23893d512a807397af5eec27fb37
```

Check that the container is running:

```
059b21fddbd2   ubuntu/squid                           "entrypoint.sh -f /e…"   About
a minute ago   Up About a minute     0.0.0.0:3128->3128/tcp, [::]:3128->3128/tcp
squid
```

You should see a container named `squid` in the list.

- In ClusterConfiguration, set proxy parameters **if** the environment uses a proxy for external access:

  ```
  # Proxy server settings.
  proxy:
    httpProxy: http://proxy.local:3128
    httpsProxy: https://proxy.local:3128
    noProxy: ["registry.local", "proxy.local", "10.128.0.8", "10.128.0.32",
  "10.128.0.18"]
  ```

  Here you specify:

  - HTTP and HTTPS proxy addresses
  - hostnames and IP addresses that **must not** use the proxy (internal names and internal IPs of your servers).
- In the `deckhouse` ModuleConfig:
  - Set `releaseChannel` to `Stable` to use the stable release channel.
  - In the `spec.settings.registry` section, specify access settings for the private container registry (Harbor in this guide):

    ```
    # Settings for accessing the container registry with Deckhouse Platform
    images.
    registry:
      mode: Unmanaged
      unmanaged:
        # Address of the registry.
        imagesRepo: <IMAGES_REPO_URI>
        # Username for authenticating with the registry.
        username: <REGISTRY_USERNAME>
        # Password for authenticating with the registry.
        password: <REGISTRY_PASSWORD>
        scheme: HTTPS
        # Root CA certificate in PEM format used to verify the registry server
    certificate.
        ca: <REGISTRY_CA>
    ```
- In the global ModuleConfig, enable self-signed certificates for modules and set `publicDomainTemplate` for system application hostnames:

```
settings:
  modules:
    # Template for system application URLs in the cluster.
    # With %s.test.local, Grafana is served at grafana.test.local.
    # MUST NOT match network.clusterDomain of the control-plane-manager module.
    # You may change this now or after installation.
    publicDomainTemplate: "%s.test.local"
    # How Deckhouse Platform modules terminate HTTPS.
    https:
      certManager:
        clusterIssuerName: selfsigned
```

The `settings.modules.https` block in ModuleConfig/global supports several modes: `CertManager` (certificate from the chosen `ClusterIssuer` — not necessarily `selfsigned`; can be corporate CA, HashiCorp Vault, Venafi, etc., see the certificate overview); `CustomCertificate` (TLS Secret in `d8-system`); with an external TLS terminator, `OnlyInURI` is possible. Using `selfsigned` together with disabling Let's Encrypt below is a simple pattern for isolated environments without ACME.

- In the `user-authn` ModuleConfig, set dexCAMode to `FromIngressSecret`:

```
settings:
  controlPlaneConfigurator:
    dexCAMode: FromIngressSecret
```

- Enable `cert-manager` and disable Let's Encrypt:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: cert-manager
spec:
  version: 1
  enabled: true
  settings:
    disableLetsencrypt: true
```

- In StaticClusterConfiguration, set `internalNetworkCIDRs` to the subnet of the nodes' internal IPs. For example:

```
internalNetworkCIDRs:
  - 10.128.0.0/24
```

Full configuration file example...

```
# Cluster-wide settings.

# Specify this if you use the virtualization module or if cluster nodes have more
than one network interface.
# If cluster nodes use only one interface, you can omit the
StaticClusterConfiguration resource.
internalNetworkCIDRs:
  - 10.128.0.0/24
```

The installation configuration file is ready.

Installing Deckhouse Platform

Copy the prepared configuration file to the host from which you run the installation (for example, `~/deckhouse` on the bastion). Go to that directory and start the installer:

```
docker run --pull=always -it -v "$PWD/config.yml:/config.yml" -v
"$HOME/.ssh/:/tmp/.ssh/" --network=host -v "$PWD/dhctl-tmp:/tmp/dhctl"
registry.local/deckhouse/<EDITION>/install:stable bash
```

If you get the `509: certificate signed by unknown authority` error...

Even if the certificates are present in `/etc/docker/certs.d/registry.local/`, Docker may still report that the certificate is signed by an unknown certificate authority (which is typical for self-signed certificates). In most cases, adding `ca.crt` to the system trusted certificate store and restarting Docker resolves the issue.

> **i** If there is no internal DNS server and hostnames are only in `/etc/hosts` on the machine where you start the installer, use `--network=host` so Docker can resolve those names.

After the image is pulled and the container starts successfully, you will see a shell prompt inside the container:

```
[deckhouse] root@guide-bastion / #
```

Start the Deckhouse Platform installation with the following command (specify the master node's internal IP address):

```
dhctl bootstrap --ssh-user=<USER> --ssh-host=<MASTER_IP> --ssh-agent-private-
keys=/tmp/.ssh/id_rsa --config=/config.yml
```

Here:

- `<USER>`: User on the master node for whom you configured SSH access and passwordless `sudo`.
- `<MASTER_IP>`: Internal IP address of the master node.

Replace `id_rsa` with the name of your private key file if it differs.

The installation process may take up to 30 minutes depending on the network speed.

If the installation completes successfully, you will see the following message:

```
┌ ⛵ ~ Bootstrap: Run post bootstrap actions
│ ┌ Set release channel to deckhouse module config
│ │ ⛵ Succeeded!
│ └ Set release channel to deckhouse module config (0.09 seconds)
└ ⛵ ~ Bootstrap: Run post bootstrap actions (0.09 seconds)

┌ ⛵ ~ Bootstrap: Clear cache
│ ⛵ ~ Next run of "dhctl bootstrap" will create a new Kubernetes cluster.
└ ⛵ ~ Bootstrap: Clear cache (0.00 seconds)

⛵ Deckhouse cluster was created successfully!
```

Adding nodes to the cluster

Add a worker node to the cluster.

Perform the following steps:

- Configure a StorageClass for local storage by running the following command on the master node:

  ```
  sudo -i d8 k create -f - << EOF
  apiVersion: deckhouse.io/v1alpha1
  kind: LocalPathProvisioner
  metadata:
    name: localpath
  spec:
    path: "/opt/local-path-provisioner"
    reclaimPolicy: Delete
  EOF
  ```

- Set the created StorageClass as the default StorageClass. To do this, run the following command on the master node:

  ```
  sudo -i d8 k patch mc global --type merge -p "{\"spec\": {\"settings\":
  {\"defaultClusterStorageClass\":\"localpath\"}}}"
  ```

- Create the `worker` NodeGroup and add a node using Cluster API Provider Static (CAPS):

  ```
  sudo -i d8 k create -f - <<EOF
  apiVersion: deckhouse.io/v1
  kind: NodeGroup
  metadata:
    name: worker
  spec:
    nodeType: Static
    staticInstances:
      count: 1
      labelSelector:
        matchLabels:
          role: worker
  EOF
  ```

- Create an SSHCredentials resource in the cluster. Run on the master node:

```
sudo -i d8 k create -f - <<EOF
apiVersion: deckhouse.io/v1alpha2
kind: SSHCredentials
metadata:
  name: caps
spec:
  user: caps
  privateSSHKey: "`cat /dev/shm/caps-id | base64 -w0`"
EOF
```

- Print the public SSH key (needed for verification). On the master node:

```
cat /dev/shm/caps-id.pub
```

- Create a StaticInstance for the node to add. On the master node, set the node IP and apply:

```
# Specify the IP address of the node to be added to the cluster.
export NODE=<NODE_IP_ADDRESS>
sudo -i d8 k create -f - <<EOF
apiVersion: deckhouse.io/v1alpha2
kind: StaticInstance
metadata:
  name: d8cluster-worker
  labels:
    role: worker
spec:
  address: "$NODE"
  credentialsRef:
    kind: SSHCredentials
    name: caps
EOF
```

- Make sure all cluster nodes are in the `Ready` status:

```
$ sudo -i d8 k get no
NAME               STATUS   ROLES                  AGE    VERSION
d8cluster          Ready    control-plane,master   30m   v1.34.10
d8cluster-worker   Ready    worker                 10m   v1.34.10
```

  It may take some time for all Deckhouse Platform components to start after the installation completes.

Configuring the Ingress controller and creating a user

Installing the ingress controller

Make sure the Kruise controller manager Pod of the ingress-nginx module is running and in the `Running` status. To do this, run the following command on the master node:

```
$ sudo -i d8 k -n d8-ingress-nginx get po -l app=kruise
NAME                                          READY   STATUS    RESTARTS    AGE
kruise-controller-manager-7dfcbdc549-b4wk7   3/3     Running   0           15m
```

Create the `ingress-nginx-controller.yml` file on the master node containing the Ingress controller configuration:

```
# Ingress NGINX controller parameters.
# https://deckhouse.io/modules/ingress-nginx/cr.html
apiVersion: deckhouse.io/v1
kind: IngressNginxController
metadata:
  name: nginx
spec:
  # The name of the IngressClass served by the Ingress NGINX controller.
  ingressClass: nginx
  # How traffic enters from outside the cluster.
  inlet: HostPort
  hostPort:
    httpPort: 80
    httpsPort: 443
  # Defines which nodes will run the component.
  # You may want to adjust this.
  nodeSelector:
    node-role.kubernetes.io/control-plane: ""
  tolerations:
    - effect: NoSchedule
      key: node-role.kubernetes.io/control-plane
      operator: Exists
```

Apply it by running the following command on the master node:

```
sudo -i d8 k create -f $PWD/ingress-nginx-controller.yml
```

Starting the Ingress controller after Deckhouse Platform installation may take some time. Before you proceed, make sure the Ingress controller is running (run the following command on the master node):

```
$ sudo -i d8 k -n d8-ingress-nginx get po -l app=controller
NAME                                          READY   STATUS    RESTARTS   AGE
controller-nginx-r6hxc                        3/3     Running   0          5m
```

Creating a user to access the cluster web-interface

Create the `user.yml` file on the master node containing the user account, group, and access rights:

```
# Static user data.
# https://deckhouse.io/modules/user-authn/cr.html#user
apiVersion: deckhouse.io/v1
kind: User
metadata:
  name: admin
spec:
  # User email.
  email: admin@deckhouse.io
  # Generate password hash using the following command and replace <PASSWORD_HASH>
with the output:
  # echo -n '<PASSWORD>' | htpasswd -BinC 10 "" | cut -d: -f2 | tr -d '\n' | base64
-w0; echo
  password: '<PASSWORD_HASH>'
---
# User group.
# https://deckhouse.io/modules/user-authn/cr.html#group
apiVersion: deckhouse.io/v1alpha1
kind: Group
metadata:
  name: admins
spec:
  name: admins
  members:
  - kind: User
    name: admin
---
# RBAC and authorization settings.
# https://deckhouse.io/modules/user-authz/cr.html#clusterauthorizationrule
apiVersion: deckhouse.io/v1
kind: ClusterAuthorizationRule
metadata:
  name: admin
spec:
  # List of Kubernetes RBAC subjects.
  subjects:
  - kind: Group
    name: admins
  # A predefined access level template.
  accessLevel: SuperAdmin
  # Allow the user to use kubectl port-forward.
  portForwarding: true
```

Apply it by running the following command on the master node:

```
sudo -i d8 k create -f $PWD/user.yml
```

Configuring DNS records

To reach the cluster web UIs, make the hostnames below resolve to the master node’s internal IP address. Names must follow the `publicDomainTemplate` you configured (here, `%s.test.local`). Replace `<MASTER_IP>` with the master’s internal IP before running:

```
export PUBLIC_IP="<MASTER_IP>"
sudo -E bash -c "cat <<EOF >> /etc/hosts
$PUBLIC_IP api.test.local
$PUBLIC_IP code.test.local
$PUBLIC_IP commander.test.local
$PUBLIC_IP registry.test.local
$PUBLIC_IP console.test.local
$PUBLIC_IP dex.test.local
$PUBLIC_IP documentation.test.local
$PUBLIC_IP grafana.test.local
$PUBLIC_IP hubble.test.local
$PUBLIC_IP istio.test.local
$PUBLIC_IP istio-api-proxy.test.local
$PUBLIC_IP kubeconfig.test.local
$PUBLIC_IP openvpn-admin.test.local
$PUBLIC_IP prometheus.test.local
$PUBLIC_IP status.test.local
$PUBLIC_IP upmeter.test.local
EOF
"
```

To confirm the cluster is healthy, open Grafana (built from `publicDomainTemplate`, e.g. `grafana.test.local` for `%s.test.local`) and sign in with the user you created earlier.

Next steps

Deckhouse Platform is installed and running. You can use the web UIs to manage the cluster:

- **Deckhouse Console** — cluster and core component management. URL: **console.test.local**. You can download the `d8` CLI from this UI.
- **Documentation** — documentation for the Deckhouse Platform version running in the cluster. URL: **documentation.test.local**.
- **Monitoring** — Grafana dashboards shipped with Deckhouse Platform. URL: **grafana.test.local** (Prometheus UI path: **/prometheus/**). More in the monitoring documentation.
- **Status page** — overall Deckhouse Platform and component status. URL: **status.test.local**.
- **Upmeter** — SLA tracking by component and period. URL: **upmeter.test.local**.
- **Production readiness** — follow the production preparation guide before taking real traffic.

Deploying your first application

- **CI/CD access** — create a ServiceAccount for deployments and grant RBAC to obtain a kubeconfig for automation. See CI/CD access section. URL: **kubeconfig.test.local**.
- **Routing traffic to an app** — create a Service and Ingress. See Ingress and incoming traffic section.
- **Application monitoring** — add annotations `prometheus.deckhouse.io/custom-target: "my-app"` and `prometheus.deckhouse.io/port: "80"` to the Service. See Application and infrastructure monitoring section.

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Switching CNI in the cluster

This document describes the procedure for changing the network plugin (CNI) in a Deckhouse Platform (DP) cluster. The tool used in DP allows performing the automated migration (e.g., from Flannel to Cilium) with minimal application downtime and without a full restart of the cluster nodes.

- This guide is applicable for DP version 1.76 and above. For DP version 1.75 and earlier, use the Switching CNI from Flannel or Simple bridge to Cilium guide.
- The tool is not intended for switching to any (third-party) CNI.
- During the migration process, the target CNI module (`ModuleConfig.spec.enabled: true`) will be automatically enabled, which must be pre-configured by the cluster administrator.

- During the migration process, all pods in the cluster using the network (in PodNetwork) created by the current CNI will be restarted. This will cause an interruption in service availability. To minimize the risks of losing critical data, it is highly recommended to stop the operation of the most critical application services yourself before carrying out the work.
- It is recommended to carry out work during an agreed maintenance window.
- Before carrying out work, it is necessary to disable external cluster management systems (CI/CD, GitOps, ArgoCD, etc.) that may conflict with the process (e.g., trying to restore deleted pods prematurely or rolling back settings). Also, ensure that the cluster management system does not enable the old CNI module.

Supported CNI switching modes (rows are the current CNI, columns are the target CNI):

Current CNI	simple-bridge	flannel (hostgw)	flannel (vxlan)	cilium (native)	cilium (vxlan)
simple-bridge	□	□	□	□	□
flannel (hostgw)	□	□	□	□	□
flannel (vxlan)	□	□	□	□	□
cilium (native)	□	□	□	□	□
cilium (vxlan)	□	□	□	□	□

There are several methods to switch CNI in a DP cluster.

Method 1: Using the d8 network cni-migration command group of the d8 utility (automated switching)

The d8 utility provides a command group for managing the migration process.

Starting the migration

To start the process, execute the `switch` command, specifying the target CNI (e.g., `cilium`, `flannel`, or `simple-bridge`):

```
d8 network cni-migration switch --to-cni cilium
```

This command will create the necessary resource in the cluster and start the migration controller. DP will automatically deploy the necessary components: Manager and Agents in the `d8-system` namespace.

Monitoring progress

To monitor the progress in real-time, use the command:

```
d8 network cni-migration watch
```

You will see a dynamic interface with the following information:

- **Current phase**: What exactly is happening at the moment (e.g., `CleaningNodes` or `RestartingPods`).
- **Progress**: List of successfully completed stages and current status of pending cluster actions.
- **Errors**: If a problem occurs on any node, it will be displayed in the `Failed Nodes` list.

Main phases of the process:

1. **Preparing**: Validating the request and waiting for the environment to be ready (e.g., webhooks disabled).
2. **WaitingForAgents**: Waiting for migration agents to start on all nodes.
3. **EnablingTargetCNI**: Enabling the target CNI module in the DP configuration.
4. **DisablingCurrentCNI**: Disabling the current CNI module.
5. **CleaningNodes**: Agents clean up the network settings of the current CNI on the nodes.
6. **WaitingTargetCNI**: Waiting for the new CNI pods (DaemonSet) to be ready.
7. **RestartingPods**: Restarting application pods to switch them to the new network.
8. **Completed**: Migration successfully completed.

Completion and cleanup

After the migration status changes to `Succeeded`, you must remove the migration resources (controllers and agents) so that they do not consume cluster resources. To do this, use the command:

```
d8 network cni-migration cleanup
```

Method 2: Using the d8 k commands (manual switching)

The user has the option to manage the migration directly via the Kubernetes API.

Starting the migration

Create a CNIMigration resource (the example uses the `cni-migration.yaml` manifest) specifying the target CNI:

```
---
apiVersion: network.deckhouse.io/v1alpha1
kind: CNIMigration
metadata:
  name: migration-to-cilium
spec:
  targetCNI: cilium
```

Apply the manifest in the cluster:

```
d8 k create -f cni-migration.yaml
```

Monitoring progress

Monitor the status of the CNIMigration resource:

```
d8 k get cnimigration migration-to-cilium -o yaml -w
# OR
watch -n 1 "d8 k get cnimigration migration-to-cilium -o yaml"
```

Pay attention to the fields:

- `status.phase`: Current stage.
- `status.conditions`: Detailed history of transitions.
- `status.failedSummary`: List of nodes with errors.

For detailed diagnostics of a specific node, you can check its local resource:

```
d8 k get cninodemigrations
d8 k get cninodemigration NODE_NAME -o yaml
```

To view the logs of migration controllers in the cluster, execute the following commands:

```
d8 k -n d8-system get pods -o wide | grep cni-migration
d8 k -n d8-system logs cni-migration-manager-HASH
d8 k -n d8-system logs cni-migration-agent-HASH
```

Completion and cleanup

After successful completion (the `CNIMigration` status shows condition `Type: Succeeded, Status: True`), delete the resource:

```
d8 k delete cnimigration migration-to-cilium
```

This action signals DP to remove all previously created resources in the cluster.

Troubleshooting

> **i** The CNI switching tool does not evaluate the network connectivity of pods and cluster components after the CNI migration in the cluster.

Agent does not start on a node

Check the status of the `cni-migration-agent` DaemonSet in the `d8-system` namespace. There may be taints on the node that are not covered by the agent's tolerations.

Node stuck in CleaningNodes phase

Check the logs of the agent pod on the corresponding node:

```
d8 k -n d8-system logs cni-migration-agent-HASH
```

Possible reason: inability to delete CNI configuration files due to permissions, stuck processes, or failure to pass Webhooks verification.

Target CNI pods do not start

If the target CNI (e.g., Cilium) is in `Init:0/1` status, check the logs of its init container `cni-migration-init-checker`. It waits for the node cleanup to complete. If cleanup is not finished (see the previous section), the new CNI will not start. In a critical situation, you can edit the Daemonset to remove the `cni-migration-init-checker` init container.

Migration stuck

If the process has stopped and hasn't moved for a long time:

1. Check `failedSummary` in the `CNIMigration` status.
2. If there are problematic nodes that cannot be fixed (e.g., a node in NotReady status), you can temporarily remove this node from the cluster or try to reboot it.

Additional resources

- Global custom resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Planning for a high pod count on a node

When you plan to place and run more than 100 pods on a single node, a number of additional requirements apply to its configuration. The most critical requirements apply to the disk (unpacking and mounting image layers), kernel, and RAM. Following the recommendations in this guide helps reduce pod startup time and make it more predictable.

> **i** For nodes with high pod density:
>
> - Plan the node subnet size in advance (via `podSubnetNodeCIDRPrefix`) — the pod limit per node will adjust automatically.
> - Use a Linux kernel version 6.12 or newer.
> - Use a fast local disk (NVMe or SSD) and do not use a network file system.
> - Use lightweight application images with minimum amount of layers (for example, `distroless`).

For such scenarios, Deckhouse Platform (DP) configures control plane components automatically — no additional manual configuration is required.

Pod limit per node

> **i** The pod limit per node in DP is calculated based on the node subnet size set via the `podSubnetNodeCIDRPrefix` parameter. To fit up to 1000 pods on a node, set the value ≤ `21` when deploying the cluster.

The subnet size allocated to a node determines the maximum number of pods that can be allocated to a node:

Value of `podSubnetNodeCIDRPrefix`	Pods per node (by default)
≥ `24`	120
`23`	250
`22`	500
≤ `21`	1000

The `podSubnetNodeCIDRPrefix` parameter is set when the cluster is deployed. If you know that you will be allocating a large number of pods on nodes, it is recommended that you set an appropriate value when the cluster is created.

Node kernel

> **i** For nodes with a high pod count, it is recommended that you use a Linux kernel version 6.12 or newer with support for the `erofs` kernel module.

Starting with version 2.x, containerd supports `EROFS` functionality that depends on the `CONFIG_EROFS_FS_BACKED_BY_FILE` kernel option. This option is enabled by default starting with Linux 6.12 and allows mounting image layers represented as regular files directly, without creating a separate loop device for each layer or container.

Without this option, starting a large number of containers can create many loop devices. On nodes with hundreds or thousands of pods, this increases system load and can significantly slow down container startup.

Therefore, for nodes where you plan to run a large number of pods, it is recommended that you use an operating system with a Linux kernel 6.12 or newer.

Node disk

> **i** Use a fast local disk (NVMe or SSD). Do not place container runtime files and kubelet data on a network file system.

Starting each pod involves disk-intensive operations of unpacking and working with image layers. During a mass startup, these operations are multiplied by the number of pods, so disk performance directly affects startup time.

Recommendations:

- Use fast disks with performance of at least 400 IOPS (see the “Resource requirements” section). For nodes with high pod density, prioritize local NVMe disks.
- Do not place container runtime and kubelet directories in a network or distributed file system. Network latency on mount operations is multiplied by the number of started pods and makes startup time unpredictable.

Application images

> **i** The more compact and simple the application image, the faster the pod starts. Use minimal images (for example, `distroless`) and reduce the number of layers.

Image size and structure affect its pull and preparation time. With a large number of simultaneously started pods, this can become a problem.

Recommendations:

- Use minimal base images (for example, `distroless`, `*-slim`, or `alpine`), without unnecessary packages and tools.
- Reduce the number of image layers and merge them when possible to decrease the amount of unpacking and mounting.
- Keep images small — remove package manager caches, build artifacts, and temporary files.
- Use multi-stage builds to reduce the size and number of layers in the final image.

Pod startup delays can also be caused not by the image itself, but by the container registry and the network bandwidth to it. During a mass startup or update of multiple applications, a node may download several images at once, which can make the registry a bottleneck.

Recommendations:

- Place the container registry close to the cluster in network terms and ensure sufficient bandwidth to it.
- For images from external (including public) container registries, use a local mirror or pull-through cache near the cluster.

Node resources

In addition to disk and kernel, pod density is limited by the node’s CPU and RAM. The following are test results where a static NGINX is used:

- A node with 4 vCPU, 8 GB RAM, and an SSD ensures a simultaneous startup of 150 pods.
- A node with 32 vCPU, 64 GB RAM, local NVMe, and a Linux kernel ≥ 6.12 starts about 1000 pods in a few minutes.

Actual values depend on application characteristics, so it is recommended that you conduct a load testing before using similar configurations in a production environment.

Additional resources

- Module `control-plane-manager` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Installing Deckhouse Platform in an existing Talos cluster

This guide applies to an existing, operational Kubernetes cluster based on Talos Linux: the control plane is running, worker nodes have joined the cluster, a CNI is installed, and the Kubernetes API is accessible with `d8 k`.

Deckhouse Platform (DP) is installed on top of the existing Kubernetes cluster in existing-cluster mode. This example uses Deckhouse Platform Open, the `EarlyAccess` release channel, and the `Managed` bundle.

In this setup:

- Talos continues to manage the operating system, MachineConfig, kubelet, containerd, etcd, the control plane, Kubernetes PKI, and Kubernetes updates.
- The existing CNI continues to provide Pod networking.
- The external provisioner or the user continues to create and delete machines.
- DP installs and updates platform modules but does not manage Talos or the node lifecycle.

⚠ The `bundle` value is selected during installation and cannot be changed afterwards. You cannot install `Managed` and then switch it to `Minimal` or `Default` with a regular patch.

Prerequisites

The following tools and access are required on the computer from which the installation will be performed:

- Docker
- Deckhouse CLI
- `yq` for validating YAML
- An administrative kubeconfig for the Talos cluster
- Access to the Kubernetes API
- HTTPS access to `registry.deckhouse.io` from both the computer and the cluster nodes
- `talosctl` and talosconfig if an administrative kubeconfig has not yet been obtained

SSH access to Talos nodes is not required: the installer communicates with the cluster through the Kubernetes API.

Before installation, it is recommended to create an etcd snapshot using Talos and save the original talosconfig and kubeconfig.

Setting the working paths

Create a separate directory for the installation files and change to it:

```
mkdir -p "$PWD/talos-deckhouse-install"
cd "$PWD/talos-deckhouse-install"
```

All subsequent commands assume that this remains the current directory. Set the paths once:

```
TALOSCONFIG="$PWD/talosconfig"
ADMIN_KUBECONFIG="$PWD/kubeconfig-admin"
INSTALLER_KUBECONFIG="$PWD/kubeconfig-installer"
CONFIG_FILE="$PWD/config.yml"
```

The files are used as follows:

Variable	Purpose
`TALOSCONFIG`	`talosctl` configuration for accessing the Talos API
`ADMIN_KUBECONFIG`	Administrative kubeconfig for running `d8 k` on the computer
`INSTALLER_KUBECONFIG`	Portable copy of the administrative kubeconfig for the Docker container
`CONFIG_FILE`	Deckhouse Platform installation configuration

If you open a new terminal, return to the working directory and define the four variables from the block above.

Preparing an administrative kubeconfig

The next steps depend on whether you already have an administrative kubeconfig.

If you already have a kubeconfig

Copy it to the working directory:

```
cp <ADMIN_KUBECONFIG_PATH> "$ADMIN_KUBECONFIG"
chmod 600 "$ADMIN_KUBECONFIG"
```

> **i** This refers to a kubeconfig for `d8 k`, not a talosconfig file for `talosctl`.

If you need to obtain a kubeconfig through Talos

First, copy the existing talosconfig to the working directory:

```
cp <TALOSCONFIG_PATH> "$TALOSCONFIG"
chmod 600 "$TALOSCONFIG"
```

Specify the address of a control-plane node:

```
CONTROL_PLANE_ADDRESS=<CONTROL_PLANE_IP_OR_DNS>
```

Obtain an administrative kubeconfig:

```
talosctl kubeconfig "$ADMIN_KUBECONFIG" --talosconfig="$TALOSCONFIG" --
nodes="$CONTROL_PLANE_ADDRESS" --merge=false
chmod 600 "$ADMIN_KUBECONFIG"
```

By default, `talosctl` uses the Talos API endpoints from the current talosconfig context. If a different endpoint is required, add:

```
--endpoints=<TALOS_API_ENDPOINT>
```

Use `--force` only when you intentionally want to overwrite an existing file.

Verifying permissions

Check how Kubernetes identifies the user:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" auth whoami
```

Installation requires stable administrative access. A Talos administrative kubeconfig usually uses the `system:masters` group. Using an OIDC user kubeconfig for the installation is not recommended: after the DP `user-authz` module is enabled, that user's access to system namespaces may change.

Verify the required permissions:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" auth can-i '*' '*' --all-namespaces
d8 k --kubeconfig="$ADMIN_KUBECONFIG" auth can-i create
customresourcedefinitions.apiextensions.k8s.io
d8 k --kubeconfig="$ADMIN_KUBECONFIG" auth can-i create clusterroles.rbac.authorization.k8s.io
```

All three commands must return `yes`.

Verifying the existing cluster

Check the nodes:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get nodes -o wide
```

All nodes must be in the `Ready` state.

Check the Kubernetes API:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get --raw='/readyz?verbose'
```

The response must end with `readyz check passed`.

Check the system Pods:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n kube-system get pods -o wide
```

Before installing DP, the following components must already be running:

- CNI
- CoreDNS
- kube-proxy, if it is used by the selected network setup
- Control-plane components

Also make sure that the Kubernetes version is supported by the selected DP version.

Verifying component ownership

DP must not manage the same components as Talos or an external provisioner.

The table below lists the components and their owners after installation:

Component	Owner after installation
Talos OS and MachineConfig	Talos
etcd and the Kubernetes control plane	Talos
Kubernetes PKI	Talos
kubelet and containerd	Talos
CNI	The existing external CNI
CoreDNS and kube-proxy, if used	The existing cluster
Machine creation and deletion	The external provisioner or the user
Platform modules	DP

The following DP modules must remain disabled:

- `control-plane-manager`
- `node-manager`
- `terraform-manager`
- `cni-cilium`
- `kube-dns`
- `kube-proxy`
- `cloud-provider-*` modules
- `registry-packages-proxy`

⚠ If Cilium is already installed in the Talos cluster, do not enable the DP `cni-cilium` module: two operators must not manage the same CNI at the same time.

The `Managed` bundle includes `ingress-nginx`, `cert-manager`, `local-path-provisioner`, VPA, monitoring, and the `user-authz` module. Before installation, check whether external equivalents are already present in the cluster:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get storageclass
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get ingressclass
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get deployments -A
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get crd
```

If a component is already installed, choose a single owner before proceeding. Do not run two ingress controllers, two `cert-manager` installations, or two VPA installations at the same time. If an external solution remains responsible for the component, explicitly disable the corresponding DP module using a

ModuleConfig with `spec.enabled: false`. If DP is to manage the component, disable or remove the external counterpart before installation.

Preparing a kubeconfig for the installer container

The installer runs inside Docker. It requires a portable kubeconfig that does not reference certificate and key files available only on the user's computer.

Create a portable copy:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" config view --raw --flatten --minify >
"$INSTALLER_KUBECONFIG"
chmod 600 "$INSTALLER_KUBECONFIG"
```

This command does not create new certificates. The `--flatten` option reads the CA, client certificate, and key from the paths specified in the source kubeconfig and embeds them in the new file.

Verify the copy:

```
d8 k --kubeconfig="$INSTALLER_KUBECONFIG" auth whoami
d8 k --kubeconfig="$INSTALLER_KUBECONFIG" auth can-i '*' '*' --all-namespaces
```

The second command must return `yes`.

Check the Kubernetes API address:

```
d8 k --kubeconfig="$INSTALLER_KUBECONFIG" config view --minify -o
jsonpath='{.clusters[0].cluster.server}{"\n"}'
```

This address must be reachable from the Docker container. A reachable Kubernetes API address, a VPN address, or a load balancer address is preferred.

If the address is `https://127.0.0.1:6443`, the installer cannot use it directly: inside the container, `127.0.0.1` refers to the container itself. Make the Kubernetes API accessible from the container before continuing with the installation.

Creating the configuration file

Create the `$CONFIG_FILE` file with the following content and replace `example.com` with your domain:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: deckhouse
spec:
  version: 1
  enabled: true
  settings:
    bundle: Managed
    releaseChannel: EarlyAccess
    logLevel: Info
---
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: global
spec:
  version: 2
  settings:
    modules:
      publicDomainTemplate: "%s.example.com"
```

The domain in `publicDomainTemplate` must not match or be a subdomain of the domain specified in `clusterDomain`. Before using the template, configure DNS services in both the networks where cluster nodes are located and the networks from which clients access the platform service web interfaces.

If the nodes have custom taints and DP components must run on them, add the corresponding values to `global.spec.settings.modules.placement.customTolerationKeys`. Do not add an example taint unless it exists in the cluster.

Validate the file:

```
yq eval-all '.' "$CONFIG_FILE" >/dev/null && echo "YAML OK"
grep -n $'\t' "$CONFIG_FILE"
```

The first command must print `YAML OK`; the second command must not print anything.

Running the Deckhouse Platform Open installer

The installer tag must match the `releaseChannel` in the configuration. The `early-access` tag is used for `EarlyAccess`.

Check that the files exist:

```
ls -l "$CONFIG_FILE" "$INSTALLER_KUBECONFIG"
```

Run the installer:

```
docker run --pull=always -it -v "$CONFIG_FILE:/config.yml:ro" -v
"$INSTALLER_KUBECONFIG:/kubeconfig:ro" registry.deckhouse.io/deckhouse/ce/install:early-access
bash
```

The installer image path still uses the `ce` designation for Deckhouse Platform Open.

Inside the installer container, run:

```
dhctl bootstrap-phase install-deckhouse --kubeconfig=/kubeconfig --config=/config.yml
```

Do not close the terminal until the bootstrap process completes. Installation can take anywhere from 5 to 30 minutes.

Monitoring the installation

In a separate terminal, change to the same working directory and define the variables from the “Setting the working paths” section again. Run the command:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n d8-system get deployment,replicaset,pods -w
```

If the `deckhouse` Pod is not created, check the events:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n d8-system get events --sort-
by=.metadata.creationTimestamp
```

Errors such as `ImagePullBackOff`, `ErrImagePull`, `401 Unauthorized`, or `403 Forbidden` usually indicate a problem with the registry address, registry access, DNS, or routing.

To diagnose a specific Pod, run:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n <NAMESPACE> describe pod <POD_NAME>
```

Verifying the installation

Wait for the main Deployment to become ready:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n d8-system rollout status deployment/deckhouse --
timeout=10m
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n d8-system get deployment,pods -o wide
```

Check the modules:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get modules -o wide
```

Enabled modules are expected to have `PHASE: Ready`, `ENABLED: True`, and `READY: True`.

The Module status alone is not sufficient: a module may be `Ready` even if one of its Deployments, StatefulSets, or DaemonSets was not created or is restarting. Check the actual resources:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get deployment,statefulset,daemonset -A
```

For each DaemonSet, the `DESIRED`, `CURRENT`, and `READY` values must match. For Deployments and StatefulSets, the expected number of replicas must be ready.

Find Pods that are not in the `Running` or `Succeeded` phase:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get pods -A --field-
selector='status.phase!=Running,status.phase!=Succeeded'
```

Check recent warnings:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get events -A --field-selector=type=Warning --sort-
by=.metadata.creationTimestamp
```

An old warning does not necessarily indicate a current problem. Consider the event timestamp, repetition count, and the current state of the related resource.

Verifying that DP does not manage Talos components

Verify that DP modules that can manage Talos components remain disabled.

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get modules control-plane-manager node-manager terraform-
manager cni-cilium kube-dns kube-proxy registry-packages-proxy -o wide
```

All listed modules must have `ENABLED: False`.

Check the cloud provider modules:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get modules -o wide | grep -E '(^NAME|^cloud-
provider-)'
```

All `cloud-provider-*` modules found by the command must have `ENABLED: False`.

Check the original cluster components again:

```
d8 k --kubeconfig="$ADMIN_KUBECONFIG" -n kube-system get pods -o wide
d8 k --kubeconfig="$ADMIN_KUBECONFIG" get nodes -o wide
```

All Talos nodes must remain `Ready`. The original CNI, CoreDNS, and control-plane components must continue to run; kube-proxy must also continue to run if it was used before the DP installation.

Successful installation criteria

The installation is considered successful when all of the following conditions are met:

- All Talos nodes remain `Ready`.
- The original CNI and CoreDNS continue to run; kube-proxy also continues to run if it was used before the DP installation.
- Deployment `deckhouse` is ready.
- Enabled modules have `READY: True`.
- The actual module Deployments, StatefulSets, and DaemonSets are ready.
- DP modules that can manage Talos components remain disabled.
- Administrative access through the Talos administrative kubeconfig is preserved.

Additional resources

- Installing Deckhouse Platform in an existing cluster

- Module `deckhouse` parameters
- Bundles and module management
- Patching Talos MachineConfig
- Global parameters
- Module `control-plane-manager` parameters

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

Migrating VMs from VMware to DP

This guide describes how to migrate an existing virtual machine from VMware to Deckhouse Platform (DP).

The migration source can be:

- a virtual machine distribution (an `OVA` file, a tar archive with disk files in `vmdk` format, VM metadata in `ovf` format, and checksums in `mf` format);
- standalone `VMDK` disk files.

Migration approaches

Direct VMDK import

DP supports importing disks in `vmdk` format. You can upload a `VMDK` file from an OVA or vSphere export to a `VirtualImage` or `ClusterVirtualImage`, create a disk from the image, and then a virtual machine. See Images for the upload procedure.

> ⚠ The platform imports the disk file as-is and does not adapt the guest OS for KVM. For disks from VMware this often causes problems: the VM fails to boot, cannot see the disk, or has no network (especially on Windows). Direct import is suitable only when the `VMDK` is already prepared for QEMU/KVM.

Recommended path

For typical VMs from VMware, use the `virt-v2v` utility: it converts `VMDK` to `qcow2` and adapts the guest OS for KVM (virtio drivers, bootloader, replacement of VMware devices). Upload the prepared disk directly to a `VirtualDisk` with `type: Upload`. The volume is provisioned in the chosen StorageClass, bypassing DVCR.

The step-by-step instructions below cover this scenario.

Migration stages

Migrating a VM from VMware to DP includes the following stages:

1. Install the required tools.
2. Convert the disk.
3. Upload the disk to the cluster as a VirtualDisk resource.
4. Create a virtual machine (VirtualMachine resource) that boots from this disk.

What you need for migration

Before you start the migration, make sure you have:

- access to the DP cluster with the Deckhouse CLI utility (`d8`) installed and permissions to create virtualization resources in the target namespace;
- a Linux host with `virt-v2v` and `libguestfs` installed and enough disk space to unpack the `OVA` (or standalone `VMDK` files) and store the conversion output;
- the VMware export files (`OVA` or `VMDK`).

For more details on uploading disks to the cluster, see Disks.

Install tools

On this step you prepare a conversion workstation. It does not have to be a DP cluster node: any Linux host with internet access or a local package repository is sufficient.

The packages you need depend on the guest OS in the VM you are migrating:

- for Linux, `virt-v2v` and `libguestfs` are sufficient;
- for Windows, you will additionally need a `virtio-win` ISO so the guest OS works correctly with virtual devices in KVM after migration.

Install the tools:

- Ubuntu/Debian workstation
- RHEL/AlmaLinux workstation

Run the following command:

```
sudo apt update
sudo apt install -y virt-v2v libguestfs-tools
```

If the VM being migrated runs Windows:

1. Download the VirtIO drivers from the `virtio-win` distribution.
2. Specify the path to the VirtIO drivers via an environment variable:

   ```
   export VIRTIO_WIN=/path/to/virtio-win.iso
   ```

⚠ Without a valid `virtio-win` ISO for a Windows guest, conversion may fail, or the guest OS may not see disks or networking after the VM starts in DP.

Run the following command:

```
sudo dnf install -y virt-v2v libguestfs-tools-c virtio-win
```

If the VM being migrated runs Windows, set the path to the ISO via an environment variable:

```
export VIRTIO_WIN=/path/to/virtio-win.iso
```

Then proceed to converting the disk.

Convert the disk

On this step you convert VMware data into one or more `qcow2` files that DP can use as virtual machine volumes. If you already have a ready `VMDK`, go straight to Convert VMDK to qcow2 via virt-v2v. If you are using a virtual machine `OVA` distribution, unpack it first.

Extract an OVA

An `OVA` file is a tar archive with a manifest, an `OVF` descriptor, and one or more `VMDK` images. Unpacking gives you the disk file path for `virt-v2v`. Keep the `OVF` file: you will use it later for CPU, memory, and bootloader settings in the VirtualMachine resource.

Extract everything if you want to verify checksums or inspect the OVF:

```
tar -xvf machine.ova
```

Typical contents:

```
machine.ova
├── machine.mf          # checksums (SHA256)
├── machine.ovf         # VM metadata (CPU, RAM, disks, networks)
└── machine-disk1.vmdk  # disk image
```

If the archive is large, you can extract only the required `VMDK` listed in the `OVF`:

```
tar -xvf machine.ova machine-disk1.vmdk
```

> **i** Virtual machines with multiple disks contain several `*.vmdk` files. Convert each disk with the `virt-v2v` utility, create a matching `VirtualDisk` in DP, then reference them from `VirtualMachine` in the desired boot order.

Convert VMDK to qcow2 via virt-v2v

With `-i disk`, `virt-v2v` processes a local `VMDK` and saves the result into the directory you specify. To perform the conversion, run:

- For a Linux guest OS
- For a Windows guest OS

```
virt-v2v -i disk ./machine-disk1.vmdk \
    -o local -os ./out -of qcow2
```

To convert a `VMDK` for a Windows guest, specify the path to `virtio-win.iso` in the command:

```
VIRTIO_WIN=/path/to/virtio-win.iso virt-v2v -i disk ./machine-disk1.vmdk \
    -o local -os ./out -of qcow2
```

After the conversion, a file such as `./out/machine.qcow2` will appear under `./out` (the basename often matches the original VM name from the metadata). That file is what you upload to the cluster next.

Upload the disk to the cluster

This section describes how to transfer the prepared `qcow2` image to DP through the Kubernetes API. At this stage the file becomes a persistent volume in the cluster: create a VirtualDisk with `type: Upload` and transfer the `qcow2` over HTTP. The disk is provisioned in the chosen StorageClass, bypassing DVCR.

Uploading the disk image to the cluster includes the following steps:

1. Choose a StorageClass.
2. Create a VirtualDisk for upload.
3. Get upload URLs.
4. Upload the image.
5. Check the status of the uploaded image.

Choose a StorageClass

StorageClass in Kubernetes defines where and how the volume is provisioned; in VMware terms this is closest to a `datastore`. Performance, replication type, and volume expansion policy depend on the class.

List classes available in your cluster:

```
d8 k get storageclass
```

Example:

```
NAME                 PROVISIONER                          VOLUMEBINDINGMODE   AGE
rv-thin-r1 (default) replicated.csi.storage.deckhouse.io  Immediate           48d
rv-thin-r2           replicated.csi.storage.deckhouse.io  Immediate           48d
```

Select the class name that fits your storage requirements for VM disks.

Create a VirtualDisk for upload

Create the disk resource, specifying StorageClass and volume size.
`spec.persistentVolumeClaim.size` must be at least the actual size of the `qcow2` you upload. If unsure, leave margin: if the size is insufficient, recreate the resource with a larger PVC.

```
d8 k apply -f - <<EOF
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualDisk
metadata:
  name: uploaded-disk
spec:
  persistentVolumeClaim:
    storageClassName: rv-thin-r1
    size: 10Gi
  dataSource:
    type: Upload
EOF
```

After creation the resource moves to `WaitForUserUpload`: the volume is allocated and you can start transferring the file.

Get upload URLs

The platform provides two URLs: internal (`imageUploadURLs.inCluster`) and external (`imageUploadURLs.external`). Use the address reachable from your network (from inside the cluster or from an administrator workstation).

Internal URL (use when uploading from a cluster node or from a pod):

```
d8 k get vd uploaded-disk -o jsonpath="{.status.imageUploadURLs.inCluster}"
```

External URL (use from an administrator workstation when access to DP is configured):

```
d8 k get vd uploaded-disk -o jsonpath="{.status.imageUploadURLs.external}"
```

Both fields together (requires `jq`):

```
d8 k get vd uploaded-disk -o jsonpath="{.status.imageUploadURLs}" | jq
```

⚠ The URL string contains a secret path segment. Do not publish it in public channels.

Upload the image

Send the `qcow2` image with an HTTP `PUT` request to the URL obtained in the previous step. The example below uses an external URL. Replace it with the address from your `VirtualDisk` status and the path to the converted file.

```
curl https://virtualization.example.com/upload/<secret-url> \
    --progress-bar -T ./out/machine.qcow2 | cat
```

Wait until the transfer completes successfully without HTTP errors. The controller will process the image and transition the disk to `Ready`.

Check status

Verify that the disk resource is healthy and the volume size looks correct:

```
d8 k get vd uploaded-disk
```

Example:

```
NAMESPACE   NAME            PHASE   CAPACITY   AGE
default     uploaded-disk   Ready   10Gi       1m
```

If the phase stays on `WaitForUserUpload` for a long time or the resource enters `Failed`, check messages with `d8 k describe vd uploaded-disk` and events in the corresponding namespace.

Continue when the disk reaches `Ready`.

Create the virtual machine

The final step is to describe the VM that will boot from the migrated disk. Specify how much CPU and memory to allocate, which network to attach, and which disk is bootable. VMware configuration (`OVF`/`VMX`) is not imported directly: carry over parameters manually using the `OVF` file and the mapping table below.

VMware vs DP terminology

If you know vSphere, the following table maps familiar VMware objects to Kubernetes and DP virtualization resources.

VMware	DP	Description
Datastore	StorageClass	Disk backing storage
VMX	VirtualMachine.spec	VM specification
Virtual disk (VMDK)	VirtualDisk	VM disk
ISO image	VirtualImage (`cdrom: true`)	Installation or driver ISO
Template	VirtualImage	Template for provisioning disks
Port group / VLAN	VirtualMachine (`networks`)	Networking
Resource pool	Project and quotas	Resource limits per project
Snapshot	VirtualDiskSnapshot / VirtualMachineSnapshot	Disk and VM snapshots
Folder	Namespace	Namespace
Cluster / resource pool	Project	Namespace grouping
ESXi host	Node	Physical server
vCenter	Kubernetes API	Cluster management

For more details on connecting VMs to networks, see Virtual machine networks.

VirtualMachine example

The VirtualMachine resource references the uploaded disk through `blockDeviceRefs`. Order in `blockDeviceRefs` determines boot order: the boot disk must be listed first.

Minimal Linux example after disk migration:

```
d8 k apply -f - <<EOF
apiVersion: virtualization.deckhouse.io/v1alpha2
kind: VirtualMachine
metadata:
  name: my-vm
spec:
  virtualMachineClassName: generic
  osType: Generic
  cpu:
    cores: 2
  memory:
    size: 4Gi
  networks:
    - type: Main
  blockDeviceRefs:
    - kind: VirtualDisk
      name: uploaded-disk
EOF
```

Set `osType: Windows` for Windows guests.

If the source VM in VMware used UEFI boot, add `bootloader: EFI` (see the parameter table below).

If additional networks and the SDN module are configured in the cluster, you can add interfaces alongside the primary network:

```
networks:
  - type: Main
  - type: Network
    name: user-net
```

Additional capabilities (cloud-init, multiple disks, VM classes for production environments) are described in Virtual machines.

Common spec fields

The following table lists fields you most often need to verify after migration from VMware. CPU, memory, and bootloader values can usually be taken from the unpacked `OVF` file.

Field	Description
`virtualMachineClassName`	VM class, e.g. `generic`, `serverful`, `high-performance`
`osType`	`Generic` (Linux and others) or `Windows`
`bootloader`	Boot firmware: `BIOS`, `EFI`, or `EFIWithSecureBoot`; for UEFI VMs in VMware, set `EFI`
`cpu.cores`	Number of vCPUs
`memory.size`	RAM
`blockDeviceRefs`	Disks and images; list order is boot order
`provisioning.type: UserData`	cloud-init user data for first boot of the guest OS

Check VM status

After applying the manifest, wait until the VM is running and has an address (when the primary network assigns IPs from `virtualMachineCIDRs`):

```
d8 k get vm my-vm
```

Example:

```
NAME    PHASE     NODE           IPADDRESS     AGE
my-vm   Running   virtlab-pt-2   10.66.10.12   2m
```

If the phase is `Pending` or startup fails, use `d8 k describe vm my-vm`, the serial console `d8 v console my-vm` (see Connect to the VM below), and review virtualization component logs in the cluster.

Connect to the VM

Choose an access method depending on whether the guest OS accepts SSH, you need a graphical console, or serial console is enough for boot troubleshooting.

Method	Purpose	Command
Serial console	Bootloader and kernel output	`d8 v console my-vm`
VNC	Graphical console without SSH	`d8 v vnc my-vm`
SSH	Remote shell access to the guest	`d8 v ssh cloud@my-vm --local-ssh`

The SSH username is defined in the guest OS; examples in the DP virtualization documentation often create a `cloud` user via cloud-init.

>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Architecture

This section describes the architecture of Deckhouse Platform (DP).

The section consists of the following subsections:

- C4 model: Overview of the C4 model used to visualize the platform architecture, as well as a description of the DP architecture at levels 1 and 2 of the C4 model.
- Modules: Description of the DP module architecture.
- Disaster resilience: Description of the disaster resilience approaches implemented in DP.
- Updating: Description of the DP update mechanisms.
- Description of platform component architecture divided in the following subsystems:
  - Deckhouse subsystem
  - Kubernetes & Scheduling subsystem
  - Cluster & Infrastructure subsystem
  - IAM subsystem
  - Security subsystem
  - Network subsystem
  - Storage subsystem
  - Observability subsystem

> This section does not yet cover all DP subsystems and modules.
> Documentation for the remaining components will be added as it becomes available.

DP architecture

DP is a platform for managing Kubernetes clusters in various infrastructures — from isolated server environments to public clouds. The platform includes:

- A Kubernetes cluster.
- The Deckhouse controller and the modules it manages.
- Bashible, an agent running as a service on cluster nodes that executes bash scripts to manage nodes.

Modules are grouped into subsystems according to their functional purpose. The Deckhouse controller is also implemented as a module and is the only mandatory module required for the platform to function.

The DP architecture at the subsystem and module level is described in the C4 model subsection.

Modules

A module is a set of resources and applications designed to extend DP functionality.

Key modules:

- `deckhouse`: The Deckhouse controller.
- `control-plane-manager`: Manages cluster control plane components.
- `node-manager`: Manages cluster nodes.

> The `control-plane-manager` and `node-manager` modules are not installed when DP is installed into an existing Managed Kubernetes cluster.

Module contents:

- Helm charts
- Addon-operator hooks
- Build rules for module components (Deckhouse components)

- Other related files

DP uses the addon-operator project to manage modules. Refer to its documentation to learn how DP works with modules, module hooks, and module parameters.

For more information about module architecture and developing custom modules, refer to Modules.

Additional resources

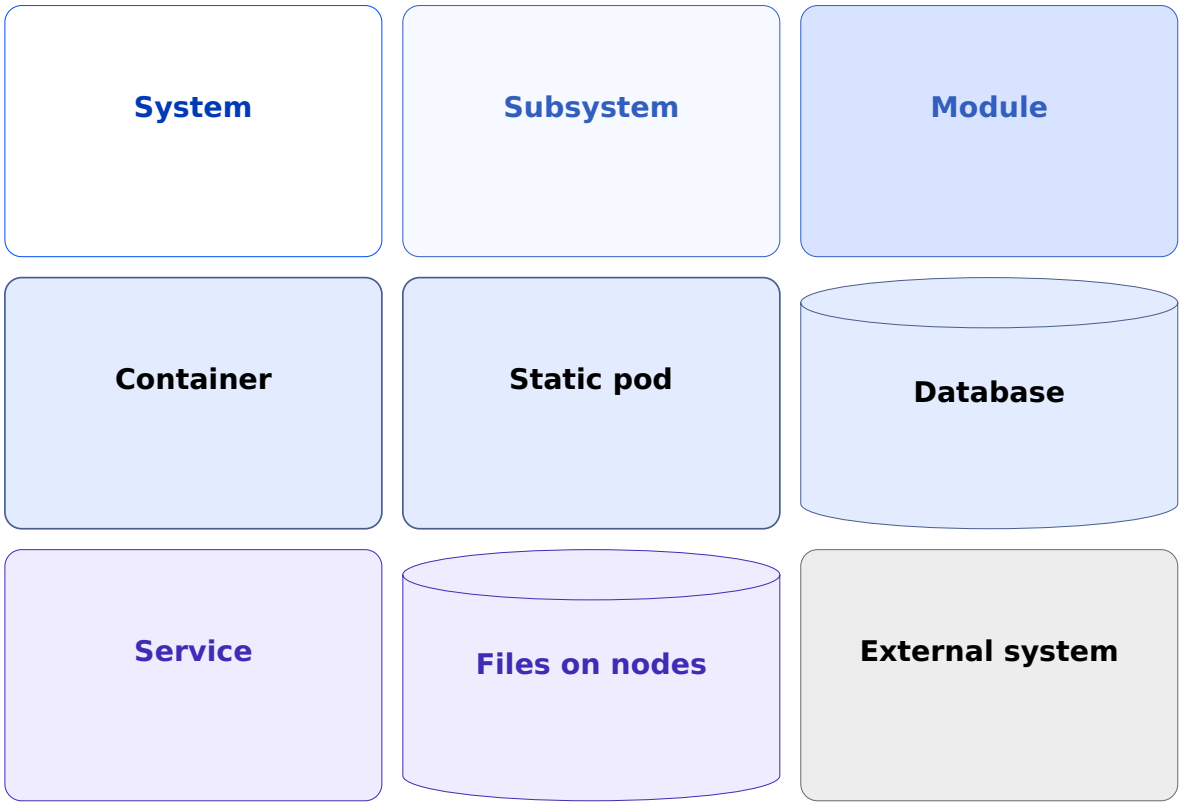
DP architecture (C4 model)

The C4 model is used to visually represent a system's architecture and explain how it is decomposed into elements. Diagrams in this model are organized according to increasing levels of scale and detail:

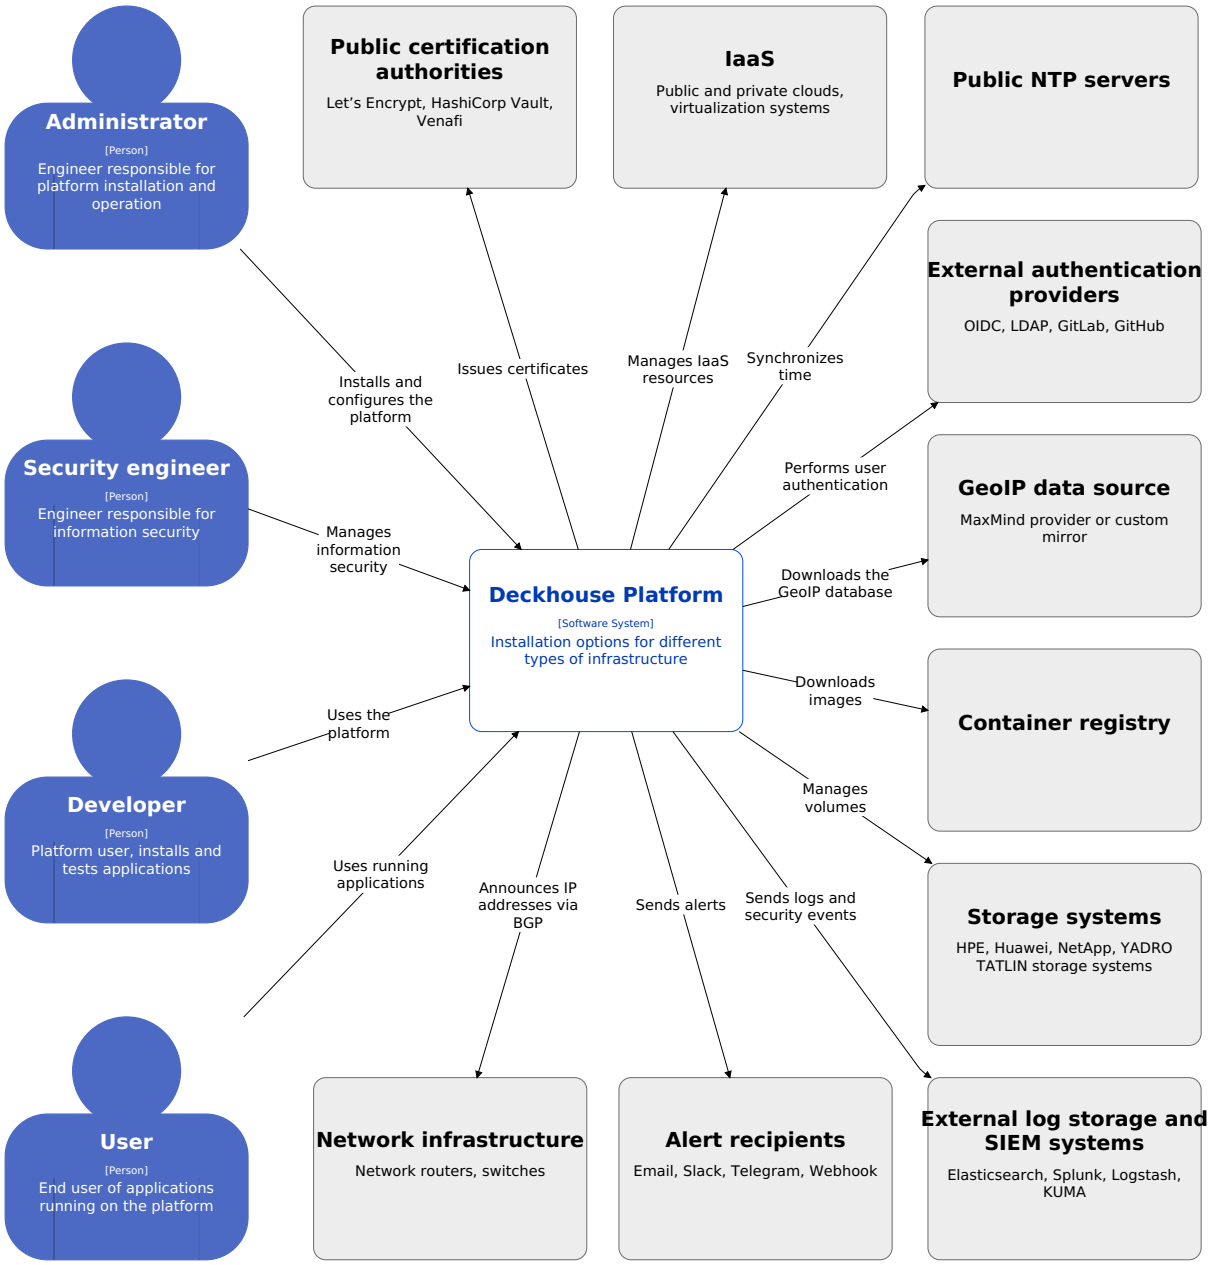
- **Level 1: Context diagram.** Shows the system within its external context: user roles and other systems that directly interact with it.
- **Level 2: Container diagram.** Breaks the system down into containers (major subsystems) and shows the main interaction paths between them. In the C4 model, a container (not to be confused with Docker containers) is an executable and deployable subsystem, such as an executable file.
- **Level 3: Component diagram.** Breaks each container down into components and shows interactions between components (within a single container) and with other containers. In the C4 model, a component is a software module (subsystem) within the container's codebase. This level is described in the architectural diagrams of individual services.
- **Level 4: Code diagram.** Describes the code elements that implement the components.

Due to the large number of elements at Level 2, the complete container diagram is not shown here. Instead, the following intermediate diagrams are provided after the Level 1 diagram:



- Subsystem diagram
- Module diagram

Level 2 and higher diagrams are provided in the sections describing the architecture of individual modules.



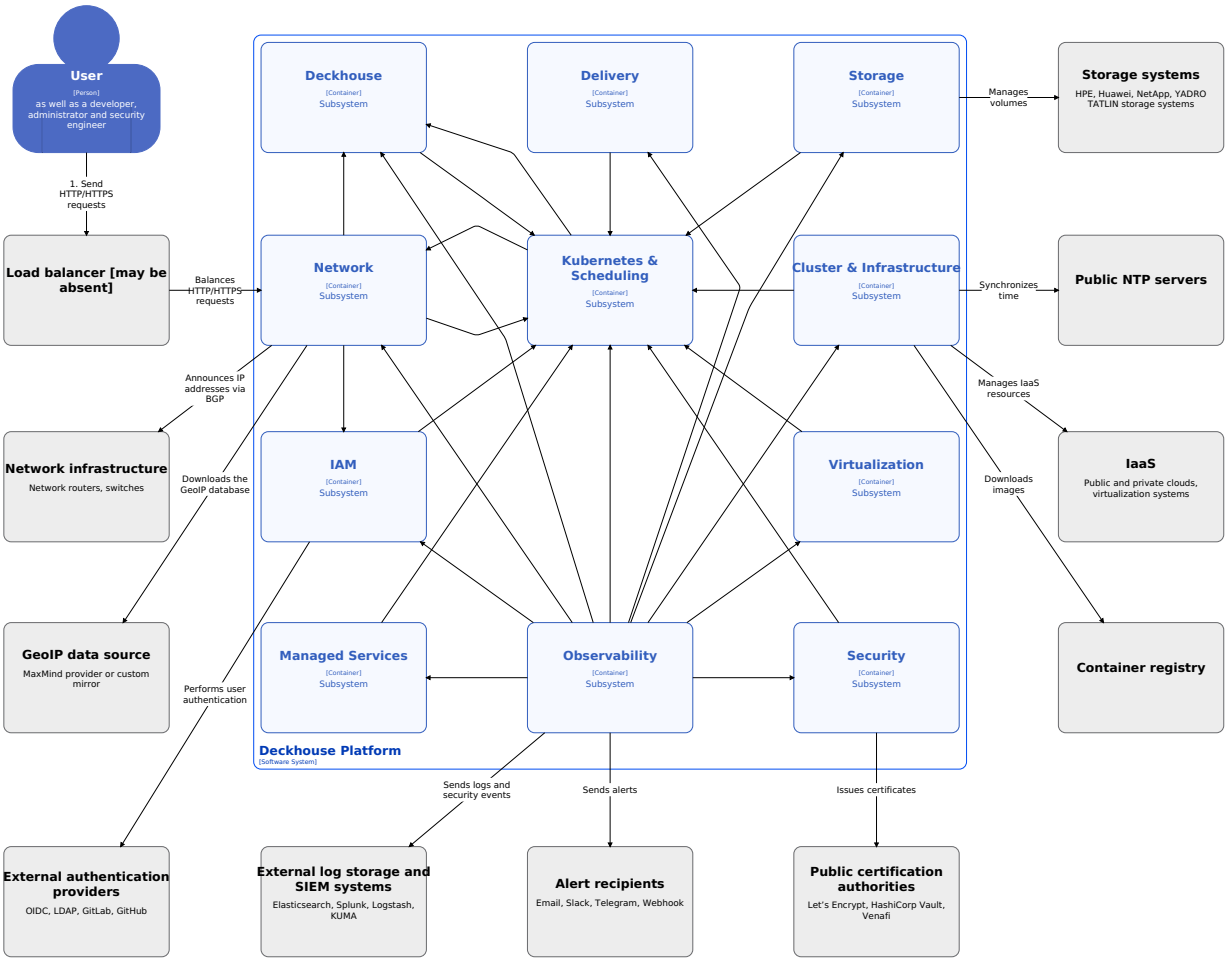
To get a general understanding of the Deckhouse Platform (DP) architecture, it is sufficient to review the Level 1 diagram as well as the subsystem and module diagrams. For a detailed view of individual services, refer to the Level 2 and higher diagrams available in the relevant sections.

Legend

The following graphical symbols are used in the diagrams:

Context diagram

The following roles interact with DP:

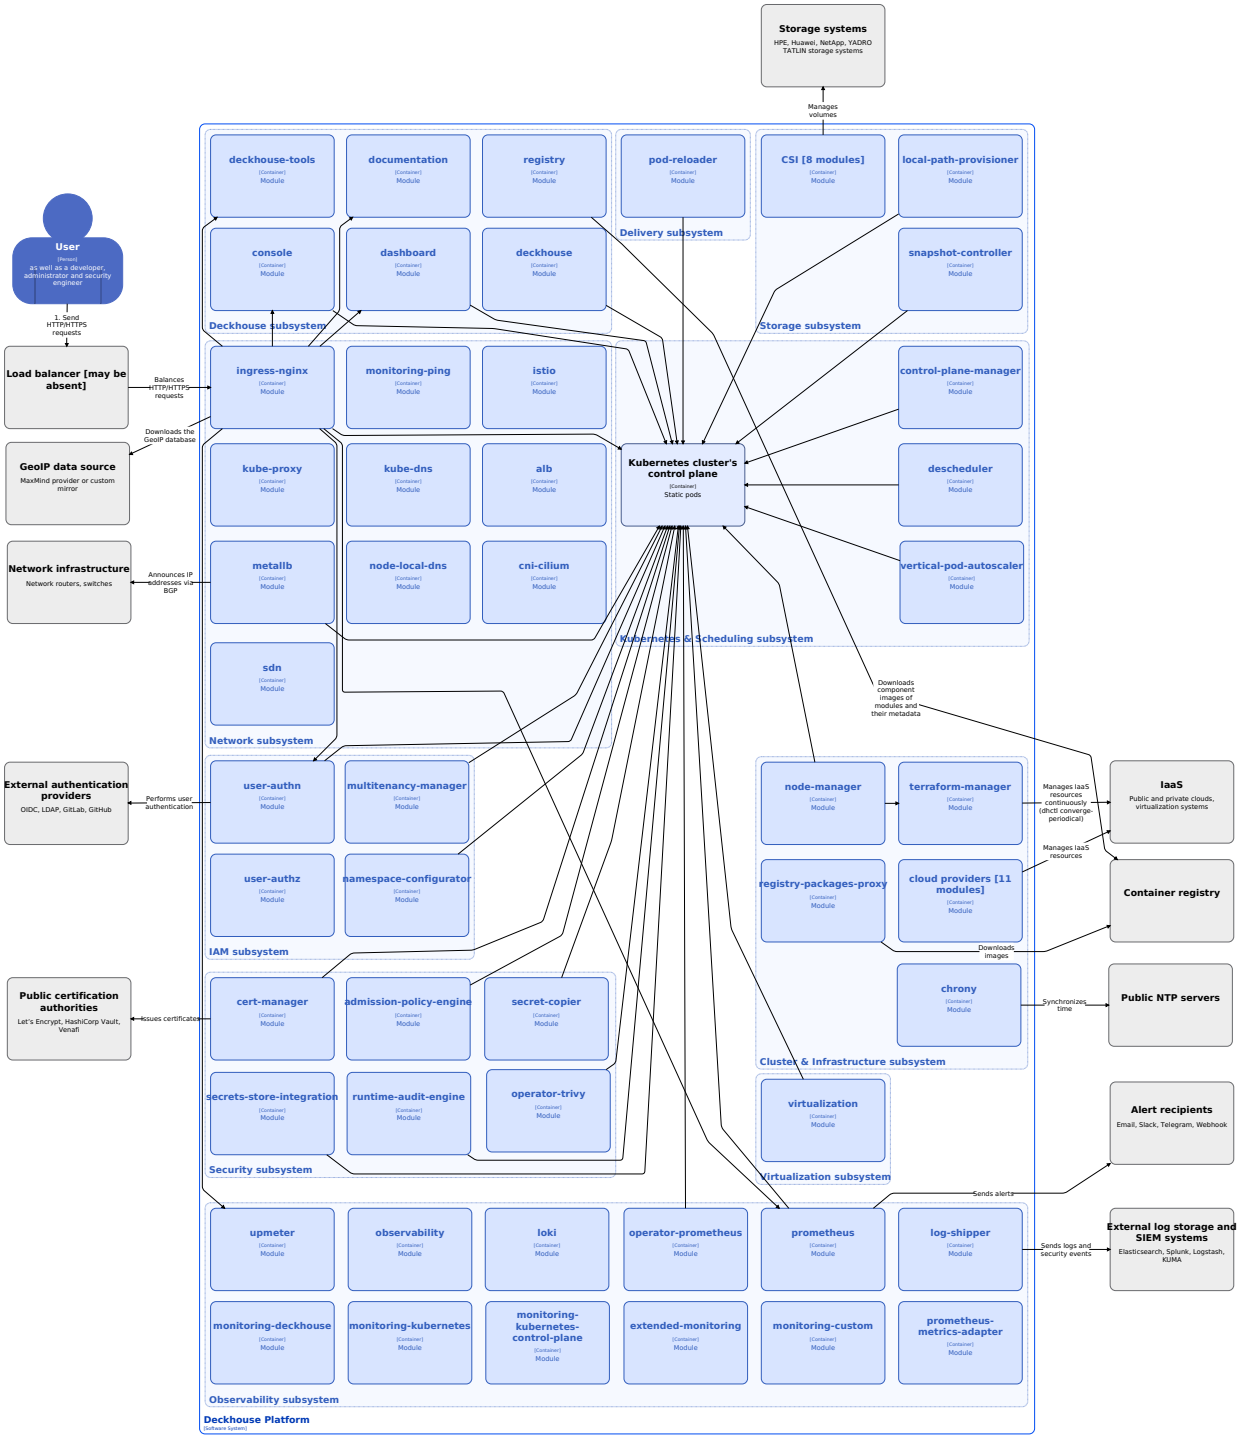


- **Administrator**: Installs and configures the platform.
- **Security Engineer**: Manages information security.
- **Developer**: Uses the platform to deploy and test applications under development.
- **User**: Uses applications running on the platform.

Interactions with external services are described in the diagrams of subsequent levels.

Subsystem diagram

The diagram below shows the DP subsystems.



> **i** Relationships between subsystems are shown in a generalized form and without detailed interactions.

Module diagram

The diagram below shows all modules included in the Default module bundle, as well as the most important additional modules. Modules are grouped by subsystem.

> **i** Relationships between modules are shown in a generalized form and without detailed interactions.

Deckhouse Platform module development

A module is a set of resources and applications designed to extend the functionality of the Deckhouse Platform.

This section is dedicated to the architecture of DP modules. It will help you understand how modules are structured, how to develop and debug them, and how they interact with other components of the

platform.

Deckhouse Platform (DP) can work with the following types of modules:

- Built-in modules. These are included in DP. Their release cycle is tied to the DP release cycle.
- Modules from module source. The release cycle for these modules is not tied to the DP release cycle.

Creating a module consists of the following stages:

- **Development**: creating module code and its structure in the Git repository. The **Module structure** section outlines which components there are and in which directories they are located.
- **Building**: creating a module artifact and pushing it to the container registry. The **Building and publishing** section describes where images are stored in the registry and at what paths they are available.
- **Running in a cluster**: delivering the module to a cluster managed by the DP. The **Running in a cluster** section describes how to activate the module, configure its parameters, and test its functionality (including handling CRDs and troubleshooting).
- **Dependencies**: configuring module dependencies, including DP versions, Kubernetes, and other critical components. This stage is covered in the **Module dependencies** section.

Requirements

You will need the following tools to develop DP modules:

- git — version control system;
- sed — stream editor;
- yq — CLI tool for processing data in JSON, YAML, and XML formats;
- jq — CLI tool for processing data in JSON, YAML, and XML formats;
- werf — (optional) CLI tool for building images. You will need it for building module artifacts locally;
- crane — (optional) CLI tool for working with the container registry. You may need it when debugging.

The container registry where module artifacts will be stored must support a nested repository structure. A registry such as Docker Registry v2 or Harbor is a good choice.

Before you start

To get an idea of how DP modules work, check out addon-operator and shell-operator.

- Review the operator documentation on the concept of hooks, e.g., what a hook configuration is and what functions it provides. The configuration is used to configure the data that will be available from the hook.
- Check out bindings. Bindings are events that trigger the hook. They are specified in the hook configuration. A hook can be triggered not only by Kubernetes events, but also, e.g., on a schedule or before a module is started.

  > **i** The Hook allows you to keep values in memory and use them later when rendering Helm templates. We recommend reading the Hooks and Helm values section to learn more about this feature as well as the module's operating cycle.

- Explore the concept of snapshots. With snapshots, you can implement a reconciliation loop approach that is more efficient than event subscription.

  > **i** This is how DP implements support for all existing backend module hooks.

- Additionally, hooks can be used instead of the Prometheus exporter. Hooks can provide metrics that DP will export. See metrics.

Got a question?

The Development and debugging section contains information about what tools can be used in module development and approaches to troubleshooting module errors.

Join the community, where you'll be sure to have your questions answered.

Module structure

The source code of the module and its assembly rules must be located in a directory with a certain structure. The best analog is a Helm chart.

Not all module folders and files are required. In short, you can use the following guidelines:

- Create a module.yaml file to describe the module metadata.
- In the templates folder, place the Helm templates that will be used in the cluster.

  If you want the objects created by the module to change their behavior depending on any module parameters, define the necessary parameters in the specification and use them in the templates.
- In the images folder, place instructions for building container images used by the module.

  If the templates only use addresses of *external* images, you don’t need to create a folder.
- If the module should respond to events or interact with the Kubernetes API, you need to create hooks that should be placed in the hooks folder.
- Place the module documentation in the docs folder. If the module documentation is missing, the module will not appear in the list of modules in the documentation web interface in the cluster.
- If the module has auxiliary Helm charts, place them in the charts folder.
- If the module needs to create custom resources (CRD), place their specifications in the crds folder.

There is a repository containing the sample module template. We recommend you start your module development with it.

Further down this page you will find a more detailed description of the module directory and file structure.

charts

The `/charts` directory contains Helm helper charts used when rendering templates.

Deckhouse Platform (DP) has its own library for working with templates called lib-helm. You can read about the library's features in the lib-helm repository. To add the library to the module, download the tgz-archive with the appropriate release and move it to the `/charts` directory of the module.

crds

This directory contains *CustomResourceDefinitions* (CRDs) used by the module components. CRDs are

updated every time the module is started, if there are updates.

Nested directories in the `/crds` folder are ignored.

> **i** If your module's resources have fields that reference cluster-wide resources (such as a StorageClass, ClusterIssuer, or ClusterRole), consider registering such fields using a GrantableClusterResourceReference. In this case, the specified cluster-wide resources will be validated per-project and can use the default value assignment. For details, refer to the `multitenancy-manager` documentation.

To render CRDs from the `/crds` directory in the site documentation or documentation module in the cluster, follow these steps:

- Create a translation file with a structure identical to the original resource file:
  - in it, keep only the `description` parameters containing the translation text;
  - use the `doc-ru-` prefix in the name: e.g., `/crds/doc-ru-crd.yaml` for `/crds/crd.yaml`.
- Create `/docs/CR.md` and `/docs/CR.ru.md` files.

docs

> **i** The module lifecycle is specified in module.yaml. The availability of the module in the editions of the Deckhouse Platform is not determined by the module developer.

The `/docs` directory contains the module documentation. The following nested directories aren't involved in the documentation building process:

- `internal`
- `internals`
- `development`
- `dev`

The following files are required for building the documentation:

- `README.md` and `README.ru.md` — this file (and its localized version) describes what the module is for, what problem it solves and outlines the general architectural principles.

  The (front matter) file metadata as a YAML structure must present in all language versions of the file. You can use the following parameters in the metadata:

  - `title` — **(recommended)** The title of the module description page, for example, "Deckhouse web admin console". It is also used in navigation if `linkTitle` parameter is not specified.
  - `menuTitle` — **(recommended)** The name of the module to show in the menu on the left sidebar of the page, e.g., "Deckhouse Admin". If not set, the name of the directory or repository is used, e.g. `deckhouse-admin`.
  - `linkTitle` — **(optional)** Alternative title for navigation if, for example, the `title` is very long. If not set, the `title` parameter is used.
  - `description` — **(recommended)** A short unique description of the page content (up to 150 characters). It should not repeat the `title`. Goes on with the meaning of the title and reveals it in more detail. It is used during generation of preview links and indexing by search engines, e.g., "The module allows you to fully manage your Kubernetes cluster through a web interface with only mouse skills."

  ▼ **Metadata example...**

  ```
  ---
  title: "Deckhouse administrator web console"
  menuTitle: "Deckhouse Admin"
  description: "The module allows you to fully manage your Kubernetes cluster through a web interface with
  only mouse skills."
  ---
  ```

The following files aren't required but have a predetermined name in the sidebar menu and the page title:

- `EXAMPLES.md` and `EXAMPLES.ru.md` — this file (and its localized version) contains examples of module configuration with description.

  The (front matter) file metadata as a YAML structure must present in all language versions of the file. You can use the following parameters in the metadata:

  - `title` – **(recommended)** The title of the page, e.g., `Examples`. It is also used in navigation if there is no `linkTitle`.
  - `description` – **(recommended)** A short unique description of the page content (up to 150 characters). It should not repeat the `title`. Goes on with the meaning of the title and reveals it in more detail. It is used during generation of preview links and indexing by search engines, e.g.,

“Examples of storing secrets in a neural network and automatically substituting them into thoughts when communicating.”
  - `linkTitle` – **(optional)** Alternative title for navigation if, for example, the `title` is very long. If not set, the `title` parameter is used.

▼ **Metadata example...**

```
---
title: "Examples"
description: "Examples of storing secrets in a neural network with automatic substitution into thoughts
when communicating."
---
```

- `FAQ.md` and `FAQ.ru.md` — this file (and its localized version) contains frequently asked questions related to module operation, e.g., “What scenario should I choose: A or B?”.

  The (front matter) file metadata as a YAML structure must present in all language versions of the file. You can use the following parameters in the metadata:

  - `title` – **(recommended)** The title of the page.
  - `description` – **(recommended)** A short unique description of the page content (up to 150 characters).
  - `linkTitle` – **(optional)** Alternative title for navigation if, for example, the `title` is very long. If not set, the `title` parameter is used.

  ▼ **Metadata example...**

  ```
  ---
  title: "FAQs"
  description: "Frequently asked questions."
  ---
  ```

- `ADVANCED_USAGE.md` and `ADVANCED_USAGE.ru.md` — this file (and its localized version) contains expanded instructions on using and debugging the module.

  The (front matter) file metadata as a YAML structure must present in all language versions of the file. You can use the following parameters in the metadata:

  - `title` – **(recommended)** The title of the page.
  - `description` – **(recommended)** A short unique description of the page content (up to 150 characters).
  - `linkTitle` – **(optional)** Alternative title for navigation if, for example, the `title` is very long. If not set, the `title` parameter is used.

  ▼ **Metadata example...**

  ```
  ---
  title: "Module debugging"
  description: "This section covers all the steps for debugging the module."
  ---
  ```

- `CR.md` and `CR.ru.md` — the files for generating resources from the `/crds/` directory. Add these files if such a generation is required.

  ▼ **Metadata example...**

  ```
  ---
  title: "Custom resources"
  ---
  ```

- `CONFIGURATION.md` and `CONFIGURATION.ru.md` — this file (and its localized version) is used to generate OpenAPI specifications from `/openapi/config-values.yaml` and `/openapi/doc-<LANG>-config-values.yaml`. Add these files if such a generation is required.

  ▼ **Metadata example...**

  ```
  ---
  title: "Module settings"
  ---
  ```

All images, PDF files and other media files should be stored in the `/docs` directory or its subdirectories (e.g, `/docs/images/`). All links to files should be relative.

You need a file with the appropriate suffix for each language, for example `image1.jpg` and `image1.ru.jpg`. Use the following links:

- `[image1](image1.jpg)` in an English-language document;
- `[image1](image1.ru.jpg)` in a Russian-language document.

hooks

The `/hooks/batch` directory contains the module's hooks. A hook is an executable file executed in response to an event. Hooks are also used by the module for dynamic interaction with Kubernetes API. For example, they can be used to handle events related to the creation or deletion of objects in a cluster.

Get to know the concept of hooks before you start developing your own hook. You can use the Go library by the Deckhouse team to speed up the development of hooks.

Hook requirements:

- When run with the `hook config` arguments, it should output its hook configuration in JSON format.
- When run with the `hook list` arguments, it should output a run of all hooks with their sequence number.
- When run with the `hook run 0` arguments, the logic of the hook with number 0 should be executed.

The hook files must be executable. Add the appropriate permissions using the `chmod +x <path to the hook file>` command.

You can find Go hook examples in the module template repository. Go hook examples can also be found in the SDK.

images

The `/images` directory contains instructions for building module container images. The first level contains directories for files used to create the container image, the second level contains the building context.

There are two ways to define a container image:

1. Dockerfile — this file contains commands for building images. To build an application from source code, copy it next to the Dockerfile and include it in the image using the `COPY` command.
2. The `werf.inc.yaml` file, which is the same as the image definition section in `werf.yaml`.

The image name matches the directory name for this module, written in *camelCase* notation starting with a small letter. For example, the directory `/images/echo-server` corresponds to the image name `echoServer`.

The built images have content-based tags that can be used when building other images. To use content-based image tags, enable the lib-helm library. You can also use other features of the helm_lib library of Deckhouse Platform.

Below is an example of using a content-based image tag in a Helm chart:

```
image: {{ include "helm_lib_module_image" (list . "<image name>") }}
```

openapi

conversions

The `/openapi/conversions` directory contains module parameter conversion files and their tests.

Module parameter conversions allow you to convert the OpenAPI specification of module parameters from one version to another. Conversions may be necessary when a parameter is renamed or moved to a different location in a new version of the OpenAPI specification.

Each conversion can only be performed between two consecutive versions (e.g., from the first to the second one). There can be several conversions, and the chain of conversions must sequentially cover all versions of the parameter specification with no "gaps".

The conversion file is a YAML file named `v<N>.yaml` or `v<N>.yml`, where `<N>` is the conversion version. It has the following structure:

```
# Version number of the module parameter specification to which the data is converted
during the conversion.
version: N
# A set of jq expressions used during conversion in the cluster for the automatic
transformation
# of the previous version module parameters.
conversions: []
# Actions (in two languages) that need to be taken to convert the data
# from the previous version of the module parameter specification.
description:
  ru: ""
  en: ""
```

The description of actions specified in the description section of the conversion file must be clear and include information on which parameters and in what order need to be changed in the module's parameter specification in order to switch to the new version.

Below is an example of a module parameter conversion file `v2.yaml`, where in version 2 the `.auth.password` parameter has been removed:

```
version: 2
conversions:
  - del(.auth.password) | if .auth == {} then del(.auth) end
description:
  ru: "Remove `.auth.password`, then `auth` if empty."
  en: "Remove `.auth.password`, then `auth` if empty."
```

Conversion tests

You can use the `conversion.TestConvert` function to write conversion tests. It receives the following parameters:

- Path to the source configuration file (i.e., the version before the conversion);
- Path to the resulting configuration file (i.e., the version after the conversion).

An example of a conversion test.

config-values.yaml

This file is required to validate the module parameters that the user can configure via ModuleConfig.

To render the schema in the documentation on the site or in the documentation module in the cluster, create:

- The `doc-ru-config-values.yaml` file with a structure similar to that of the `config-values.yaml` file. Keep only the translated description parameters in the `doc-ru-config-values.yaml` file;
- The `/docs/CONFIGURATION.md` and `/docs/CONFIGURATION.ru.md` files to enable rendering of data from the `/openapi/config-values.yaml` and `/openapi/doc-ru-config-values.yaml` files.

An example of a `/openapi/config-values.yaml` schema with a single configurable `nodeSelector` parameter:

```
type: object
properties:
  nodeSelector:
    type: object
    additionalProperties:
      type: string
    description: |
      The same as the Pods' `spec.nodeSelector` parameter in Kubernetes.

      If the parameter is omitted or `false`, `nodeSelector` will be determined
      automatically.</code>
```

An example of the `/openapi/doc-ru-config-values.yaml` file:

```
properties:
  nodeSelector:
    description: |
      English description. Markdown markup.</code>
```

Validations with x-deckhouse-validations

When developing a module for the Deckhouse Platform, you can use the OpenAPI extension `x-deckhouse-validations` to describe complex validation rules for module parameters using Common Expression Language (`CEL`).

When using these validation rules, keep the following features in mind:

- Validations can be placed at the root level or inside any property (including inside objects, arrays, and additionalProperties).
- All parameters at the current level are available in expressions via the `self` variable.
- The previous value at the same level is available in expressions via the `oldSelf` variable. Rules that

reference `oldSelf` are treated as transition rules and are evaluated only on updates (when a previous value exists at this level); on the initial create or for newly added subtrees they are silently skipped. This is the same model as `x-kubernetes-validations`.
- Validation works recursively: all nested objects, arrays, and maps can also contain their own `x-deckhouse-validations`.
- Supported types: scalars, arrays, objects, and maps (`additionalProperties`).
- If there are multiple validation errors, the user will see all messages from the corresponding rules.

Examples of rules

Below are examples of complex validation rules described in CEL:

- Checking whether the parameter value falls within the range:

```
type: object
properties:
  replicas:
    type: integer
  minReplicas:
    type: integer
  maxReplicas:
    type: integer
x-deckhouse-validations:
  - expression: "self.minReplicas <= self.replicas && self.replicas <=
self.maxReplicas"
    message: "replicas must be between minReplicas and maxReplicas"
```

- Checking for the presence of a key:

```
- expression: "'Available' in self.stateCounts"
  message: "The key 'Available' must be present"
```

- Checking that exactly one of two lists is non-empty:

```
- expression: "(self.list1.size() == 0) != (self.list2.size() == 0)"
  message: "Exactly one of the lists must be non-empty"
```

- Checking a value by regular expression:

```
- expression: "self.details.all(key, self.details[key].matches('^[a-zA-Z]*$'))"
  message: "All values must contain only letters"
```

- Marking a field as immutable using the `oldSelf` variable (transition rule):

```
type: object
properties:
  clusterDomain:
    type: string
x-deckhouse-validations:
  - expression: "self.clusterDomain == oldSelf.clusterDomain"
    message: "clusterDomain is immutable"
```

  The rule is only evaluated on updates: on the initial create (when there is no previous value) it is automatically skipped, just like a transition rule in `x-kubernetes-validations`.

- Allowing a list to only grow (each existing item must be preserved on update):

```
- expression: "oldSelf.items.all(x, x in self.items)"
  message: "items can only be appended to, not removed"
```

Scalar and array value validation

Validation of scalar values and arrays has the following features:

- If the property is a scalar (e.g., number or string), then in the `CEL` expression the `self` variable will be

that value.
- If the property is an array, then `self` will be an array, and you can use methods like `.size()`, `.all()`, `.exists()`, etc.

Example for an array:

```
type: object
properties:
  items:
    type: array
    items:
      type: string
    x-deckhouse-validations:
      - expression: "self.size() > 0"
        message: "The items list must not be empty"
```

Validation of additionalProperties (map)

For objects with additionalProperties (map), you can validate keys and values using methods like `.all(key, ...)`, `.exists(key, ...)`, etc.

Example:

```
type: object
properties:
  mymap:
    type: object
    additionalProperties:
      type: integer
    x-deckhouse-validations:
      - expression: "self.all(key, self[key] > 0)"
        message: "All values in mymap must be greater than 0"
```

values.yaml

This file is required for validating the source data when rendering templates without using extra Helm chart functions. Its closest analogs are Helm's schema files.

You can automatically add parameter validation from `config-values.yaml` to `values.yaml`. In this case, the basic `values.yaml` looks as follows:

```
x-extend:
  schema: config-values.yaml
type: object
properties:
  internal:
    type: object
    default: {}
```

templates

The `/templates` directory contains Helm templates.

- Use the path `.Values.<moduleName>` to access module settings in templates, and `.Values.global` for global settings. The module name is converted to `camelCase` notation.
- To facilitate working with templates, use lib-helm, which is a set of extra functions that make it easier to work with global and module values.
- Accesses to the registry from the ModuleSource resource are available at the `.Values.<moduleName>.registry.dockercfg` path.
- To use these functions to pull image pools in controllers, create a secret and add it to the corresponding parameter: `"imagePullSecrets": [{"name":"registry-creds"}]`.

```
apiVersion: v1
kind: Secret
metadata:
  name: registry-creds
type: kubernetes.io/dockerconfigjson
data:
  .dockerconfigjson: {{ .Values.<moduleName>.registry.dockercfg }}
```

A module can have parameters with which it can alter its behavior. Module parameters and their validation scheme are described in OpenAPI-schemes in `/openapi` directory.

The settings are stored in two files: `config-values.yaml` and `values.yaml`.

You can find an example of an OpenAPI schema in module template.

.helmignore

`.helmignore` allows you to exclude files from the Helm release. In case of DP modules, directories `/crds`, `/images`, `/hooks`, `/openapi` must be added to `.helmignore` to avoid exceeding 1 Mb limit of Helm release size.

Chart.yaml

This is a file for a chart, similar to `Chart.yaml` in Helm. It must contain at least a `name` parameter with the module name and a `version` parameter with the version. You don’t need to create this file, Deckhouse will create it automatically.

An example:

```
name: echoserver
version: 0.0.1
dependencies:
- name: deckhouse_lib_helm
  version: 1.38.0
  repository: https://deckhouse.github.io/lib-helm
```

module.yaml

The `module.yaml` file in the root of the module folder contains the module’s metadata.

The file might not be present, but it is recommended to fill it in. Most of the metadata will be available in the Module object in the cluster. The Module object will be created automatically after the module source (resource ModuleSource) is configured and synchronization is successful.

Parameters that can be used in `module.yaml`:

Parameter	Type	Description
`namespace`	String	Namespace where the module components will be deployed
`subsystems`	Array of strings	List of subsystems the module belongs to
`accessibility`	Object	Module accessibility settings
`accessibility.editions`	Object	Module operation settings in DP editions
`accessibility.editions.available`	Boolean	Defines whether the module is available in a DP edition
`accessibility.editions.enabledInBundles`	Array of strings	List of module bundles in which the module should be enabled by default
`descriptions`	Object	Arbitrary text description of the module’s purpose
`descriptions.en`	String	Description in English
`descriptions.ru`	String	Description in Russian

Parameter	Type	Description
`disable`	Object	Parameters related to the behavior when disabling a module
`disable.confirmation`	Boolean	Requires confirmation when disabling the module
`disable.message`	String	Message explaining what will happen when the module is disabled

If confirmation is required to disable a module (`confirmation` is set to `true`), then disabling the module is only possible if the corresponding ModuleConfig object has the annotation `modules.deckhouse.io/allow-disabling=true`. If this annotation is not present, Deckhouse will block the disabling attempt and display the warning message from the `message` field.

Other `module.yaml` parameters:

Parameter	Type	Description
`name`	String, mandatory parameter	Name of the module in Kebab Case. For example, `echo-server`
`exclusiveGroup`	String	If several modules share the same value of this parameter, only one of them can be active in the system at any given time. This prevents conflicts between modules performing similar or incompatible functions
`requirements`	Object	Module dependencies — a set of conditions that must be met for Deckhouse Platform (DP) to run the module
`requirements.deckhouse`	String	Dependency on the Deckhouse Platform version that the module is compatible with
`requirements.kubernetes`	String	Dependency on the Kubernetes version that the module is compatible with
`requirements.modules`	Object	Dependency on the version of other modules
`stage`	String	Module lifecycle stage. Possible values: `Experimental`, `Preview`, `General Availability`, `Deprecated`. If `stage` is set to `Experimental`, the module cannot be enabled by default. To allow the use of such modules, set the corresponding parameter to `true`
`tags`	Array of strings	Additional module tags. Tags are converted to labels of the Module object using the template `module.deckhouse.io/<TAG>=""`. For example, if you specify two tags `test` and `example`, the Module object will get the labels `module.deckhouse.io/test=""` and `module.deckhouse.io/example=""`
`weight`	Number	Module weight. Affects the module startup order: modules with a lower `weight` start earlier. Default: `900`. The startup order is also affected by module dependencies

Parameter	Type	Description
`critical`	Boolean	Marks the module as critical for the initial cluster bootstrap. Such modules (if used in the cluster) start during the initial cluster boot, before the cluster is considered fully ready. Other modules (non-critical) start only after the cluster is fully ready. Default: `false`

Example of metadata description for the `hello-world` module:

```
name: hello-world
tags: ["test", "myTag"]
weight: 960
stage: "Experimental"
namespace: "test"
exclusiveGroup: "group"
subsystems:
  - test
  - test1
accessibility:
  editions:
    ee:
      available: true
      enabledInBundles:
        - Default
descriptions:
  en: "The module to say hello to the world."
  ru: "Модуль, который приветствует мир."
requirements:
  deckhouse: ">= 1.61"
  kubernetes: ">= 1.27"
disable:
  confirmation: true
  message: "Disabling this module will delete all resources created by the module."
```

Configuring module accessibility in DP editions

The `accessibility` parameter lets you define the DP editions and module bundles in which a module is available, and whether it should be enabled by default.

```
accessibility:
  editions:
    _default:
      available: true
      enabledInBundles:
        - Default
        - Managed
    ce:
      available: false
    ee:
      available: true
      enabledInBundles:
        - Managed
```

Parameter description:

- `accessibility`: *Object.* Root block for configuring module accessibility.
- `editions`: *Object.* Set of keys representing edition names. Each edition can have its own accessibility settings.
- `_default`: *Object.* Default configuration used when no settings are defined for a specific edition.
- `available`: *Boolean.* Defines whether the module is available in the specified edition.
- `enabledInBundles`: *Array of strings.* Module bundles in which the module is enabled by default. Supported module bundles (the full contents of each bundle are listed on this page):

  - `Default`: Recommended set of modules for running a cluster. Includes monitoring, authorization control, networking, and other essential components.
  - `Managed`: Set of modules for clusters managed by cloud providers (for example, Google Kubernetes Engine).
  - `Minimal`: Minimal set that includes only the current module.

    > ⚠ Note that basic modules (such as the CNI module) are not included in this set. Without basic modules, DP can only operate in an already deployed cluster. The list of modules that must be enabled manually during installation is given in “Things to keep in mind when working with the Minimal module set”.

- Sections containing edition names. Define module behavior in specified editions. Possible values: `be`, `ce`, `ee`, `se`, `se-plus`.

Module accessibility logic

The following diagram illustrates the logic for determining module accessibility and whether it is enabled by default:

Configuration examples

In the following example, the module will be unavailable in all editions except DP Enterprise Edition. In DP Enterprise Edition, the module will be enabled by default in the `Managed` bundle.

```
accessibility:
  editions:
    _default:
      available: false
    ee:
      available: true
      enabledInBundles:
        - Managed
```

In the next example, the module will be available in all DP editions. In the `Managed` and `Default` bundles, the module will be enabled by default.

```
accessibility:
  editions:
    _default:
      available: true
      enabledInBundles:
        - Managed
        - Default
```

In the following example, the module will be available in all DP editions. It will be enabled in the `Default` and `Managed` bundles for all editions, except for DP Basic Edition and DP Community Edition.

```
accessibility:
  editions:
    _default:
      available: true
      enabledInBundles:
        - Default
        - Managed
    be:
      available: false
    ce:
      available: false
```

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Build and publish

Deckhouse Platform (DP) uses container registry to pull a module and update it. The container registry stores module artifacts. Module artifacts are created when a module is built and can then be uploaded (published) to the registry.

Types of module artifacts

Module builds create three types of artifacts that are pushed to the container registry:

- **Images of application containers**. The build rules and source code for these images are stored in the images subdirectory of the *application name* directory. The built images are then specified in the templates and run in the cluster. Images are tagged with the content-based tags. Note that the lib-helm library must be enabled to use them in the templates.
- **Module image**. The module assembly rules are in the `werf.yaml` file in the module directory. The semantic versioning is used as image tags.
- **Release**. Module version artifact. Based on the release data, DP decides whether to update a module in the cluster. Releases have two types of tags: a semantic versioning tag (just like with the module image) and a tag that matches the release channel (e.g., `alpha`, `beta`, etc.). In the module template there is an example of workfklow for GitHub Actions, where the release is created automatically during building.

Building module artifacts and publishing them to the container registry

We suggest using the pre-compiled GitHub Actions to build module artifacts and upload them to the container registry as part of the CI/CD process.

The module template repository provides an example module. It contains a basic workflow for GitHub Actions and uses GitHub Packages (ghcr.io) as the container registry. The example workflow follows the logic outlined below:

- Build module artifacts when changes are made to the PR and when changes are merged into the main branch.
- Build module artifacts from tags using the production container registry.
- Publish module to GitHub Packages container registry to the selected release channel from a tag.

Module artifacts will be uploaded to `ghcr.io/<OWNER>/modules/`, which will serve as module source.

For the module workflow to run smoothly, adjust the properties of your project on GitHub as follows:

- Open the *Settings -> Actions -> General* page.
- Enable the *Read and write permissions* parameter in the *Workflow permissions* section.

You can also modify the workflow, use your own container registry, and design a more complex build and publish process (e.g., use separate container registries for development and production).

⚠ When developing **multiple modules** and publishing them to GitHub Packages, you should use your account's Personal Access Token (PAT).

Do not use `GITHUB_TOKEN` in GitHub Workflows. This way, you can avoid access rights issues when uploading images, as the final release images are stored at `ghcr.io/<OWNER>/modules/` — the address that belongs to the first repository created.

Here is how you can adapt a module template to use a PAT:

- On the *Settings -> Secrets and variables -> Actions* page create a Secret named `TOKEN` containing a PAT.
- Replace the `GITHUB_TOKEN` variable with `TOKEN` in `.github/workflows/`:

```
cd <REPO>
sed -i -e 's/GITHUB_TOKEN/TOKEN/g' $(find .github/workflows/ -type f)
```

i You can build module artifacts locally using werf (this may come in handy, for example, when debugging).

You can also set up a custom module artifact build and publish processes for your CI/CD system similar to the workflow for GitHub Actions provided in the module template. However, this may require an in-depth understanding of the module build and publish processes. Please contact the community should you have any questions or issues.

Here is a general scenario for using the workflow provided in the module template:

1. Publish the changes to the module code in the project branch on GitHub. This will trigger the module artifacts to be built and published to the container registry.
2. Create a new module release or add a tag in the semantic versioning format to the target commit.
3. Go to the *Actions* section of the module repository on GitHub and select *Deploy* in the workflow list on the left.
4. On the right side of the page, click on the *Run workflow* drop-down list, select the desired release channel, and enter the target tag in the tag input box. Click the *Run workflow* button.
5. Once the workflow is successfully executed, a new version of the module will be added to the container registry. The published version of the module can then be used in the cluster.

Additional resources

- Global custom resources

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

How to run and verify a module in the DP cluster

This section describes the process of running a module in a Deckhouse Platform (DP) cluster, as well as connecting Deckhouse Module Tools for setting up validation and metrics collection.

Run the module in the DP cluster

Follow these steps to run the module in a cluster:

- Define ModuleSource (the ModuleSource resource).
- *(optional)* Define the module update policy (the ModuleUpdatePolicy resource).
- Enable the module in the cluster (the ModuleConfig resource).

Module source

Deckhouse Platform (DP) can work with the following types of modules:

- Built-in modules. These are included in DP. Their release cycle is tied to the DP release cycle.

- Modules from module source. The release cycle for these modules is not tied to the DP release cycle.

Create a ModuleSource resource to set the source to fetch module information from. This resource will contain the address of the container registry to pull modules from, authentication parameters, and other settings.

An example of a ModuleSource resource:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleSource
metadata:
  name: example
spec:
  registry:
    repo: registry.example.com/deckhouse/modules
    dockerCfg: <base64 encoded credentials>
```

After the ModuleSource resource is created, DP will start to perform periodic data synchronization with the module source (fetching information about the modules available in the source). By default, synchronization runs every 30 minutes. To change the interval, use the `scanInterval` parameter.

Use the following command to check the synchronization status:

```
d8 k get ms
```

If the synchronization is successful, you will see output similar to the one below:

```
$ d8 k get ms
NAME        COUNT   SYNC   MSG
example     2       16s    Ready
```

If there are synchronization errors, the `MSG` column will contain a general description of the error, e.g.:

```
$ d8 k get ms
NAME        COUNT   SYNC   MSG
example     2       16s    Some errors occurred. Inspect status for details
```

Detailed error information can be found in the `pullError` field in the status of the ModuleSource resource.

For example, here's how you can get detailed error description from the `example` module source:

```
$ d8 k get ms example -o jsonpath='{range .status.modules[*]}{.name}{" module error:\n\t"}
{.pullError}{"\n"}{end}'
module-1 module error:
  fetch image error: GET https://registry.example.com/v2/deckhouse/modules/module-
1/release/manifests/stable: MANIFEST_UNKNOWN: manifest unknown; map[Tag:stable]
module-2 module error:
  fetch image error: GET https://registry.example.com/v2/deckhouse/modules/module-
2/release/manifests/stable: MANIFEST_UNKNOWN: manifest unknown; map[Tag:stable]
```

If synchronization is successful, the `.status.modules` field of the ModuleSource resource will contain a list of modules ready to be enabled in the cluster.

Here is an example of how you can get a list of modules available from the `example` module source:

```
$ d8 k get ms example -o jsonpath='{.status.modules[*].name}'
module-1 module-2
```

The complete list of modules available from all module sources created in the cluster can be retrieved using the following command:

```
d8 k get ms  -o jsonpath='{.items[*].status.modules[*].name}'
```

After creating the ModuleSource resource and successful synchronization, *modules* — Module resources should start appearing in the cluster (DP creates them automatically, you do not need to create them). You can view the list of modules using the following command:

```
d8 k get module
```

Example of getting a list of modules:

```
$ d8 k get module
NAME       STAGE    SOURCE   PHASE       ENABLED   READY
module-one                   Available   False     False
module-two                   Available   False     False
```

To get additional information about the module, use the following command:

```
d8 k get module module-one -oyaml
```

Example of output:

```
apiVersion: deckhouse.io/v1alpha1
kind: Module
metadata:
  creationTimestamp: "2024-12-12T10:49:40Z"
  generation: 1
  name: module-one
  resourceVersion: "241504954"
  uid: 3ae75474-8e96-4105-a939-6df71cba82d8
properties:
  availableSources:
  - example
status:
  conditions:
  - lastProbeTime: "2024-12-12T10:49:41Z"
    lastTransitionTime: "2024-12-12T10:49:41Z"
    message: disabled
    reason: Disabled
    status: "False"
    type: EnabledByModuleConfig
  - lastProbeTime: "2024-12-12T10:49:41Z"
    lastTransitionTime: "2024-12-12T10:49:41Z"
    status: "False"
    type: EnabledByModuleManager
  - lastProbeTime: "2024-12-16T15:46:26Z"
    lastTransitionTime: "2024-12-12T10:49:41Z"
    message: not installed
    reason: NotInstalled
    status: "False"
    type: IsReady
  phase: Available
```

You can find available sources from which the module can be downloaded in the Module (there is only one in the example).

Next, you need to enable the module. To do this, you need to create a ModuleConfig with the name of the module.

The parameter `enabled` in ModuleConfig is responsible for enabling the module. If the module is available from multiple sources (resource ModuleSource), the required source can be specified in the `source` parameter.

The update policy (the name of the ModuleUpdatePolicy) can be specified in the `updatePolicy` parameter. It is not necessary to specify the update policy; in this case, it will be inherited from the Deckhouse Platform update parameters (releaseChannel and update of the ModuleConfig `deckhouse`).

Example of ModuleConfig for enabling the module `module-one` from the source `example`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: module-one
spec:
  enabled: true
  source: example
```

⚠ If there are mandatory parameters in the module configuration and the module is enabled without specifying them, a configuration validation error will occur. In this case, the `D8DeckhouseModuleValidationError` alert will appear, and the module will not be successfully activated.

To get more details, use the following command:

```
d8 k get mr -l module=<MODULE_NAME>
```

Make sure to specify the required configuration parameters in `ModuleConfig` according to the module's documentation.

After turning on the module, it should enter the download phase:

```
$ d8 k get module module-one
NAME        STAGE    SOURCE   PHASE         ENABLED   READY
module-one           example  Downloading   False     False
```

⚠ If the module has not entered the download phase, check the module source (ModuleSource), as the module may not be able to download.

After a successful download, the module will enter the installation phase (`Installing`):

```
$ d8 k get module module-one
NAME        STAGE    SOURCE   PHASE         ENABLED   READY
module-one           example  Installing    False     False
```

If the module was successfully installed, it will enter the `Ready` phase:

```
$ d8 k get module module-one
NAME        STAGE    SOURCE   PHASE  ENABLED  READY
module-one           example  Ready  True     True
```

Example of a Module object in the cluster when the module has been successfully installed:

```
apiVersion: deckhouse.io/v1alpha1
kind: Module
metadata:
  creationTimestamp: "2024-11-18T15:34:15Z"
  generation: 1
  name: module-one
  resourceVersion: "242153004"
  uid: 7111cee7-50cd-4ecf-ba20-d691b13b0f59
properties:
  availableSources:
  - example
  releaseChannel: Stable
  requirements:
    deckhouse: '> v1.63.0'
    kubernetes: '> v1.25.0'
  source: example
  version: v0.7.24
  weight: 910
status:
  conditions:
  - lastProbeTime: "2024-12-12T15:49:35Z"
    lastTransitionTime: "2024-12-12T15:49:35Z"
    status: "True"
    type: EnabledByModuleConfig
  - lastProbeTime: "2024-12-17T09:35:27Z"
    lastTransitionTime: "2024-12-12T15:49:39Z"
    status: "True"
    type: EnabledByModuleManager
  - lastProbeTime: "2024-12-17T09:35:27Z"
    lastTransitionTime: "2024-12-17T09:35:25Z"
    status: "True"
    type: IsReady
  - lastProbeTime: "2024-12-17T09:32:50Z"
    lastTransitionTime: "2024-12-17T09:32:50Z"
    status: "False"
    type: IsOverridden
  hooksState: 'v0.7.24/hooks/moduleVersion.py: ok'
  phase: Ready
```

In the Module, you can see the current installed version of the module, its size, the source from which it was downloaded, its dependencies, and the release channel.

In case of any errors, the module will enter the `Error` phase:

```
$ d8 k get module module-one
NAME         STAGE    SOURCE   PHASE  ENABLED  READY
module-one            example  Error  True     Error
```

If the enabled module has several available sources, and a source for the module is not explicitly selected in its ModuleConfig, the module will enter the `Conflict` phase:

```
$ d8 k get module module-one
NAME         STAGE    SOURCE   PHASE     ENABLED  READY
module-one                     Conflict  False    False
```

To resolve the conflict, specify the source of the module (ModuleSource name) explicitly in ModuleConfig.

After downloading the module, the module releases will appear in the cluster — ModuleRelease objects.

You can view the list of releases using the following command:

```
d8 k get mr
```

An example of retrieving the list of module releases:

```
$ d8 k get mr
NAME                         PHASE        UPDATE POLICY   TRANSITIONTIME   MESSAGE
module-one-v0.7.23           Superseded   deckhouse       33h
module-one-v0.7.24           Deployed     deckhouse       33h
module-two-v1.2.0            Superseded   deckhouse       48d
module-two-v1.2.1            Superseded   deckhouse       48d
module-two-v1.2.3            Deployed     deckhouse       48d
module-two-v1.2.4            Superseded   deckhouse       44d
module-two-v1.2.5            Pending      deckhouse       44d              Waiting for the
'release.deckhouse.io/approved: \"true\"' annotation
```

If the module release is in the `Superseded` status, it means that the module release is outdated, and there is a newer release that has replaced it.

⚠ If a module release is `Pending`, it means that manual confirmation is required to install it (see module update policy below). You can confirm the module release using the following command (specify the moduleRelease name):

```
d8 k annotate mr <module_release_name> modules.deckhouse.io/approved="true"
```

This can also be done using the `d8` CLI for convenience (module names and versions are autocompleted):

```
d8 system module approve <module-name> <version>
```

Switching the module to a different module source

Follow these steps to deploy a module from a different module source:

1. Create a new ModuleSource resource.
2. Specify it in the `source` field in ModuleConfig.
3. Ensure that new module releases (ModuleRelease objects) are created from the new module source in accordance with the update policy:

   ```
   d8 k get mr
   ```

Module update policy

The module update policy refers to the rules that DP uses to update modules in the cluster. It is set by the ModuleUpdatePolicy resource with the following settings:

- module update mode (automatic, manual, updates are disabled);
- the release channel to use for updates;
- time windows for automatic updates during which the module update is permitted.

You do not have to create the ModuleUpdatePolicy resource. If the update policy for a module is not defined (there is no corresponding ModuleUpdatePolicy resource), the update settings match the update settings of DP (the update parameter of the `deckhouse` module).

Example of the ModuleUpdatePolicy resource, whose update policy allows automatic module updates on Mondays and Wednesdays from 13:30 to 14:00 UTC:

```
apiVersion: deckhouse.io/v1alpha2
kind: ModuleUpdatePolicy
metadata:
  name: example-update-policy
spec:
  releaseChannel: Alpha
  update:
    mode: Auto
    windows:
    - days:
      - "Mon"
      - "Wed"
      from: "13:30"
      to: "14:00"
```

The update policy is specified in the `updatePolicy` field in ModuleConfig.

Enabling the module

Before enabling the module, make sure that it can be enabled. Run the following command to list all the available DP modules:

```
d8 k get modules
```

The module must be in the list.

Below is an example of the output:

```
$ d8 k get module
NAME        STAGE    SOURCE   PHASE       ENABLED   READY
...
module-one                    Available   False     False
module-two                    Available   False     False
...
```

It shows that the `module-one` module can be enabled.

If the module is not in the list, check that module source is defined and the module is listed in the module source. Also check the update policy of the module (if defined). If the module update policy is not defined, it matches the DP update policy (the releaseChannel parameter and the update section of the `deckhouse` module parameters).

You can enable the module similarly to built-in DP modules using any of the following methods:

- Run the command below (specify the name of the module):

  ```
  d8 system module enable <MODULE_NAME>
  ```

- Create a `ModuleConfig` resource containing the `enabled: true` parameter and module settings..

  Below is an example of a ModuleConfig that enables and configures the `module-one` module in the cluster:

  ```
  apiVersion: deckhouse.io/v1alpha1
  kind: ModuleConfig
  metadata:
    name: module-one
  spec:
    enabled: true
    settings:
      parameter: value
    version: 1
  ```

Troubleshooting

If there were errors while enabling a module in the cluster, you can learn about them as follows:

- View Deckhouse log:

  ```
  d8 k -n d8-system logs -l app=deckhouse
  ```

- View the Module object in more detail:

  ```
  d8 k get module module-one -oyaml
  ```

- View the ModuleConfig object of the module.

  Here is an example of the error message for `module-one`:

  ```
  $ d8 k get moduleconfig module-1
  NAME         ENABLED   VERSION   AGE   MESSAGE
  module-one   true                7s    Ignored: unknown module name
  ```

- View the ModuleSource object.

  Example output if the module source has problems with downloading the module:

  ```
  $ d8 k get ms
  NAME         COUNT   SYNC   MSG
  example      2       16s    Some errors occurred. Inspect status for details
  ```

Similar to DeckhouseRelease (a DP release resource), modules have a ModuleRelease resource. DP creates ModuleRelease resources based on what is stored in the container registry. When troubleshooting module issues, check the ModuleRelease available in the cluster as well:

```
d8 k get mr
```

Output example:

```
$ d8 k get mr
NAME                  PHASE        UPDATE POLICY          TRANSITIONTIME   MESSAGE
module-1-v1.23.2      Pending      example-update-policy  3m               Waiting for
the 'release.deckhouse.io/approved: "true"' annotation
```

The example output above illustrates ModuleRelease message when the update mode (update.mode of the ModuleUpdatePolicy is set to `Manual`. In this case, you must manually confirm the installation of the new module version by adding the `modules.deckhouse.io/approved="true"` annotation to the ModuleRelease:

```
d8 k annotate mr module-1-v1.23.2 modules.deckhouse.io/approved="true"
```

This can also be done using the `d8` CLI for convenience (module names and versions are autocompleted):

```
d8 system module approve module-1 v1.23.2
```

Integrating Deckhouse Module Tools for Module Validation

To enable automatic validation of the module structure and, if needed, metrics reporting, you can integrate Deckhouse Module Tools (DMT) into your build process.

For GitHub Projects

A dedicated GitHub Action is available for integrating the DMT into your module.

To connect the DMT, add the following step to your build workflow configuration in `[project].github/workflows/build.yml`:

```
jobs:
  lint:
    runs-on: ubuntu-latest
    continue-on-error: true
    name: Linting
    steps:
      - uses: actions/checkout@v4
      - uses: deckhouse/modules-actions/lint@main
      env:
         DMT_METRICS_URL: ${{ secrets.DMT_METRICS_URL }}
         DMT_METRICS_TOKEN: ${{ secrets.DMT_METRICS_TOKEN }}
```

The `DMT_METRICS_URL` and `DMT_METRICS_TOKEN` variables are optional. If set, the DMT will send telemetry to the specified endpoint.

> **i** If the module resides in the `deckhouse` GitHub organization, these variables will be automatically populated from the configured secrets.

A complete example of the configuration can be found in the build_dev.yml file.

To simplify your setup, you can also use the provided configuration templates.

For GitLab Projects

For GitLab projects, ready-to-use templates are available and can be included in your `.gitlab-ci.yml` file to automatically configure the build and validation processes:

- **Setup**: Setup configuration template
- **Build**: Build process configuration template

Steps to connect

1. In your project's `.gitlab-ci.yml` file, add references to the templates:

   ```
   include:
     - remote: https://raw.githubusercontent.com/deckhouse/modules-gitlab-
   ci/refs/heads/main/templates/Setup.gitlab-ci.yml
     - remote: https://raw.githubusercontent.com/deckhouse/modules-gitlab-
   ci/refs/heads/main/templates/Build.gitlab-ci.yml
   ```

2. After adding the templates, in the same `.gitlab-ci.yml` configuration, add a step to perform the check:

   ```
   Lint:
     extends: .lint
   ```

Additional resources

- Global custom resources
- Module `deckhouse` parameters

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Dependencies of the Deckhouse Platform modules

This section covers the dependencies you can set for the module.

Dependencies are a set of conditions (requirements) that must be met in order for Deckhouse Platform to be able to run a module.

Deckhouse Platform (DP) supports the following module dependencies:

- Deckhouse Platform version;
- Kubernetes version;
- version of other modules.

Deckhouse Platform version dependency

This dependency defines the minimum or maximum DP version with which the module is compatible.

An example of setting up a dependency for Kubernetes 1.27 and higher in the `module.yaml` file:

```
name: test
weight: 901
requirements:
   deckhouse: ">= 1.61"
```

> **i** For testing, you can set the `TEST_EXTENDER_DECKHOUSE_VERSION` environment variable to imitate the desired version of Deckhouse Platform.

Deckhouse checks whether the dependency is met in the following cases:

1. **When installing or upgrading a module** If the DP version does not meet the requirements specified in the release module dependencies, the latter will not be installed or upgraded.

   Below is an example of the ModuleRelease resource for which the DP version does not meet the module requirements:

   ```
   root@dev-master-0:~# d8 k get mr
   ```

   Output information:

   ```
      NAME                    PHASE        UPDATE POLICY   TRANSITIONTIME   MESSAGE
      test-v0.8.3             Pending      test-alpha      2m30s            requirements are not satisfied:
   current deckhouse version is not suitable: 1.0.0 is less than or equal to v1.64.0
   ```

2. **When upgrading Deckhouse Platform** Deckhouse checks if the new DP version matches the dependencies of the installed and active modules. If at least one module is not compatible with the new version, the DP upgrade will not be performed.

   Below is an example of the DeckhouseRelease resource for which the DP version does not meet the module requirements:

   ```
   root@dev-master-0:~# d8 k get deckhousereleases.deckhouse.io
   ```

   Output information:

   ```
   NAME                    PHASE         TRANSITIONTIME   MESSAGE
   v1.73.3                 Skipped       74m
   v1.73.4                 Pending       2m13s            requirements of test are not satisfied: v1.73.4
   deckhouse version is not suitable: v1.73.4 is greater than or equal to v1.73.4
   ```

3. **When conducting initial module analyses** Deckhouse checks the current version of DP and the dependencies of the installed modules. If a mismatch is discovered, the module will be disabled.

Kubernetes version dependency

This dependency defines the minimum or maximum Kubernetes version with which the module is compatible.

Here is how you can enable the Kubernetes version dependency for Kubernetes 1.28 and higher in the `module.yaml` file:

```
name: test
weight: 901
requirements:
   kubernetes: ">= 1.28"
```

> **i** For testing, you can set the `TEST_EXTENDER_KUBERNETES_VERSION` environment variable to imitate the desired version of Deckhouse Platform.

Deckhouse checks whether the dependency is met in the following cases:

1. **When installing or upgrading a module** If the Kubernetes version does not meet the requirements specified in the release module dependencies, the latter will not be installed or upgraded.

   Below is an example of the ModuleRelease resource for which the Kubernetes version does not meet the module requirements:

   ```
   root@dev-master-0:~# d8 k get modulereleases.deckhouse.io
   ```

   Output information:

   ```
   NAME                          PHASE        UPDATE POLICY   TRANSITIONTIME   MESSAGE
   test-v0.8.2                   Pending      test-alpha      24m              requirements are not
   satisfied: current kubernetes version is not suitable: 1.29.6 is less than or equal to 1.29
   virtualization-v.0.0.0-dev4   Deployed      deckhouse      142d
   ```

2. **When upgrading Kubernetes** Deckhouse examines the dependencies of active modules, and if at least one module is incompatible with the new Kubernetes version, the version upgrade will not proceed.

   Below is an example of the output you may encounter when a module is incompatible with a newer version of Kubernetes:

   ```
   root@dev-master-0:~# d8 system edit cluster-configuration
   ```

   Output information:

   ```
   Save cluster-configuration back to the Kubernetes cluster
   Update cluster-configuration secret
   Attempt 1 of 5 |
           Update cluster-configuration secret failed, next attempt will be in 5s"
           Error: admission webhook "kubernetes-version.deckhouse-webhook.deckhouse.io" denied the request:
   requirements of test are not satisfied: 1.27 kubernetes version is not suitable: 1.27.0 is less than or
   equal to 1.28
   ```

3. **When conducting initial module analyses** If the Kubernetes version does not conform to the dependencies of the modules that are already installed, DP will disable those modules.

4. **When upgrading Deckhouse Platform** Deckhouse checks the default Kubernetes version value for DP and if it is not compatible with the active modules, the DP update will not be carried out.

   Below is an example of the DeckhouseRelease resource for which the Kubernetes version does not meet the module requirements:

   ```
   root@dev-master-0:~# d8 k get deckhousereleases.deckhouse.io
   ```

   Output information:

   ```
   NAME                    PHASE         TRANSITIONTIME   MESSAGE
   v1.73.3                 Pending       7s              requirements of test are not satisfied: 1.27
   kubernetes version is not suitable: 1.27.0 is less than or equal to 1.28
   ```

Dependency on the version of other modules

Dependencies on other modules describe the conditions for enabling, updating, and disabling a module. A module in the Deckhouse Platform may have required and conditional dependencies on versions of other modules.

Required dependencies

This dependency defines the list of **enabled** modules and their versions that are required for the module to work.

> **i** The built-in DP module version is considered equal to the DP version.

If you need to specify that some module is simply enabled, no matter what version, then you can use the following syntax (using the `user-authn` module as an example):

```
requirements:
  modules:
    user-authn: ">= 0.0.0"
```

Example of setting up a dependency on three modules:

```
name: hello-world
requirements:
  modules:
    ingress-nginx: '> 1.67.0'
    node-local-dns: '>= 0.0.0'
    operator-trivy: '> v1.64.0'
```

Conditional module requirements

✖ Conditional dependencies for modules are available for Deckhouse Platform starting with version 1.73. If you need to use them for a module, set a Deckhouse Platform version dependency 1.73 or higher for that module.

Use this when your module works alone, but integrates with another module **if it is present**.

i Conditional dependencies may affect the ability to enable, disable, and update both modules: the dependent module and the module on which it depends.

To mark a requirement as conditional, add `!optional` to the version constraint string:

```
name: prometheus
requirements:
  modules:
    test: ">v0.22.1 !optional"
```

i The following sections describes restrictions on the use of conditional module dependencies and provides examples of settings where:

- `prometheus` — the target module for which an conditional dependency is specified;
- `test` — a module that can be used in conjunction with the target module.

Restrictions on enabling and disabling prometheus when there is an conditional dependency on test

When there is an conditional dependency on the version of another module, the target module has the following restrictions on enabling and disabling:

1. If `test` is not enabled in the cluster, `prometheus` can be enabled.

   Example: `test` is disabled + `prometheus` has an conditional requirement `test: ">v0.22.1 !optional"` → `prometheus` will be enabled, the requirement is skipped.

2. If `test` is already enabled in the cluster, enabling `prometheus` with `requirements` is only possible if `requirements` specifies requirements that the current version of `test` meets.

   Example: `test` version `v0.21.1` is enabled in the cluster + an conditional requirement `test: ">v0.22.1 !optional"` is set for `prometheus` → installing/enabling `prometheus` will result in a dependency mismatch error (the current version of `test` does not match `requirements`).

3. If `test` is disabled in the cluster, `prometheus` will remain enabled.

   Example: `test` is enabled in the cluster + an conditional requirement `test: ">v0.22.1 !optional"` is set for `prometheus` → disabling `test` will be successful, `prometheus` will not be disabled.

Restrictions on updating prometheus when there is an conditional dependency on test

When there is an conditional dependency on the version of another module, the target module has the following update restrictions:

1. `prometheus` can be updated even if the cluster does not have the `test` module.

   Example: `test` is disabled + `prometheus` has an conditional requirement `test: ">v0.22.1 !optional"` → `prometheus` will be updated.

2. The update for `prometheus` will be blocked until `test` specified in `requirements` is updated in the cluster.

   Example: `test` is enabled + an conditional requirement `test: ">v0.22.1 !optional"` is set for `prometheus` → `prometheus` will not be updated until `test` is updated.

Restrictions on enabling test, whose version is specified in prometheus dependencies

If the `prometheus` module is enabled, it is not possible to enable `test`, whose version does not match the expression specified in `requirements` for `prometheus`.

Example: `prometheus` is included + an conditional requirement `test: ">v0.22.1 !optional"` is specified for `prometheus` → an attempt to include `test v0.21.1` will result in a dependency mismatch error (the version `test v0.21.1` does not match the condition in `requirements` for `prometheus`).

Restrictions on updating test, whose version is specified in prometheus dependencies

If prometheus and test are included in the cluster, test can only be updated to a version that meets the requirements specified in requirements for prometheus.

Example: The `prometheus` and `test` modules are included in the cluster + an conditional requirement `test: '=v0.22.1 !optional'` is set for `prometheus` + an attempt to update `test` to version `0.23.1` → `test` will not be updated because the required version does not meet the `requirements` for `prometheus`.

⚠
- Enabling or disabling modules may take longer because of extra extender checks.
- Known limitation: during reconciliation the list of enabled modules may briefly be empty, which in rare cases lets an conditional dependency check pass incorrectly. If this happens, retry the operation.

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Versioning modules

Deckhouse Platform (DP) uses semantic versioning for modules.

When choosing a version, stick to the following guidelines:

- updating the **patch version** (e.g., from `0.0.1` to `0.0.2`) means that some issue has been fixed;
- updating the **minor version** (e.g., from `0.0.1` to `0.1.0`) means that some new feature has been added;
- updating the **major version** (e.g., from `0.0.1` to `1.0.0`) means that a feature has been added that radically changes the module's capabilities; the interface has undergone significant changes or a major phase of development has been completed.

The git tag and registry container **always** have a "v" before the version number, e.g., `v0.0.73` or `v1.0.0`.

Release channels

Release channels allow you to publish a module version not for all users at once, but for a limited group of users. You define the stability level of the module version and the maximum release channel to which it can be published.

Note that the choice of a specific release channel does not determine how stable the module is. The channels are an instrument for delivery of updates and determine the degree of stability of a particular release.

When publishing a new version of the module to the release channel, first use the `Alpha` release channel. Then, if module version has no issues, publish the module version sequentially to other release channels, taking their stability into account: `Alpha` → `Beta` → `Early Access` → `Stable` → `Rock Solid`. If the module

version requires fixing, the publication of that version should be halted. After releasing a version with fixes, the publication stage must be repeated starting from the `Alpha` release channel.

Procedure for publishing a new version

The recommended sequence of publication of the module version in release channels:

1. Publish a new version of the module in the `Alpha` release channel.
2. If the version works stably, publish it in the following release channels sequentially: `Beta` → `Earlyaccess` → `Stable` → `Rocksolid`.
3. If errors arise, stop the publication and correct them.
4. Repeat the publication of the version, starting from the release channel `alpha`.

Module lifecycle

During its life cycle, the module goes through the following stages:

- **Experimental** refers t to an experimental version. The module functionality may undergo significant changes. Compatibility with future versions is not guaranteed.

  > **i** Modules in the `Experimental` stage cannot be enabled by default. To allow the use of such modules, set the allowExperimentalModules parameter to true.

- **Preview** refers to a preliminary version. The module functionality may change, but the basic features will be preserved. Compatibility with future versions is ensured, but may require additional migration actions.
- **General Availability (GA)** refers to a generally available version. The module is ready to be used in production environments.
- **Deprecated** refers to a module version that has been deprecated. Further development and support of the module is discontinued.

Definition of module stability

Depending on the stage of the module lifecycle and the release channel from which the specific module version was installed, the overall stability can be determined by the following table:

Lifecycle Stage	Release Channels				
	Alpha	**Beta**	**Early Access**	**Stable**	**Rock Solid**
Experimental	Experiments	Experiments	Experiments	Beta testing	Beta testing
Preview	Experiments	Limited use	Limited use	Production use	Production use
General Availability	Experiments	Limited use	Limited use	Production use	Production use in critical systems
Deprecated	Deprecated	Deprecated	Deprecated	Deprecated	Deprecated

- **Experiments** — Functionality checks, experiments, and testing;
- **Beta testing** — Functionality checks, experiments, and testing. Limited use by experienced users in environments equivalent to production;
- **Limited use** — Development environments, pilot projects, low-impact production environments;
- **Production use** — Production environments and those equivalent to them;
- **Production use in critical systems** — Mission-critical production environments and those equivalent to them;
- **Deprecated** — Should be phased out of use.

Highlights:

- A module in `Experimental` status on the `Stable` channel is recommended to be used in production environments only with limitations.
- A module in `General Availability` status on the `Alpha` channel is also not recommended for use in production environments.
- Only `GA` modules installed from `Early Access`, `Stable`, or `Rock Solid` channels are suitable for production environments.
- `Deprecated` modules are recommended to be replaced.

API versioning

Modules in DP use custom resources to interact with users. The `apiVersion` parameter with the API version of these resources is set according to the following rules:

- `v1alphaX` refers to an API that has just been published. This API needs to be tested to see how user-friendly it is, as well as how valid and consistent its settings are.
- `v1betaX` refers to the API that has passed initial testing. Its logical development and refinement is in progress.
- `v1stableX` refers to a stable API. At this point, its fields are kept in the specification while its validation rules do not change to be more stringent.

If necessary, a new version of API v2 can be released, which goes through the same stages but with the prefix `v2`. It's important to remember that after the release of the `v1stableX` version, Kubernetes will consider it more prioritized than the `alpha` or `beta` versions until a new stable version `v2stableX` is released. When executing `kubectl apply` and `kubectl edit` commands, the `v1stableX` version will be used by default.

Release of the new API version

The reasons for releasing a new version may be as follows:

- structure changes;
- updating obsolete parameters.

You can add new parameters without changing the version.

Automatic API Conversion

To enable automatic conversion of module parameters from one version to another, you can include the appropriate module conversions. Conversions may be necessary when a parameter is renamed or moved to a different location in a new version of the OpenAPI specification.

Recommendations for Releasing New Versions of CRD

Please follow these recommendations when releasing a new version of the CustomResourceDefinition (CRD):

- Set the parameter `deprecated: true` for previous versions of the CRD. For more details on working with deprecated versions of CRD, refer to the Kubernetes documentation.
- Do not change the storage version, in which data is stored inside etcd, until at least two months have passed since the release of the new version.

Additional resources

- Module `deckhouse` parameters

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

An example of creating a module with adaptation of an existing chart

This section provides an example of creating a `helloworld` module based on module template and an adaptation of the hello-world Helm-chart.

Preparing module source code and building

1. Install the tools you will need:
   - git
   - sed
   - yq
2. Fork the module template repository or copy it.

   ```
   git clone git@github.com:deckhouse/modules-template.git helloworld \
     && cd helloworld
   ```

3. Enter the name of the module in the `module.yaml` file.

   We will use the `helloworld` module name in this example, but you can use any name you like. For this, replace 'helloworld' in the commands and in your repo's name with the one you prefer.

> **i** Note that the module name may differ depending on the command. In may be written in *kebab-case* as well as *camelCase*. If you use a custom module name, make sure to modify it accordingly.

Run the following command to add the module name to the `module.yaml` file or edit it manually:

```
sed -i -e 's/^name:.*$/name: helloworld/' module.yaml
```

4. Clone the hello-world chart source code into a temporary directory.

```
git clone https://github.com/giantswarm/hello-world-app .tmp-chart
```

5. Copy the chart templates to the `templates` directory of the module (make sure to empty it beforehand).

```
rm -rf templates/*
cp -fR .tmp-chart/helm/hello-world/templates/* templates/
cp .tmp-chart/helm/hello-world/values.yaml values.yaml
```

6. Replace the `.Values` path in the chart templates with `.Values.helloworld`.

> **i** This is due to the architectural feature of addon-operator. You have to stick to it to be able to access module values.

```
sed -i -e 's/.Values/.Values.helloworld/g' $(find templates/ -type f)
```

7. Add the OpenAPI schema of the module settings.

   The module parameters are specified in the OpenAPI schema in the openapi directory. Execute the following command to convert the JSON schema of the chart parameters to the OpenAPI schema of the module:

```
jq 'walk(
   if type == "object" and .type == "object" and (keys | length) == 1
   then . + {additionalProperties: true}
   else .
   end
)' .tmp-chart/helm/hello-world/values.schema.json > openapi/config-values.yaml
```

8. Define a rule for building an application container image.

   The rules for building application container images must reside in a subdirectory of the images directory of the module. Run the following commands to create an application image directory and a Dockerfile with the image build rules:

```
rm -rf images/*
mkdir images/helloworld
echo "FROM quay.io/giantswarm/helloworld:0.2.0" > images/helloworld/Dockerfile
```

9. Replace the image in the Deployment manifest with the Deckhouse Platform library helper. This will allow you to use the current content-based image tag.

```
sed -Ei 's/image\:(.*)/image: {{ include "helm_lib_module_image" (list .
"helloworld") }}/g' templates/deployment.yaml
```

10. Delete module hooks, CRDs, and temporary files.

    In our example, hooks and CustomResourceDefinitions are not used. Run the following commands to clear the `hooks` and `crds` directories:

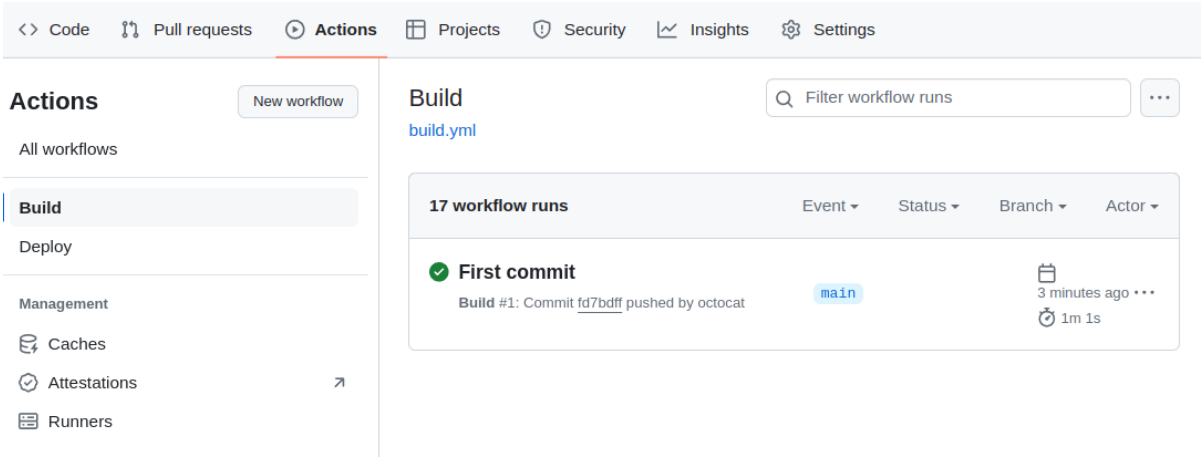
```
rm -rf hooks/
rm -rf crds/
rm -rf .tmp-chart
```

11. Set up CI/CD.

    The project template in the `.github` directory contains pre-built GitHub Actions workflow files that implement a simple scheme for building and publishing a module using the GitHub Packages registry (ghcr.io). Module artifacts will be pushed to `ghcr.io/<OWNER>/modules/`, which will be the module source. Make changes to the workflow files if the suggested option does not work for you.

    Do the following in the properties of your project on GitHub to make the module workflow run smoothly:

    - Open the *Settings -> Actions -> General* page.
    - Enable *Read and write permissions* in the *Workflow permissions* section.



12. Commit the changes to the repository (specify the address of the module's Git repository).

    ```
    git add .
    git commit -m "Initial Commit"
    git push --set-upstream origin <GIT_REPO_URL>
    ```

13. Confirm that the module was built successfully.

    Go to the *Actions* section of the module repository and select *Build* from the workflow list on the left. The workflow that starts after you have executed the `git push` command at the previous step is expected to run successfully.

    An example:

Publishing the module to the release channel

Here's how you can publish version `v0.0.1` of the module to the *Alpha* release channel:

1. Create a new release `v0.0.1` of the module in the GitHub repository or add the `v0.0.1` tag.
2. Go to the *Actions* section of the module repository and select *Deploy* in the workflow list on the left.
3. Click on the *Run workflow* drop-down list on the right of the page and select `alpha`. Enter the `v0.0.1` tag in the tag input field. Click the *Run workflow* button.

4. Confirm that the module publishing workflow has completed successfully.

You can now access your module in a cluster managed by Deckhouse Platform.

Enabling a module in a cluster

The following is the sequence of steps to enable the `helloworld` in a cluster managed by Deckhouse Platform.

1. Create an access token in the GitHub repository with permissions to handle GitHub Packages.
2. Generate an authentication string to access the GitHub Packages container registry in dockerconfigjson format; insert your GitHub username (or organization) and access token in the angle brackets below:

```
base64 -w0 <<EOF
{
  "auths": {
    "ghcr.io": {
      "auth": "$(echo -n '<OWNER>:<TOKEN>' | base64 -w0)"
    }
  }
}
EOF
```

3. Create a ModuleSource resource in the cluster (specify the container registry address and authentication string).

```
d8 k apply -f - <<EOF
apiVersion: deckhouse.io/v1alpha1
kind: ModuleSource
metadata:
  name: ghcr
spec:
  registry:
    # Insert your GitHub username (or organization), e.g., ghcr.io/octocat/modules.
    repo: ghcr.io/<!OWNER>/modules
    # Paste the authentication string for accessing GitHub Packages that you got in
the previous step
    dockerCfg: <!REGISTRY_CREDENTIALS>
EOF
```

   Note that it may take a few seconds to synchronize data after a resource has been created.

4. Check the list of available modules

```
$ d8 k get module
NAME       STAGE    SOURCE   PHASE       ENABLED   READY
...
helloworld                   Available   False     False
...
```

5. Create a ModuleUpdatePolicy resource that defines the module update policy.

   Run the following command to create an update policy with the *Alpha* release channel and *Auto* update mode:

   ```
   d8 k apply -f - <<EOF
   apiVersion: deckhouse.io/v1alpha2
   kind: ModuleUpdatePolicy
   metadata:
     name: helloworld-policy
   spec:
     releaseChannel: Alpha
     update:
       mode: Auto
   EOF
   ```

6. Create a ModuleConfig where you specify the module source (the `source` parameter), the update policy (the `updatePolicy` parameter), and set the `enabled` parameter to `true`:

   ```
   d8 k apply -f - <<EOF
      apiVersion: deckhouse.io/v1alpha1
      kind: ModuleConfig
      metadata:
        name: helloworld
      spec:
         enabled: true
         source: ghcr
         updatePolicy: helloworld-policy
   ```

7. Check the ModuleSource (the status should have no errors and list the available modules):

   ```
   d8 k get ms ghcr -o yaml
   ```

8. Confirm that the new ModuleRelease objects have been created for the module:

   ```
   d8 k get mr
   ```

   An example of output:

   ```
   $ d8 k get mr
   NAME                                PHASE        UPDATE POLICY
   TRANSITIONTIME   MESSAGE
   helloworld-v0.0.1                   Deployed     helloworld-policy    22m
   ```

9. If the release has been successfully installed, wait for the Deckhouse Platform pod to restart.

   ```
   d8 k -n d8-system get pod -l app=deckhouse
   ```

   After a while, the module objects will be available in the cluster.

   If you run into errors while starting the module, check the DP log:

   ```
   d8 k -n d8-system logs deploy/deckhouse -f | jq -rc '.msg'
   ```

or check the status of the DP queue:

```
d8 system queue list
```

Migration of ModuleUpdatePolicy to version v1alpha2

If there is a ModuleUpdatePolicy of version v1alpha1 in the cluster, the following migration steps to version v1alpha2 must be performed:

If any ModuleUpdatePolicy of version v1alpha1 in the cluster defines `moduleReleaseSelector`, alerts `ModuleHasDeprecatedUpdatePolicy` will be triggered in the monitoring system for all modules that match this selector. In this case, follow these steps to migrate to version v1alpha2 of ModuleUpdatePolicy:

- Specify the update policy for the corresponding modules in the ModuleConfig `spec.updatePolicy` parameter.
- Execute the following command, specifying the required ModuleUpdatePolicy:

```
d8 k patch moduleupdatepolicies.v1alpha1.deckhouse.io <MUP_NAME> --type='json' \
  -p='[{"op": "replace", "path":
"/spec/moduleReleaseSelector/labelSelector/matchLabels", "value": {"": ""}}]'
```

Additional resources

- Global custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Module development and debugging

When developing modules, you may want to pull and deploy a module bypassing the release channels. The ModulePullOverride resource is used for this purpose.

> ⚠ The ModulePullOverride resource is intended **for development and debugging environments only**. Using it in production clusters is *not recommended*. Support for the resource might be removed in future Deckhouse Platform versions.

An example of ModulePullOverride:

```
apiVersion: deckhouse.io/v1alpha2
kind: ModulePullOverride
metadata:
  name: <module-name>
spec:
  imageTag: <tag of the module image>
  scanInterval: <image digest check interval. Default: 15s>
```

The `maintenance mode` can also be used for development purposes. In this mode, Deckhouse disables resource management for the module and does not apply changes automatically. This mode is not intended for use in production clusters.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
...
spec:
  enabled: true
  maintenance: NoResourceReconciliation
  settings:
```

Requirements for the resource parameters:

- The module name (`metadata.name`) must match the module name in the ModuleSource (`.status.modules.[].name`).

- The container image tag (`spec.imageTag`) can be anything, e.g., `pr333`, `my-branch`.

The `spec.scanInterval` time interval (optional) defines the interval for scanning images in the registry. The default interval is 15 seconds. To force scan you can change the interval or set the `modules.deckhouse.io/renew=true` annotation on ModulePullOverride. The annotation forces the module to be re-pulled and redeployed even when the image digest has not changed, and is removed once the redeploy succeeds.

The `spec.rollback` indicates whether the deployed module release should be rollback after deleting the ModulePullOverride.

You can get the result of applying ModulePullOverride in the message (column `MESSAGE`) when retrieving ModulePullOverride information. The value `Ready` indicates the successful application of ModulePullOverride parameters. Any other value indicates conflict.

Example of absence of conflicts when using ModulePullOverride:

```
$ d8 k get modulepulloverrides.deckhouse.io
NAME      UPDATED   MESSAGE   ROLLBACK
example1  10s       Ready     false
```

Requirements for the module:

- The module must exist; otherwise the message for ModulePullOverride will be *The module not found*.

  An example:

  ```
  $ d8 k get modulepulloverrides.deckhouse.io
  NAME      UPDATED   MESSAGE                ROLLBACK
  example1  10s       The module not found   false
  ```

- The module must not be embedded Deckhouse module; otherwise the message in ModulePullOverride will be *The module is embedded*.

  An example:

  ```
  $ d8 k get modulepulloverrides.deckhouse.io
  NAME           UPDATED  MESSAGE                  ROLLBACK
  ingress-nginx  10s      The module is embedded   false
  ```

- The module must be enabled; otherwise, the message for ModulePullOverride will be *The module disabled*.

  An example:

  ```
  $ d8 k get modulepulloverrides.deckhouse.io
  NAME     UPDATED   MESSAGE               ROLLBACK
  example  7s        The module disabled   false
  ```

- The module must have a source; otherwise the message at ModulePullOverride will be *The module does not have an active source*.

  An example:

  ```
  $ d8 k get modulepulloverrides.deckhouse.io
  NAME       UPDATED   MESSAGE                                      ROLLBACK
  example    12s       The module does not have an active source   false
  ```

- The source for the module must exist; otherwise the message for ModulePullOverride will be *The source not found*.

  An example:

  ```
  $ d8 k get modulepulloverrides.deckhouse.io
  NAME       UPDATED   MESSAGE                 ROLLBACK
  example    12s       The source not found    false
  ```

To update the module without waiting for the next update cycle to begin, you can execute the following command:

```
d8 k annotate mpo <name> modules.deckhouse.io/renew=true --overwrite
```

Module availability and enabling by default

To assign Deckhouse editions the module should be available in, as well as module bundles where it should be enabled by default, use the `accessibility` field in `module.yaml`:

```
name: test
accessibility:
  editions:
    ee:
      available: true
      enabledInBundles:
        - Default
```

In this configuration, the module will be available in `ee` (DP Enterprise Edition)
and can be enabled using the ModuleConfig object, and will be enabled by default in the `Default` bundle.

How ModulePullOverride works

After creating ModulePullOverride, the corresponding module will not consider ModuleUpdatePolicy, and will also not load and create ModuleRelease objects. The module will be loaded upon every change of the `imageDigest` parameter, after which it will be applied in the cluster. The ModuleSource status will have `overridden: true`, which indicates that ModulePullOverride is being used instead of ModuleUpdatePolicy. Also, the corresponding Module object will have an `IsOverridden` field in its status, and the module version from `imageTag`.

An example:

```
apiVersion: deckhouse.io/v1alpha1
kind: Module
metadata:
  creationTimestamp: "2024-11-18T15:34:15Z"
  generation: 16
  labels:
    deckhouse.io/epoch: "1326105356"
  name: example
  resourceVersion: "230347744"
  uid: 7111cee7-50cd-4ecf-ba20-d691b13b0f59
properties:
  availableSources:
  - example
  releaseChannel: Stable
  requirements:
    deckhouse: '> v1.63.0'
    kubernets: '> v1.30.0'
  source: example
  version: mpo-tag
  weight: 910
status:
  conditions:
  - lastProbeTime: "2024-12-03T15:57:20Z"
    lastTransitionTime: "2024-12-03T15:57:20Z"
    status: "True"
    type: EnabledByModuleConfig
  - lastProbeTime: "2024-12-03T15:59:58Z"
    lastTransitionTime: "2024-12-03T15:57:26Z"
    status: "True"
    type: EnabledByModuleManager
  - lastProbeTime: "2024-12-03T15:59:58Z"
    lastTransitionTime: "2024-12-03T15:56:23Z"
    status: "True"
    type: IsReady
  - lastProbeTime: "2024-12-03T15:59:48Z"
    lastTransitionTime: "2024-12-03T15:56:47Z"
    status: "True"
    type: IsOverridden
  phase: Ready
```

The module will keep running after ModulePullOverride is removed. But if there is a ModuleUpdatePolicy for the module, new releases of the module (ModuleRelease) will be pulled to replace the current “developer version”.

An example

1. Suppose there are two modules, `echo` and `hello-world`, defined in ModuleSource. The update policy is set for them, and they are pulled in and installed in DP:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleSource
metadata:
  name: test
spec:
  registry:
    ca: ""
    dockerCfg: someBase64String==
    repo: registry.example.com/deckhouse/modules
    scheme: HTTPS
status:
  modules:
  - name: echo
    policy: test-alpha
  - name: hello-world
    policy: test-alpha
  modulesCount: 2
```

2. Enable the module and create ModulePullOverride for the `echo` module:

```
apiVersion: deckhouse.io/v1alpha2
kind: ModulePullOverride
metadata:
  name: echo
spec:
  imageTag: main-patch-03354
```

After creating ModulePullOverride, the image tag `registry.example.com/deckhouse/modules/echo:main-patch-03354` will be used for the module (`ms:spec.registry.repo/mpo:metadata.name:mpo:spec.imageTag`).

1. The ModulePullOverride will change with each update of the module:

```
apiVersion: deckhouse.io/v1alpha2
kind: ModulePullOverride
metadata:
  name: echo
spec:
  imageTag: main-patch-03354
  scanInterval: 15s
status:
  imageDigest:
sha256:ed958cc2156e3cc363f1932ca6ca2c7f8ae1b09ffc1ce1eb4f12478aed1befbc
  message: "Ready"
  updatedAt: "2023-12-07T08:41:21Z"
```

   where:

   - `imageDigest` is the unique identifier of the container image that was pulled.
   - `lastUpdated` is the time when the image was last pulled.

2. In this case, ModuleSource would look as follows:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleSource
metadata:
  name: test
spec:
  registry:
    ca: ""
    dockerCfg: someBase64String==
    repo: registry.example.com/deckhouse/modules
    scheme: HTTPS
status:
  modules:
  - name: echo
    overridden: true
  - name: hello-world
    policy: test-alpha
  modulesCount: 2
```

Module auto-update logic

> **i** ModuleRelease versions v1.0.0 and v1.1.1 are provided as examples.

1. **Module installation**. When a module is enabled (`enable module <module name>`), the latest available version from the selected stability channel is automatically downloaded and deployed to the cluster. For example, this could be ModuleRelease v1.0.0. The most recent version is used; older versions are not installed.
2. **Module disabling**. When a module is disabled (`disable module <module name>`):
   - The module stops receiving new releases.
   - The currently deployed version remains in the cluster with the `Deployed` status.
3. **Behavior on re-enabling**.

   If the module is re-enabled within 72 hours:

   - The previously deployed version (ModuleRelease v1.0.0) is used.
   - New releases are checked.
   - If available, they are downloaded (e.g., v1.1.0, v1.1.1).
   - The module is then updated according to the standard update rules (Update). More information

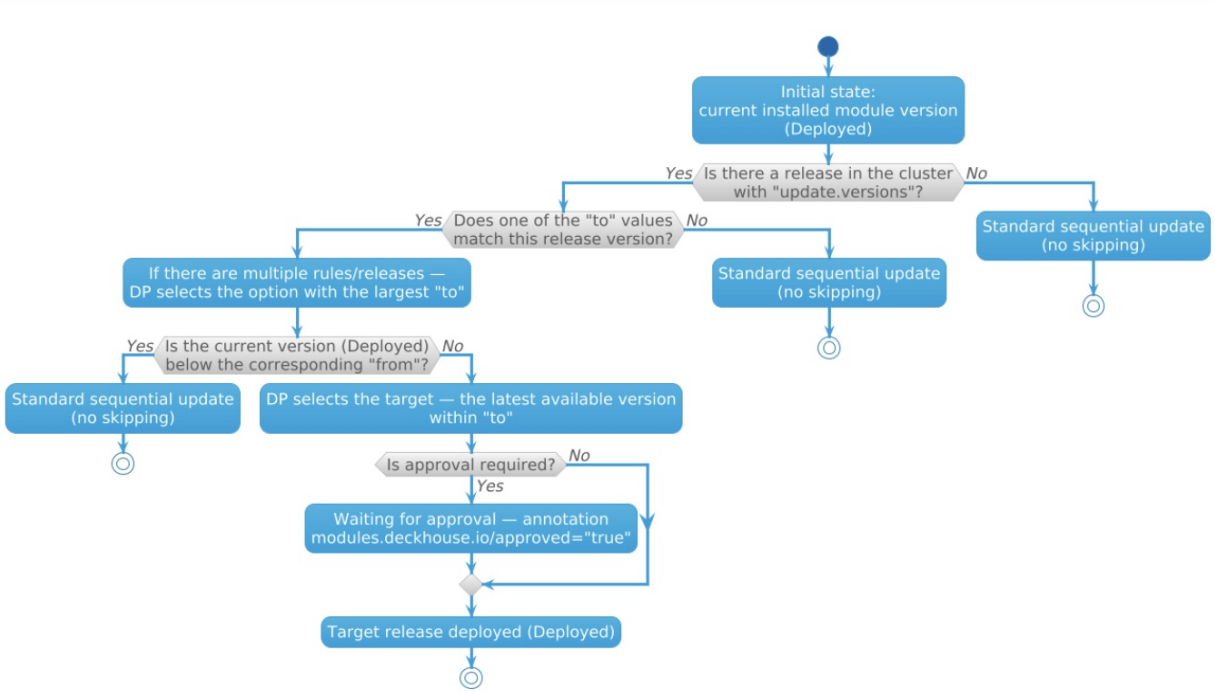
   If the module is re-enabled after 72 hours:

   - The old version is deleted (`delete ModuleRelease v1.0.0`).
   - Upon re-enabling, the latest available version is downloaded (e.g., v1.1.1).
   - The cycle starts again as if the module was enabled for the first time (see step 1).
4. **Behavior of a disabled module**. If a module is disabled, no new releases are downloaded. The previously deployed version (the last one that was enabled) is removed after 72 hours if the module is not re-enabled within that time.

Skipping intermediate releases (from-to)

The `from-to` mechanism allows you to skip step-by-step module updates. If the current installed module version (status `Deployed`) falls within the `from-to` range, DP skips intermediate releases and installs the latest available version within `to`.

To enable the mechanism, set transition rules in the module configuration (`module.yaml`). Example:



```
update:
  versions:
    - from: "1.67"
      to:   "1.75"
    - from: "1.99"
      to:   "2.0" # Transitions between major versions are specified in the X.Y format.
```

> **i** A constrained release is a module release whose `module.yaml` contains the `update.versions` section. The `from-to` mechanism works only with such releases.

Conditions for applying `from-to`:

- Target release version. The rule is read from the release you want to move to — the `to` value must match the version of that very release (constrained release).
- Current version threshold. The current installed module version (`Deployed`) is not lower than `from`. If the current version is lower than `from`, the rule does not apply — the update proceeds sequentially.
- If multiple releases match at the same time, the option with the largest `to` is chosen (the rules may reside in different ModuleRelease objects of the same module).
- If no release meets these conditions, the update proceeds as usual — without skipping intermediate versions.

If a release with update.versions appears in the cluster, DP does not require updating in order — such a release appears “as is” in the list, DP automatically selects a suitable option and, if necessary, waits for approval. You can immediately approve installation of the latest available version within `to`. After approval, intermediate releases between `from` and `to` get the `Skipped` status after reconciliation (not immediately); for some time between `Superseded` and `Deployed` there may be releases in the `Pending` status.

Check available releases (ModuleRelease) with:

```
d8 k get mr
```

Example output if the current module version is `0.3.33`, and `module.yaml` contains the rule `from: "0.3" → to: "0.7"`:

```
p-o-test-v0.1.0    Superseded
p-o-test-v0.2.22   Superseded
p-o-test-v0.3.33   Deployed
p-o-test-v0.4.1    Pending      Release is waiting for the
'modules.deckhouse.io/approved: "true"' annotation
p-o-test-v0.5.27   Pending      awaiting for v0.4.1 release to be deployed
p-o-test-v0.6.11   Pending      awaiting for v0.4.1 release to be deployed
p-o-test-v0.7.25   Pending      Release is waiting for the
'modules.deckhouse.io/approved: "true"' annotation
```

In this example output, the current installed version is `0.3.33` (status `Deployed`). According to the rule `from: 0.3 → to: 0.7`, the latest available version within `0.7` is selected for installation — `p-o-test-v0.7.25` (status `Pending`). After approval, versions `0.4.1`, `0.5.27`, and `0.6.11` change to `Skipped`, and `p-o-test-v0.7.25` becomes `Deployed`.

To approve the module release, apply the annotation:

```
d8 k annotate mr p-o-test-v0.7.25 modules.deckhouse.io/approved="true"
```

This can also be done using the `d8` CLI for convenience (module names and versions are autocompleted):

```
d8 system module approve p-o-test v0.7.25
```

Example output after approval:

```
p-o-test-v0.4.1    Skipped
p-o-test-v0.5.27   Skipped
p-o-test-v0.6.11   Skipped
p-o-test-v0.7.25   Deployed
```

Whether an annotation is required depends on the module's update policy. More details — Module update policy.

Examples

Example 1. The target release contains the rule, and its version equals `to` — the transition is performed.

In this example, the `from-to` rule is defined in the **target** release, and the `to` value equals the version of that release. The current installed version (`Deployed`) is not lower than `from`, so the transition is possible. As soon as the release appears in the cluster, DP prepares the update. If the update policy requires approval, mark the release with the annotation. After approval, intermediate releases will be skipped and the target release becomes `Deployed`:

```
# Module version (Deployed): v1.67.23 (≥ 1.67) → the 'from' condition is satisfied.
metadata:
  name: module-test-v1.67.23
status:
  phase: Deployed

# Target release: the release version equals update.versions.to (1.75).
metadata:
  name: module-test-v1.75.25
update:
  versions:
  - from: "1.67"
    to:   "1.75"   # The update will be performed to this version after approval (if
required).
```

Likewise, if the current version is even higher than `from`, the transition is also performed:

```
# Module version (Deployed): v1.69.0  (≥ 1.67) → the 'from' condition is satisfied.
metadata:
  name: module-test-v1.69.0
status:
  phase: Deployed

# Target release: the release version equals update.versions.to (1.75).
metadata:
  name: module-test-v1.75.25
update:
  versions:
  - from: "1.67"
    to:   "1.75"  # The update will be performed to this version after approval (if
required).
```

Example 2. The current version is lower than `from` — the transition is not performed.

If the current installed version is lower than `from`, the rule does not apply. The update proceeds sequentially (without skipping):

```
# Module version (Deployed): v1.61.0  (< 1.67) → the 'from' condition is NOT satisfied.
metadata:
  name: module-test-v1.61.0
status:
  phase: Deployed

metadata:
  name: module-test-v1.75.25
update:
  versions:
  - from: "1.67"
    to:   "1.75"   # The from-to transition is not performed → sequential update.
```

Example 3. `to` does not match the version of the release that contains the rule — the transition is not performed.

A transition is possible only to a release where `to` equals the version of that release. If the rule is described in another release (for example, `to: "1.74"` is placed in release `v1.75.25`), it will not work — the update goes sequentially.

```
# Module version (Deployed): v1.67.0.
metadata:
  name: module-test-v1.67.0
status:
  phase: Deployed

metadata:
  name: module-test-v1.74.0  # This release has no update.versions.

# The rule is written in another release (v1.75.25), and 'to' does not equal its
version.
metadata:
  name: module-test-v1.75.25
update:
  versions:
  - from: "1.67"
    to:   "1.74"   # 'to' does not equal this release version (1.75.25) → the rule is
ignored.
```

Module artifacts in the container registry

After a module has been built, its artifacts must be pushed to the container registry at a path that is the *source* path for pulling and running modules in DP. The path where module artifacts are pushed to the registry is specified in the ModuleSource resource.

Below is an example of the container image hierarchy after pushing the `module-1` and `modules-2` module artifacts into the registry:

```
registry.example.io
 modules-source
├─  module-1
│  ├─  v1.23.1
│  ├─  d4bf3e71015d1e757a8481536eeabda98f51f1891d68b539cc50753a-1589714365467
│  ├─  e6073b8f03231e122fa3b7d3294ff69a5060c332c4395e7d0b3231e3-1589714362300
│  ├─  v1.23.2
│  └─  release
│     ├─  v1.23.1
│     ├─  v1.23.2
│     ├─  alpha
│     └─  beta
└─  module-2
   ├─  v0.30.147
   ├─  d4bf3e71015d1e757a8481536eeabda98f51f1891d68b539cc50753a-1589714365467
   ├─  e6073b8f03231e122fa3b7d3294ff69a5060c332c4395e7d0b3231e3-1589714362300
   ├─  v0.31.1
   └─  release
      ├─  v0.30.147
      ├─  v0.31.1
      ├─  alpha
      └─  beta
```

> ⚠ The container registry must support a nested repository structure. See the requirements section for more details.

Below is a list of commands for working with the module source. The examples use the crane tool. Follow the instructions to install it. For macOS, use `brew`.

Print the list of modules in the module source

```
crane ls <REGISTRY_URL>/<MODULE_SOURCE>
```

An example:

```
$ crane ls registry.example.io/modules-source
module-1
module-2
```

Print the list of module images

```
crane ls <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>
```

An example:

```
$ crane ls registry.example.io/modules-source/module-1
v1.23.1
d4bf3e71015d1e757a8481536eeabda98f51f1891d68b539cc50753a-1589714365467
e6073b8f03231e122fa3b7d3294ff69a5060c332c4395e7d0b3231e3-1589714362300
v1.23.2
```

In the example above, there are two module images and two application container images in `module-1`.

Print the list of files in the module image

```
crane export <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>:<MODULE_TAG> - | tar -tf -
```

An example:

```
crane export registry.example.io/modules-source/module-1:v1.23.1 - | tar -tf -
```

The output will be quite large.

Print the list of images of the module's application containers

```
crane export <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>:<MODULE_TAG> - | tar -Oxf - images_digests.json
```

An example:

```
$ crane export registry.example.io/modules-source/module-1:v1.23.1 -  | tar -Oxf - images_digests.json
{
  "backend": "sha256:fcb04a7fed2c2f8def941e34c0094f4f6973ea6012ccfe2deadb9a1032c1e4fb",
  "frontend": "sha256:f31f4b7da5faa5e320d3aad809563c6f5fcaa97b571fffa5c9cab103327cc0e8"
}
```

Configuring extra images

Modules can include additional images (such as vulnerability databases or other supplementary data) by adding an `extra_images.json` file. This file specifies extra images that need to be manually pushed to the registry and are separate from the main module images.

To view the extra images configuration:

```
crane export <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>:<MODULE_TAG> - | tar -Oxf - extra_images.json
```

An example of `extra_images.json` for neuvector vulnerability database:

```
{
  "scanner": 3
}
```

Important notes:

- Extra images must be manually pushed to the module registry under the `extra/` path.
- Use the `d8 mirror pull --only-extra-images` command to pull only extra images.
- Extra images are stored in the registry as `<module-name>/extra/<image-name>`.

Print the list of releases

```
crane ls <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>/release
```

An example:

```
$ crane ls <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>/release
v1.23.1
v1.23.2
alpha
beta
```

In the example above, there are two releases in the container registry; two release channels, `alpha` and `beta`, are also used:

Print the version in use on the `alpha` release channel

```
crane export <REGISTRY_URL>/<MODULE_SOURCE>/<MODULE_NAME>/release:alpha - | tar -Oxf - version.json
```

An example:

```
$ crane export registry.example.io/modules-source/module-1/release:alpha - | tar -Oxf - version.json
{"version":"v1.23.2"}
```

Additional resources

- Global custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Marketplace

Marketplace is a package management system in Deckhouse Platform (DP). There are two types of packages:

- **Application**: A user workload deployed into a namespace.
- **Module**: A cluster capability extension.

Currently, only Application packages are supported. Module support is planned for a future DP version.

> Marketplace is available in DP starting from version 1.76.

To learn about connecting package repositories and managing repository scanning, refer to “Administration”.

To learn about installing and removing applications from Marketplace, as well as troubleshooting, refer to “Usage”.

Sections

The Marketplace documentation is divided into the following sections:

- The “Concepts” section describes package types, resource model, Application constraints, and application installation steps.
- The “Application development” section describes how to create an Application package from scratch: bootstrapping, project structure, `package.yaml`, local rendering and linting, build, CI/CD, and package artifacts in the container registry.
- The “Application settings” section describes the OpenAPI schemas of settings and values: validation, default values, and the extensions that control the settings form in the web interface.
- The “Templates” section describes the values available to Application templates, object naming, container images, Ingress, and application endpoints.
- The “Nelm annotations” section covers the full set of Nelm annotations used in Application templates to control deployment order, resource lifecycle, tracking, and logging.
- The “Hooks” section describes how to write Go hooks for Applications using the `ApplicationHookInput` type from module-sdk.
- The “Lifecycle and debugging” section describes how DP installs, updates, and deletes an Application, and which tools help to debug a package.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Concepts

This section describes package types, resource model, Application constraints, and application installation steps.

Package types

A package is an abstract unit that encompasses either an **Application** or a **Module**. The distinction is based on scope and purpose:

Characteristic	Module	Application
Purpose	Infrastructure extension for the cluster	User workload
Scope	Cluster-wide (one per cluster)	Namespaced (unlimited instances)
Multiple instances	No (1:1 with the cluster)	Yes (N instances in different namespaces)
Enabled by default	Can be enabled via bundle	Only by explicit user action
CRD creation	Allowed	Forbidden
Cluster-wide objects	Allowed	Forbidden

Resource model

Deckhouse Platform (DP) Marketplace uses five custom resources:

```
flowchart TD
    PR[PackageRepository] -->|Triggers| PRO[PackageRepositoryOperation]
    PR -->|Populates| APV[ApplicationPackageVersion]
    APV -->|Aggregated by| AP[ApplicationPackage]
    APV -->|Referenced by| APP[Application\nnamespace-scoped]
```

Resource	Short name	Scope	Role

Resource	Short name	Scope	Role
PackageRepository	—	Cluster	Connection to a container registry and scan schedule
PackageRepositoryOperation	`pro`	Cluster	Scan job that discovers versions
ApplicationPackageVersion	`apv`	Cluster	One per discovered package version. Carries metadata, OpenAPI schemas, and requirements
ApplicationPackage	`ap`	Cluster	Package summary: which repos have the package, which versions the release channels point to, how many instances use it
Application	—	Namespace	Installed instance. Drives Nelm deployment

ApplicationPackageVersion content

ApplicationPackageVersion contains package version metadata and information required to configure and deploy an application:

Content	Field
Localized package description (`en`/`ru`)	`status.packageMetadata.description`
Package maturity stage (`Preview`, `General Availability`, and others)	`status.packageMetadata.stage`
DP and Kubernetes version requirements and module dependencies (`mandatory`, `conditional`, `anyOf`, `noneOf`)	`status.packageMetadata.requirements`
Application removal confirmation settings. For details, refer to “Deletion confirmation”	`status.packageMetadata.disableOptions`
Package version changes from `changelog.yaml`	`status.packageMetadata.changelog`
OpenAPI v3 schema for validating `Application.spec.settings`	`status.packageSchemas.settingsSchema`
OpenAPI v3 schema for validating the final set of `values` passed to hooks and templates	`status.packageSchemas.valuesSchema`

Application installation steps

Installing an application from a package involves several stages, from connecting and scanning the package repository to creating an Application resource, deploying the application, and checking its status.

1. Administrator creates a PackageRepository.
2. DP creates a PackageRepositoryOperation automatically. The initial scanning is performed when the resource is created, and then repeated based on the `scanInterval` value.
3. The operation scans the repository and creates ApplicationPackageVersion objects for each discovered version.
4. User creates an Application in their namespace referencing package repository name (`packageRepositoryName`), application package name (`packageName`), and version (`packageVersion`).
5. DP validates `spec.settings` against the `settingsSchema` from the corresponding ApplicationPackageVersion.
6. Nelm deploys the Helm templates from the package bundle.
7. The `Installed` condition on the Application reflects deployment progress and is the only condition reported until the installation completes. Once it becomes `True`, the other conditions (`ConfigurationApplied`, `Scaled`, `Ready`, and so on) appear.

Application constraints

All constraints exist to enforce namespace isolation and prevent Applications from interfering with cluster-level resources.

Functional constraints

The following constraints apply:

1. **No CRD creation**: Application templates must not include CustomResourceDefinition objects.
2. **No cluster-wide objects**: All resources created by an Application must be namespaced.
3. **No cross-Application dependencies**: An Application can declare dependencies only on Modules (via `requirements.modules` in `package.yaml`), not on other Applications.
4. **Hooks are namespace-scoped**: Hooks must not read or write resources outside their own namespace.
5. **Manual install only**: Applications are never activated by default; installation requires explicit user action.

Naming constraints

The objects of an Application are named in the format `d8a-<INSTANCE_NAME>-<SUFFIX>` (for details, refer to “Templates”), so the instance name is a part of every object name. To keep the object names within the Kubernetes limits, the following naming constraints apply:

- **Application instance name** (`metadata.name`) can’t exceed **24 characters**. The validating webhook rejects an Application with a longer name.
- **Resource name suffix inside the Application** can’t exceed **23 characters** for StatefulSets, Jobs, and CronJobs, whose names must fit 52 characters (4 + 24 + 1 + 23 = 52), and at most **34 characters** for other objects, whose names must fit 63 characters.

For example, the `master` StatefulSet of the `redis-cache` instance (11 characters) is named `d8a-redis-cache-master` (22 characters).

Additional resources

- Global custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Application development

Prerequisites

Before you start, do the following:

1. Install the Deckhouse CLI (`d8`):

   ```
   sh -c "$(curl -fsSL https://raw.githubusercontent.com/deckhouse/deckhouse-cli/main/tools/install.sh)"
   ```

2. Log in to the container registry with your license key:

   ```
   d8 dk cr login -u license-token dev-registry.deckhouse.io --password <LICENSE_TOKEN>
   ```

Bootstrapping an Application package

To create a `<APPLICATION_NAME>/` directory in the current working directory with the package skeleton and initialize a Git repository with the first commit, run the command `d8 package bootstrap app <APPLICATION_NAME>` (you can use the short name `app` instead of `application`):

```
d8 package bootstrap application myapp --hooks
cd myapp
git remote add origin <GITLAB_REPO_URL>
git push --set-upstream origin main
```

Available options:

Option	Description

Option	Description
`--hooks`	Generate Go hooks: a hook example and a settings validation hook
`--werf`	Describe the image build in a `werf.inc.yaml` file instead of a `Dockerfile`
`--extended`	Add the `oss.yaml` file with the list of open source components used by the application
`-o, --output <OUTPUT_PATH>`	Path where the package will be created (default: `<CURRENT_WORKING_DIRECTORY>/<APPLICATION_NAME>`)

Project structure

In the generated project, the package manifest, schemas, templates, hooks, images, documentation, and continuous integration and continuous delivery (CI/CD) configuration are stored in separate directories and files.

```

```

Don’t add `Chart.yaml` or `values.yaml` to the package root. The `d8 package build` command doesn’t include these files in the package bundle. Deckhouse Platform (DP) renders the templates as a chart without metadata, and default values are described in the OpenAPI schemas.

File package.yaml

The `package.yaml` file is the main manifest for an Application package and defines metadata, type, requirements, and compatibility.

Example `package.yaml` file:

```
apiVersion: v1
type: "Application"
name: redis
descriptions:
  ru: "<RU_DESCRIPTION>"
  en: "Redis — in-memory database"
# Injected automatically at build time.
version: "v1.0.1"
stage: "Preview"
category: "Databases"
# Environment requirements.
requirements:
  deckhouse:
    constraint: ">= 1.70"
  kubernetes:
    constraint: ">= 1.31"
  modules:
    mandatory:
      - name: cert-manager
        constraint: ">= 1.0.0"
```

Field reference:

Field	Required	Description
`name`	Yes	Unique package name
`descriptions`	Yes	Localized description for the catalog and user interface (UI) (`ru`, `en`)
`version`	Yes	Version in Semantic Versioning (SemVer) format; added automatically at build time
`type`	Yes	`Application` or `Module`
`stage`	Yes	Maturity stage (`Preview`, `General Availability`, etc.)
`category`	Yes	Category for catalog classification
`requirements.deckhouse`	No	Minimum DP version constraint
`requirements.kubernetes`	No	Minimum Kubernetes version constraint
`requirements.modules`	No	Module dependencies (SemVer constraints). For details, refer to “Requirements”
`disable`	No	Confirmation before the application is deleted. For details, refer to “Deletion confirmation”

When DP scans a repository, it publishes the description, stage, requirements, deletion confirmation, and the contents of `changelog.yaml` in the `status.packageMetadata` field of the ApplicationPackageVersion resource.

Requirements

The `requirements` section defines the conditions under which the application can be installed and run:

Requirement	Field
Supported DP version	`requirements.deckhouse.constraint`
Supported Kubernetes version	`requirements.kubernetes.constraint`
Modules that must be enabled. A version constraint (`constraint`) can be specified for each module	`requirements.modules.mandatory`

Requirement	Field
Optional modules. If such a module is enabled, its version must match the specified constraint (`constraint`)	`requirements.modules.conditional`
Groups of alternative modules. At least one module in each group must be enabled, and its version must match the corresponding `constraint`, if specified	`requirements.modules.anyOf`
Groups of incompatible modules. No module in such a group can be enabled. `constraint` specifies the incompatible versions; if no constraint is specified, all versions of the module are considered incompatible	`requirements.modules.noneOf`

Each `anyOf` and `noneOf` group has a unique `name`, which is used in error messages, an optional `description`, and a non-empty `modules` list. A module can be listed in only one of the `mandatory`, `conditional`, `anyOf`, and `noneOf` sections. Within `anyOf` or `noneOf`, the same module can be listed in several groups.

Example of a populated `requirements` section:

```
requirements:
  deckhouse:
    constraint: ">= 1.76"
  kubernetes:
    constraint: ">= 1.31"
  modules:
    mandatory:
      - name: cert-manager
    conditional:
      - name: prometheus
        constraint: ">= 1.60"
    anyOf:
      - name: storage
        description: "A storage for application data"
        modules:
          - name: sds-local-volume
          - name: csi-ceph
    noneOf:
      - name: local-path-storage
        description: "Local path volumes are not supported"
        modules:
          - name: local-path-provisioner
```

DP checks the requirements:

- **When an Application is created or changed**. If the requirements are not met, the request is rejected, and the message names the unmet requirement.
- **Before the installation**. DP installs the application only after the modules from `requirements.modules.mandatory` are enabled.
- **While the application is installed**. If the requirements stop being met, for example, a mandatory module is disabled, DP uninstalls the application (for details, refer to “Lifecycle and debugging”).

Module versions are compared with constraints without the pre-release and build metadata parts.

Deletion confirmation

The `disable` section defines a confirmation the user must give before the application is deleted in the web interface:

```
disable:
  confirmation: true
  messages:
    en: "Deleting the application deletes all the data stored in its volumes."
    ru: "<RU_MESSAGE>"
```

DP publishes the section in the `status.packageMetadata.disableOptions` field of the

ApplicationPackageVersion, and the web interface shows the message in the language of the user. DP doesn’t check the confirmation when an Application is deleted through the Kubernetes API.

File changelog.yaml

The `changelog.yaml` file describes the changes in the package version:

```
features:
  - "Added support for Redis 7.4."
fixes:
  - "Fixed the readiness probe of the replica."
```

DP publishes the contents of the file in the `status.packageMetadata.changelog` field of the ApplicationPackageVersion.

OpenAPI schemas

The `openapi/` directory defines two schemas:

- `settings.yaml`: Schema for `Application.spec.settings` (user-facing configuration). The legacy name `config-values.yaml` is also supported.
- `values.yaml`: Schema for the full set of Helm values.

The schemas, validation rules, and the extensions that control defaulting, immutability, and the settings form in the web interface are described in “Application settings”.

Templates and hooks

- The values available to templates and the rules for templates are described in “Templates”.
- Go hooks and the settings validation hook are described in “Hooks”.
- How DP installs, updates, and deletes an application and how to debug it is described in “Lifecycle and debugging”.

Local rendering

To render the templates of the package and print the resulting manifests, run the following command in the package directory:

```
d8 package render
```

Each object in the output is preceded by a comment with the name of its template file.

Available options:

Option	Description
`--file <FILE_NAME>`	Print only the objects rendered from the template with the specified file name
`--render-file <PATH>`	Write the manifests to a file, without the template file name comments
`-r, --remote <REPOSITORY>/<PACKAGE_NAME>:<PACKAGE_VERSION>`	Render a published package bundle instead of the local directory. A tag or a digest is required
`--remote-user`, `--remote-password`	Container registry credentials. They can also be set in the `PACKAGE_REMOTE_USER` and `PACKAGE_REMOTE_PASSWORD` environment variables

The command uses stub values instead of the values from a cluster: the `test` instance in the `default` namespace, the `dev` package version, and settings generated from `openapi/settings.yaml` (from `x-example`, `x-examples`, `enum`, or `default`). Image references are stubs keyed by the names of the image directories. To render the templates of an installed application with its actual values, use `deckhouse-controller packages render` (for details, refer to “Lifecycle and debugging”).

Linting

To check the structure, manifests, and schemas of the package, run the following command in the package directory:

```
d8 package verify
```

The command reports errors and warnings of the built-in rules and exits with an error if at least one error is

found. To get the full list of rules with descriptions, run `d8 package doc`.

The rules are grouped by linters:

Linter	What it checks
`package`	Required files (`changelog.yaml`, `docs/`), absence of build artifacts (`werf.yaml`, `.werf/`, `.helmignore`), and correctness of `requirements` in `package.yaml`
`openapi`	Types of `x-deckhouse-*` extension values, `x-deckhouse-ui-advanced` only on top-level settings, `enum` values in CamelCase, and a `doc-ru-*` file for each schema except `values.yaml`
`templates`	Object names (the `d8a-<INSTANCE_NAME>-` prefix, the suffix length of Job and CronJob names), absence of `metadata.namespace`, PodDisruptionBudget and VerticalPodAutoscaler objects for workloads, and named `targetPort` in Services. The templates are rendered with the `test` instance name in the `default` namespace
`docs`	Non-empty `docs/README.md`, a Russian version of every document, and no Cyrillic in English documents
`images`	Image directory names without `_` and the format of patch files
`icon`	Application icon `docs/icon.{png,webp,jpg,jpeg,svg}`: format, size up to 150 KB, and dimensions up to 300×300 pixels
`oss`	Format of `oss.yaml`, if the file exists

Available options:

`--hide-warnings`: Don’t show warnings. `--show-ignored`: Show the findings of ignored rules. `--lint-config <PATH>`: Path to the settings file.

To check a published package, run the following command:

```
d8 package verify remote <REPOSITORY> <PACKAGE_NAME>
```

By default, the command checks the bundle of the latest version. Use `--version <PACKAGE_VERSION>` to choose the version and `--release` to also check the version metadata image. The command uses the container registry credentials saved with `d8 dk cr login`.

File .pkglint.yaml

The `.pkglint.yaml` file lowers the severity of the rules. The command looks for it in the package directory and its parent directories (for `verify remote`, in the current directory).

Example:

```
version: "1"
static:          # d8 package verify.
  linters:
    templates:
      rules:
        vpa:
          impact: ignored
        service-port:
          impact: warn
remote:          # d8 package verify remote.
  bundle:
    linters:
      docs:
        impact: warn
```

The `impact` field takes the `error`, `warn`, and `ignored` values. The impact of a rule can’t be higher than the impact of its linter. The rules of the `package` and `openapi` linters can’t be configured, and the

`instance-prefix`, `instance-namespace`, and `job-name` rules follow the impact of the `templates` linter.

Local build

To build the package and publish it to a container registry, run:

```
d8 package build -v v0.0.1 -r dev-registry.deckhouse.io/deckhouse/packages
```

For local development, use the `payload-registry` module as your own container registry.

When using the command, consider the following:

- Specify the root path of the packages in `-r`, the same as the `spec.registry.repo` field of the PackageRepository resource. The command appends the package name to the path itself.
- Specify the version in the `vMAJOR.MINOR.PATCH` format. DP finds only the versions in this format when it scans the repository.
- The images are built with werf (`d8 delivery-kit`) for the `linux/amd64` platform, so the package directory must be a Git repository. Uncommitted changes are also included in the build.
- The `images/` directory must contain at least one image.
- If the version already exists in the registry, the command exits without building. To rebuild the version, use `-f`.

Available options:

Option	Environment variable	Description
`-v, --version`	—	Package version (required)
`-r, --repo`	`PACKAGE_BUILD_REPOSITORY`	Root path of the packages in the container registry. Without it, the package is only built locally
`-u, --user`, `-t, --token`	`PACKAGE_BUILD_REPOSITORY_USER`, `PACKAGE_BUILD_REPOSITORY_TOKEN`	Container registry credentials
`--final-repo`, `--final-user`, `--final-token`	`PACKAGE_BUILD_FINAL_REPOSITORY`, `PACKAGE_BUILD_FINAL_REPOSITORY_USER`, `PACKAGE BUILD_FINAL_REPOSITORY_TOKEN`	Container registry to publish the package to (path and credentials), if it differs from the build registry
`-f, --force`	—	Rebuild and publish a version that already exists in the registry
`--insecure`	`PACKAGE_BUILD_INSECURE`	Allow HTTP and skip the verification of the TLS certificates of the container registries
`--sign`, `--sign-cert`, `--sign-key`	`PACKAGE BUILD SIGN CERT`, `PACKAGE_BUILD_SIGN_KEY`	Sign the images with the specified certificate and key

CI/CD setup

The CI/CD pipeline publishes package releases to the container registry. To publish a release, configure the container registry credentials, then create a Git tag in SemVer format and push it to the repository.

Environment variables

The pipeline uses the following variables to authenticate to the container registry:

Variable	Description
`PACKAGES_REGISTRY_LOGIN`	Container registry username for publishing
`PACKAGES_REGISTRY_PASSWORD`	Container registry password or token

Triggering a release

The pipeline is triggered by a Git tag in SemVer format:

```
git tag v0.1.0
git push origin v0.1.0
```

The pipeline builds the package and pushes it to the container registry. Once the pipeline completes, the package version is available for scanning via PackageRepository.

Package artifacts in the container registry

The package and related data are published to a container registry. The package bundle, container images, and version metadata are stored at separate paths.

Path	Description
`<REPOSITORY>:<PACKAGE_NAME>`	Package name tag — used to list packages
`<REPOSITORY>/<PACKAGE_NAME>:<PACKAGE_VERSION>`	Bundle — contains templates, `openapi/`, `hooks/`
`<REPOSITORY>/<PACKAGE_NAME>@<DIGEST>`	Container images of the application. Templates reference them by digest (for details, refer to “Templates”)
`<REPOSITORY>/<PACKAGE_NAME>/version:<PACKAGE_VERSION>`	Version metadata
`<REPOSITORY>/<PACKAGE_NAME>/release-channel:<RELEASE_CHANNEL>`	Version recommended for a release channel

Here `<REPOSITORY>` is the root path of the packages, for example, `registry.deckhouse.io/deckhouse/<EDITION>/packages`.

Bundle contents

The main bundle image (`<PACKAGE_NAME>:<PACKAGE_VERSION>`) contains:

```
├── package.yaml         # Package manifest with the version.
├── images_digests.json  # Digests of the container images.
├── openapi/             # Settings and values schemas.
├── templates/           # Helm templates.
├── charts/              # Helm subcharts, if any.
├── hooks/               # Hooks binary.
├── docs/                # Documentation and icon.
├── changelog.yaml       # Release notes.
└── oss.yaml             # Open source components, if any.
```

Version metadata image contents

The metadata image (`<PACKAGE_NAME>/version:<PACKAGE_VERSION>`) contains:

```
├── package.yaml       # Package manifest.
├── version.json       # SemVer version.
├── changelog.yaml     # Release notes.
├── openapi/           # Settings and values schemas.
└── docs/              # Documentation and icon.
```

DP reads the version metadata when it scans the repository and creates ApplicationPackageVersion objects from it.

Release channels

A release channel is a tag of the `<PACKAGE_NAME>/release-channel` path that points to a copy of the version metadata image of the recommended version. DP recognizes the `alpha`, `beta`, `early-access`, `stable`, `rock-solid`, and `lts` channels. The `d8 package build` command doesn’t create release channel tags; they are published by the CI/CD pipeline.

When DP scans a repository, it records the versions the channels point to in the `status.releaseChannels` field of the ApplicationPackage resource:

```
status:
  releaseChannels:
    my-registry:      # PackageRepository name.
      alpha: v0.2.0
      stable: v0.1.21
```

The channels are informational: the version of an application is set in `spec.packageVersion` of the Application resource and changes only when the user changes it.

Additional resources

- Global custom resources
- Module `payload-registry` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Application settings

The user configures an application instance in the `spec.settings` field of the Application resource. The package describes the allowed settings with an OpenAPI schema. Deckhouse Platform (DP) validates the settings against this schema, applies default values, and passes the result to templates and hooks. The DP web interface builds the application settings form from the same schema.

Schema files

The `openapi/` directory of the package contains two schemas:

- `settings.yaml`: Schema of `Application.spec.settings`, that is, of the settings the user can change. The legacy file name `config-values.yaml` is supported for backward compatibility: DP reads it only if `settings.yaml` is absent.
- `values.yaml`: Schema of the full set of values available to templates as `.Values`, including internal values set by hooks. In this schema, the package also lists the kinds of orphan resources that DP deletes together with the application.
- `doc-ru-settings.yaml`: Russian descriptions of the settings. The `d8 package verify` command requires a `doc-ru-<NAME>.yaml` file for every schema file except `values.yaml`.

The settings are located at the root of the values, so the values schema must declare them too. To include all settings in the values schema without duplicating them, add the `x-extend` extension to `openapi/values.yaml`. Without it, the values fail the validation when a hook changes them.

Example `openapi/values.yaml`:

```
x-extend:
  schema: settings.yaml
type: object
properties:
  internal:
    type: object
    default: {}
    properties:
      adminPassword:
        type: string
```

When DP scans a repository, it publishes both schemas in the `status.packageSchemas` field of the ApplicationPackageVersion resource. The web interface and the Application validating webhook use the published schemas. Only standard OpenAPI keywords and the `x-deckhouse-*` extensions described on this page are published. Other `x-*` extensions are removed from the published schema.

How DP builds values

DP builds values from the following sources, in the order listed:

1. Default values from `openapi/settings.yaml`.
2. Project defaults for fields with the `x-deckhouse-grantable-resource` extension.
3. User settings from `Application.spec.settings`. They override the values from the previous sources.
4. Default values from `openapi/values.yaml` for the fields that are still not set.
5. Values set by hooks.

Templates get the result as `.Values`. The effective settings (sources 1–3) are also available to templates as `.Application.Settings`. After the settings are applied successfully, DP saves the effective settings in the `status.lastAppliedConfiguration` field of the Application.

Validation

Undeclared fields

DP adds `additionalProperties: false` to every object of both schemas that doesn't define `additionalProperties` explicitly. As a result, a setting or a value that is not declared in the schema is rejected.

To allow arbitrary keys in an object, for example, in a map of labels, define `additionalProperties` explicitly:

```
type: object
properties:
  podLabels:
    type: object
    additionalProperties:
      type: string
```

⚠ Fields declared only inside `oneOf`, `anyOf`, or `allOf` branches are also rejected. Declare every field of an object in its `properties`, and use the branches only to restrict combinations of values.

When settings are validated

When	What DP checks	Result of a failed check
An Application is created or changed	The settings schema published in ApplicationPackageVersion, including CEL rules that don't reference `oldSelf`, and fields with `x-deckhouse-immutable`	The request is rejected
The settings of an installed application are changed (`spec.packageVersion` matches the installed version)	Additionally: CEL rules that reference `oldSelf`, availability of grantable resources, and the settings validation hook	The request is rejected
DP applies the settings	The same as in the previous row	The settings are not applied, the error is reported in the Application conditions
A hook changes values	The `openapi/values.yaml` schema, including CEL rules	The hook fails

CEL rules

Both schemas support the `x-deckhouse-validations` extension with rules in the Common Expression Language (CEL). The syntax and the semantics are the same as in module schemas: a rule consists of `expression` and `message`, the value at the current level is available as `self`, and the previous value is available as `oldSelf`.

Example `openapi/settings.yaml` with a rule that checks two fields together:

```
type: object
properties:
  replicas:
    type: integer
    default: 1
  maxReplicas:
    type: integer
    default: 3
x-deckhouse-validations:
  - expression: "self.replicas <= self.maxReplicas"
    message: "replicas must not exceed maxReplicas"
```

Rules that reference `oldSelf` compare the new settings with the previously applied ones. Such rules are checked only when the settings of an installed application change: they are skipped on installation and when `spec.packageVersion` changes. To forbid changing a field after installation, use `x-deckhouse-immutable`, which is checked on every update.

Defaulting a grantable cluster-wide resource value

A `settings` field of type `string` can be bound to a grantable cluster-wide resource managed by the `multitenancy-manager` (for example, a StorageClass).

When the field is bound and the user leaves it empty, the resource name configured as the project default is injected into `values`. When the user provides a value, it is checked against the resources available to the project. A value that is not in this list is rejected.

To bind the field to a cluster-wide resource, add the `x-deckhouse-grantable-resource` extension and specify the name of the resource available to the project through a grant (`AvailableClusterResource` or `GrantableClusterResourceDefinition`), for example, `storageclasses`.

> **i** The resource group, version, and kind (GVK) are defined by the grant. You do not need to specify them in `openapi/settings.yaml`.

Example `openapi/settings.yaml` with `x-deckhouse-grantable-resource`:

```
type: object
properties:
  storageClass:
    type: string
    x-deckhouse-grantable-resource: storageclasses
  postgres:
    type: object
    properties:
      storageClass:
        type: string
        x-deckhouse-grantable-resource: postgresclasses
```

Behavior:

- The default is resolved per project from the AvailableClusterResource in the Application’s namespace, so different projects can receive different defaults.
- An explicitly specified user value has higher priority than the project default.
- If the custom resource definition (CRD) is absent, no catalog exists for the project, or the catalog has no default value, the field remains unchanged. No value is injected or validated.

Immutable fields

Some settings should not be changed after the application configuration is applied. For example, changing a `storageClass` after volumes have been created either has no effect or can cause application failures. To prevent changes to the value of such a field after the application configuration has been successfully applied, add the `x-deckhouse-immutable: true` extension to it.

Example `openapi/settings.yaml` with `x-deckhouse-immutable`:

```
type: object
properties:
  storageClass:
    type: string
    default: default
    x-deckhouse-immutable: true
  postgres:
    type: object
    properties:
      storageClass:
        type: string
        x-deckhouse-immutable: true
      volumeSize:
        type: string
```

Behavior:

- The extension is effective only when set to `true`. Any other value is ignored.
- When `x-deckhouse-immutable` is added to an object, the entire object becomes immutable. After the application configuration has been successfully applied for the first time, changing any nested field is rejected, even if `x-deckhouse-immutable` is not set on that field. Set the extension on an object only

when the entire object must be immutable. To make only one field immutable, add `x-deckhouse-immutable` directly to it, as with `postgres.storageClass` in the example above. In this case, the restriction does not apply to `postgres.volumeSize`, and its value can be changed.
- If an update changes an immutable value, the validating webhook rejects it and reports the field name.
- In the web interface, the value of a field with the extension can be set when installing the application. In the edit form of an installed application, the field is read-only.
- Comparison uses the configuration that was actually applied, after schema defaults are applied. Therefore, a field with the extension can be omitted from the manifest only if its `default` matches the value that has already been applied. If there is no default value or it differs from the applied value, the change is rejected.
- The extension doesn’t apply to array elements and map entries that an update adds: a new element has no previous value to compare with.

> **i** If an entire object is removed from the manifest, default values are not applied to its nested fields. Therefore, removing an object that contains fields using `x-deckhouse-immutable` can cause frozen values to be lost and is rejected.

Web interface form

The web interface builds the application settings form from `openapi/settings.yaml`. The following extensions control how fields are displayed:

Extension	Value	Effect
`x-deckhouse-ui-order`	Integer	Display order of the field. Fields with lower values are shown first
`x-deckhouse-ui-group`	String	The field is shown in the root-level group with this name. The path of the field in the settings doesn’t change
`x-deckhouse-ui-advanced`	`true`	The field is hidden behind the advanced settings toggle. The extension is taken into account only for top-level fields
`x-deckhouse-ui-validation-message`	String	The message shown under the field instead of the schema validation error, for example, instead of a regular expression that the value doesn’t match
`x-deckhouse-ui-resource-name`	Object with the `apiVersion` and `kind` fields and an optional `labelSelector` field	For a field of type `string`: a drop-down list with the names of resources of the specified kind from the application namespace. `labelSelector` is a standard Kubernetes label selector that narrows the list
`x-deckhouse-ui-text-area`	`true`	For a field of type `string`: a multi-line text field instead of a single-line one. See “Multi-line and masked fields”
`x-deckhouse-ui-secure-field`	`true`	For a field of type `string`, `integer`, or `number`: the input is masked like a password. The value is stored in the settings as is. See “Multi-line and masked fields”
`x-deckhouse-ui-sizing-memory`	Object with the `defaultUnit` field	For a field of type `integer` that stores a memory size in bytes: the size is entered with a unit, for example, `512Mi`. See “Memory size fields”
`x-deckhouse-enum-switch-settings`	List, declared on a `oneOf` branch	Confirmation dialogs shown before switching to another branch. See the next section

Example `openapi/settings.yaml` with form extensions:

```
type: object
properties:
  replicas:
    type: integer
    default: 1
    x-deckhouse-ui-order: 10
  domain:
    type: string
    pattern: '^[a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*$'
    x-deckhouse-ui-order: 20
    x-deckhouse-ui-validation-message: "Enter a domain name, for example,
app.example.com."
  tlsSecretName:
    type: string
    x-deckhouse-ui-group: TLS
    x-deckhouse-ui-resource-name:
      apiVersion: v1
      kind: Secret
      labelSelector:
        matchLabels:
          example.com/tls: "true"
  logLevel:
    type: string
    enum: [Info, Debug]
    default: Info
    x-deckhouse-ui-advanced: true
```

Confirmation before switching a mode

Some settings switches can’t be reverted without data loss, for example, switching the storage of an application from an in-cluster one to an external one. To make the web interface ask for a confirmation before such a switch, add the `x-deckhouse-enum-switch-settings` extension to a `oneOf` branch. The confirmation is shown when the branch discriminator (the field whose `enum` value selects the branch) changes from a value of this branch to one of the target values.

Each list item contains the following fields:

- `to`: Target discriminator values the confirmation applies to. The values are compared as strings, so boolean discriminators are specified as `"true"` and `"false"`.
- `impact`: Severity of the switch: `info` (default), `warning`, or `destructive`. The web interface applies a `destructive` switch only after an explicit acknowledgement and records it in the `applications.deckhouse.io/allow-destructive-settings-switch` annotation of the Application.
- `messages`: Dialog text in Markdown by language code (`en`, `ru`).

Example `openapi/settings.yaml` with `x-deckhouse-enum-switch-settings`:

```
type: object
properties:
  storage:
    type: object
    default: {}
    properties:
      mode:
        type: string
        enum: [Internal, External]
        default: Internal
      size:
        type: string
      url:
        type: string
    oneOf:
      - properties:
          mode:
            enum: [Internal]
        x-deckhouse-enum-switch-settings:
          - to: [External]
            impact: destructive
            messages:
              en: "Switching to external storage **deletes the data** stored in the
cluster."
              ru: "<RU_MESSAGE>"
      - properties:
          mode:
            enum: [External]
        required: [url]
```

Multi-line and masked fields

The `x-deckhouse-ui-text-area` and `x-deckhouse-ui-secure-field` extensions change only how the web interface shows the input of a field:

- `x-deckhouse-ui-text-area: true`: A field of type `string` is shown as a multi-line text field, for example, for a configuration fragment or a certificate.
- `x-deckhouse-ui-secure-field: true`: The input of a field of type `string`, `integer`, or `number` is masked like a password.

A field of type `string` with both extensions is a multi-line text field with masked input. Fields with `enum` ignore both extensions. The extensions take effect only with the boolean `true` value. If the value is a string, for example, `"true"`, Deckhouse Platform can’t load the package version.

Example `openapi/settings.yaml` with `x-deckhouse-ui-text-area` and `x-deckhouse-ui-secure-field`:

```
type: object
properties:
  adminPassword:
    type: string
    minLength: 12
    x-deckhouse-ui-secure-field: true
  guestPin:
    type: integer
    minimum: 100000
    maximum: 999999
    x-deckhouse-ui-secure-field: true
  welcomeMessage:
    type: string
    x-deckhouse-ui-text-area: true
  sshPrivateKey:
    type: string
    x-deckhouse-ui-text-area: true
    x-deckhouse-ui-secure-field: true
```

⚠ The `x-deckhouse-ui-secure-field` extension doesn't protect the value. The value is stored in the `spec.settings` field of the Application as is and is available to everyone who can read the Application. To pass a secret, let the user create a Secret and select it in the form with the `x-deckhouse-ui-resource-name` extension.

Memory size fields

To let the user enter a memory size with a unit, for example, a cache limit, add the `x-deckhouse-ui-sizing-memory` extension to the field. The field must be of type `integer` and store the size in bytes. The `default`, `minimum`, and `maximum` values of the field are specified in bytes too.

The extension value is an object with the `defaultUnit` field. This field sets the unit in which the web interface shows the value when the form is opened: `Ki`, `Mi`, `Gi`, or `Ti`. These are the binary suffixes that Kubernetes uses for resource quantities: 1 Ki is 1024 bytes. If the extension value is not an object, for example, `x-deckhouse-ui-sizing-memory: Mi`, Deckhouse Platform can't load the package version.

The field works as follows:

- The user enters a size with a suffix, for example, `512Mi` or `2Gi`. A number without a suffix is a number of bytes. The web interface saves the size to the settings in bytes: `512Mi` becomes `536870912`. Fractional bytes are rounded.
- When the form is opened, the field shows the value in `defaultUnit` if the value is a whole number in this unit. Otherwise, the field shows the value in the largest unit in which it is a whole number: for example, with `defaultUnit: Gi`, `1610612736` is shown as `1536Mi`. A value that is not a multiple of 1024 is shown in bytes.
- For fields of other types, fields with `enum`, and `defaultUnit` values not listed above, the extension is ignored, and the field is shown as a regular number field.

Example `openapi/settings.yaml` with `x-deckhouse-ui-sizing-memory`:

```
type: object
properties:
  cache:
    type: object
    default: {}
    properties:
      maxMemory:
        type: integer
        default: 536870912
        minimum: 67108864
        x-deckhouse-ui-sizing-memory:
          defaultUnit: Mi
```

In the templates, the size is a number. Print it with the `int64` function: otherwise, a large number is printed in exponential notation, for example, `1.073741824e+09`:

```
env:
  - name: CACHE_MAX_MEMORY
    value: "{{ .Values.cache.maxMemory | int64 }}"
```

Additional resources

- Global custom resources

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Templates

The `templates/` directory of the package contains Helm templates. Deckhouse Platform (DP) renders them and applies the result with Nelm, so the templates can use Nelm annotations to control the deployment order, resource lifecycle, and readiness tracking. This page describes the data DP passes to the templates

and the rules the templates must follow.

Template values

DP renders the templates with three value roots:

Root	Contents
`.Values`	Application values: settings with default values, internal values, and values set by hooks (for details, refer to “How DP builds values”). The values are not nested under the package name: a setting is available as `.Values.<SETTING_NAME>`
`.Application`	Instance and package parameters
`.Platform`	DP global parameters (read-only)

Root .Application

The `.Application` root contains instance and package parameters.

Path	Description
`.Application.Instance.Name`	Instance name, that is, the name of the Application resource
`.Application.Instance.Namespace`	Namespace the application is installed into
`.Application.Package.Name`	Package name (the `name` field of `package.yaml`)
`.Application.Package.Version`	Package version
`.Application.Package.Images`	Container images of the package: a map of image names to image references with a digest (for details, refer to “Container images”)
`.Application.Package.Registry`	Access parameters of the repository the package is installed from (for details, refer to “Container images”)
`.Application.Settings`	Effective settings: `Application.spec.settings` with default values applied

Root .Platform

`.Platform` contains the DP global parameters. The following parameters are useful in application templates:

Path	Description
`.Platform.applications.publicDomainTemplate`	DNS name template for application Ingresses (for details, refer to “Ingress and HTTPS”)
`.Platform.applications.ingressClass`	IngressClass for application Ingresses. Default: `nginx`
`.Platform.applications.https.mode`	HTTPS mode for applications: `CertManager` (default), `CustomCertificate`, `Disabled`, or `OnlyInURI`
`.Platform.applications.https.certManager.clusterIssuerName`	The ClusterIssuer of the `cert-manager` module for application certificates. Default: `letsencrypt`
`.Platform.discovery.clusterDomain`	Cluster domain, for example, `cluster.local`
`.Platform.discovery.kubernetesVersion`	Kubernetes version of the cluster
`.Platform.deckhouseVersion`	DP version
`.Platform.deckhouseEdition`	DP edition

The administrator configures the `.Platform.applications` parameters for all applications of the cluster in the `applications` section of the global settings.

Object names

Name every object in the templates as `d8a-<INSTANCE_NAME>-<SUFFIX>`:

```
metadata:
  name: d8a-{{ .Application.Instance.Name }}-server
```

The `d8 package verify` command reports an error (the `instance-prefix` rule) for every rendered object whose name doesn't start with `d8a-{{ .Application.Instance.Name }}-`. For Job and CronJob objects, the suffix after this prefix must be at most 23 characters long (the `job-name` rule).

The prefix serves the following purposes:

- Several instances of the package can be installed into the same namespace without name conflicts.
- The `d8a-` prefix is reserved for applications: the `d8a-prefix.deckhouse.io` admission policy forbids users to create, change, and delete objects whose names start with `d8a-`. Deleting Pods and changing Secrets with the `packages.deckhouse.io/initial-secret` label are allowed (for details, refer to "Credentials in the web interface").
- DP adds the same prefix to the names of objects that hooks create, patch, or delete. Therefore, a hook can address an object rendered by the templates by its suffix only (for details, refer to "Hooks").

Don't use `.Release.Name` in object names: the Helm release of an application is named `<NAMESPACE>.<INSTANCE_NAME>`, and the dot is not allowed in the names of many resource kinds.

Keep suffixes short: the instance name can be up to 24 characters long, and the full object name must fit the Kubernetes limits (for details, refer to "Naming constraints").

Labels and object protection

DP adds the following labels to the metadata of every rendered object:

Label	Value
`heritage`	`deckhouse`
`packages.deckhouse.io/package`	Package name
`packages.deckhouse.io/instance`	Instance name
`health.deckhouse.io/package`	`<NAMESPACE>.<INSTANCE_NAME>`

The labels are added only to the metadata of the rendered objects, not to Pod templates. Define the labels used in Pod selectors in the templates yourself.

When the Application is deleted, DP finds the objects that the instance has left in the namespace by the `packages.deckhouse.io/instance` label (for details, refer to "Orphan resources").

Objects with the `heritage: deckhouse` label are protected by the `label-objects.deckhouse.io` admission policy, and objects with the `d8a-` name prefix are protected by the `d8a-prefix.deckhouse.io` policy. As a result:

- Users can't change or delete objects rendered by the templates. The exception is Secrets with the `packages.deckhouse.io/initial-secret` label: users can change them, but not create or delete them (for details, refer to "Credentials in the web interface"). To change them manually, for example, when debugging, switch the application to maintenance mode.
- Workloads of the application can't change objects rendered by the templates either.
- The `d8a-prefix.deckhouse.io` policy doesn't apply to service accounts whose names start with `d8a-`. Workloads that run under such service accounts can manage objects with the `d8a-` prefix they create themselves, while these objects stay protected from users.

Container images

Reference the container images of the package through `.Application.Package.Images`. The key is the name of the image directory in `images/` converted to camelCase (for example, `images/my-server` becomes `myServer`). The value is a full image reference with a digest, for example, `registry.example.com/packages/myapp@sha256:...`:

```
containers:
  - name: server
    image: {{ index .Application.Package.Images "server" }}
```

The `d8 package render` command uses the directory names as is, so use single-word names for image directories: then the same key works both in local rendering and in the cluster.

To pull images from the repository, create an image pull Secret from `.Application.Package.Registry.dockercfg` and reference it in `imagePullSecrets`:

```
apiVersion: v1
kind: Secret
metadata:
  name: d8a-{{ .Application.Instance.Name }}-registrysecret
type: kubernetes.io/dockerconfigjson
data:
  .dockerconfigjson: {{ .Application.Package.Registry.dockercfg }}
```

The section `.Application.Package.Registry` contains the following fields:

Field	Description
`name`	Name of the PackageRepository resource
`repository`	Repository address from the PackageRepository resource
`dockercfg`	Base64-encoded Docker configuration for accessing the repository. If the PackageRepository uses `login` and `password`, DP builds the configuration from them
`scheme`	Protocol for accessing the repository as specified in the PackageRepository resource, for example, `HTTPS`. DP passes the value as is: it can be in any case or empty, which means HTTPS
`ca`	CA certificate of the repository, if specified

Ingress and HTTPS

Build host names and TLS settings of application Ingresses from the `.Platform.applications` parameters:

- `publicDomainTemplate`: DNS name template with two `%s` placeholders. The first one is replaced with the instance name, the second one with the namespace. For example, with the `%s.%s.apps.example.com` template, the `grafana` instance in the `monitoring` namespace gets the `grafana.monitoring.apps.example.com` host name. If the parameter is not set, don’t create Ingresses.
- `ingressClass`: IngressClass of the Ingresses.
- `https.mode`: HTTPS mode. In the `CertManager` mode, request a certificate from the ClusterIssuer specified in `https.certManager.clusterIssuerName`. In the `Disabled` and `OnlyInURI` modes, don’t configure TLS on the Ingress.

Example Ingress:

```
{{- $applications := .Platform.applications }}
{{- if $applications.publicDomainTemplate }}
{{- $host := printf $applications.publicDomainTemplate .Application.Instance.Name
.Application.Instance.Namespace }}
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: d8a-{{ .Application.Instance.Name }}-web
  annotations:
    packages.deckhouse.io/application-endpoint-description: "Web UI"
    {{- if eq $applications.https.mode "CertManager" }}
    cert-manager.io/cluster-issuer: {{ $applications.https.certManager.clusterIssuerName
}}
    {{- end }}
spec:
  ingressClassName: {{ $applications.ingressClass }}
  {{- if eq $applications.https.mode "CertManager" }}
  tls:
    - hosts:
       - {{ $host }}
      secretName: d8a-{{ .Application.Instance.Name }}-web-tls
  {{- end }}
  rules:
    - host: {{ $host }}
      http:
        paths:
          - path: /
            pathType: Prefix
            backend:
              service:
                name: d8a-{{ .Application.Instance.Name }}-server
                port:
                  name: http
{{- end }}
```

The package skeleton created by `d8 package bootstrap app` contains helpers for these parameters in `templates/_helpers/`:

- `public domain`
- `ingress_class`
- `https mode`
- `https_ingress_tls_enabled`
- `https_cert_manager_cluster_issuer_name`

Application endpoints

To show the addresses of an application in the `status.urls` field of the Application (for example, the web interface shows them as links to the application), add the `packages.deckhouse.io/application-endpoint-description` annotation to an Ingress, to an HTTPRoute if the application is published through the `alb` module, or to a ServiceAccount:

- The annotation value is the endpoint description. The `"true"` value adds the endpoint without a description, and the `"false"` value excludes the object.
- Only objects rendered by the templates are taken into account: Ingress objects of the `networking.k8s.io` API group, HTTPRoute objects of the `gateway.networking.k8s.io` API group, and ServiceAccount objects (`apiVersion: v1`).
- Deckhouse Platform updates `status.urls` after every successful apply of the templates.

For an Ingress, Deckhouse Platform builds a URL for every `host` and `path` pair of `spec.rules`. The scheme is `https` if the host is listed in `spec.tls`, and `http` otherwise. A rule without paths gives the `<SCHEME>://<HOST>/` URL. Rules without `host` are skipped.

Example status of an Application with the Ingress from the previous section:

```
status:
  urls:
    - url: https://myapp.my-namespace.apps.example.com/
      description: Web UI
```

HTTPRoute endpoints

For an HTTPRoute, Deckhouse Platform builds a URL for every host name of `spec.hostnames` and every path of `spec.rules`:

- The path is the value of a `PathPrefix` or `Exact` match. A rule without matches and a match without a path give the `/` path. Matches of the `RegularExpression` type are skipped.
- If `spec.hostnames` is empty, Deckhouse Platform takes the host names of the listeners the HTTPRoute is attached to.
- The scheme is `https` if the HTTPRoute is attached to an `HTTPS` listener that serves the host name, and `http` otherwise. Deckhouse Platform takes into account only the listeners of ListenerSet objects rendered by the templates. For an HTTPRoute attached directly to a Gateway or to a ListenerSet created outside the templates, the scheme is `http`.

Example ListenerSet and HTTPRoute:

```
{{- $applications := .Platform.applications }}
{{- if $applications.publicDomainTemplate }}
{{- $host := printf $applications.publicDomainTemplate .Application.Instance.Name
.Application.Instance.Namespace }}
apiVersion: gateway.networking.k8s.io/v1
kind: ListenerSet
metadata:
  name: d8a-{{ .Application.Instance.Name }}-web
spec:
  parentRef:
    name: <GATEWAY_NAME>
    namespace: <GATEWAY_NAMESPACE>
  listeners:
    - name: web
      port: 443
      protocol: HTTPS
      hostname: {{ $host }}
      tls:
        mode: Terminate
        certificateRefs:
          - name: d8a-{{ .Application.Instance.Name }}-web-tls
---
apiVersion: gateway.networking.k8s.io/v1
kind: HTTPRoute
metadata:
  name: d8a-{{ .Application.Instance.Name }}-web
  annotations:
    packages.deckhouse.io/application-endpoint-description: "Web UI"
spec:
  parentRefs:
    - group: gateway.networking.k8s.io
      kind: ListenerSet
      name: d8a-{{ .Application.Instance.Name }}-web
      sectionName: web
  hostnames:
    - {{ $host }}
  rules:
    - matches:
        - path:
            type: PathPrefix
            value: /
      backendRefs:
        - name: d8a-{{ .Application.Instance.Name }}-server
          port: 80
{{- end }}
```

where:

- `<GATEWAY_NAME>` and `<GATEWAY_NAMESPACE>` are the name and namespace of the Gateway object that the cluster administrator provides for publishing applications;
- `d8a-{{ .Application.Instance.Name }}-web-tls` is a Secret with the TLS certificate for the host

name, for example, issued by cert-manager. For details, refer to the `alb` module documentation.

For this HTTPRoute, Deckhouse Platform adds the same endpoint to `status.urls` as for the example Ingress: `https://myapp.my-namespace.apps.example.com/` with the `Web UI` description.

ServiceAccount endpoints

If the application gives users a ServiceAccount token for accessing the Kubernetes API, add the annotation to this ServiceAccount. For a ServiceAccount, Deckhouse Platform adds the in-cluster address of the Kubernetes API, `https://kubernetes.default.svc/`, to `status.urls`. This address is the same for all ServiceAccounts and is reachable only from inside the cluster.

Example ServiceAccount:

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: d8a-{{ .Application.Instance.Name }}-api
  annotations:
    packages.deckhouse.io/application-endpoint-description: "Kubernetes API"
```

For this ServiceAccount, Deckhouse Platform adds the `https://kubernetes.default.svc/` endpoint with the `Kubernetes API` description to `status.urls`. To show the ServiceAccount token next to this endpoint in the web interface, bind a Secret with the token to the ServiceAccount (for details, refer to “ServiceAccount token”).

Credentials in the web interface

The web interface can show the credentials for signing in next to an application endpoint, for example, the login and password of the administrator account that the application creates during installation. To do this, add a Secret with the login and password to the templates and bind this Secret to the endpoint:

```
apiVersion: v1
kind: Secret
metadata:
  name: d8a-{{ .Application.Instance.Name }}-web-credentials
  labels:
    packages.deckhouse.io/application-instance: {{ .Application.Instance.Name }}
    packages.deckhouse.io/application-ingress: d8a-{{ .Application.Instance.Name }}-web
    packages.deckhouse.io/initial-secret: "true"
type: Opaque
data:
  login: {{ "admin" | b64enc }}
  password: {{ .Values.internal.adminPassword | b64enc }}
```

The web interface finds the credentials as follows:

- The `packages.deckhouse.io/application-instance` label with the instance name is required. The web interface looks for credentials only among the Secrets with this label in the namespace of the application. Deckhouse Platform doesn’t add this label to the objects, and the `packages.deckhouse.io/instance` label that Deckhouse Platform adds (for details, refer to “Labels and object protection”) is not taken into account.
- The `packages.deckhouse.io/application-ingress` label binds the Secret to an Ingress from the templates by its name. For an application published through the `alb` module, use the `packages.deckhouse.io/application-alb` label with the name of an HTTPRoute from the templates instead, and for a ServiceAccount token, the `packages.deckhouse.io/application-serviceaccount` label with the name of a ServiceAccount from the templates. The web interface shows the credentials next to the endpoints with the description of this object. A label value can’t be longer than 63 characters, so the name of the Ingress, HTTPRoute, or ServiceAccount must fit this limit.
- Instead of the label, you can set the endpoint description in the `packages.deckhouse.io/application-endpoint-description` annotation of the Secret. If both are set, the description of the Ingress, HTTPRoute, or ServiceAccount is used.
- The web interface shows the credentials only if the application has endpoints with a matching description. Endpoints without a description don’t get credentials, so set a description in the annotation of the Ingress, HTTPRoute, or ServiceAccount instead of `"true"`.
- The `packages.deckhouse.io/initial-secret` label marks the Secret as one-time credentials. Deckhouse Platform creates such a Secret once and doesn’t update it afterwards: it adds the `werf.io/resource-policy: skip-update` annotation to the Secret (an existing policy is kept, for example, `skip-delete` becomes `skip-delete,skip-update`). The admission policies let users change such a Secret, so the web interface can mark it as shown, and users can change the credentials. Without this label, the policies deny the change, and the credentials can be requested

again. Deckhouse Platform checks only that the label is present, its value doesn’t matter.

Put the login into the `login` key and the password into the `password` key. The web interface shows every key of `data` as a separate field named after the key, so don’t store other data in this Secret.

In the web interface, endpoints with credentials get a button for getting the login and password. The credentials can be obtained only once: after showing them, the web interface adds the `packages.deckhouse.io/showed-credentials: "true"` annotation to the Secret and doesn’t offer this Secret again. This restriction applies only to the web interface: users with permission to read Secrets in the namespace can still read the Secret.

Since Deckhouse Platform doesn’t update a Secret with the `packages.deckhouse.io/initial-secret` label, changes to its template, including `data`, apply only when the Secret is created, for example, in a new instance.

Generate the credentials once and keep them unchanged: the web interface doesn’t offer a Secret again even if its data changes. Don’t generate the password in the template: functions such as `randAlphaNum` give a new value on every render (for details, refer to “Known issues and troubleshooting”). Instead, for example, generate it in a hook if the Secret doesn’t exist yet, and otherwise take it from the snapshot of the existing Secret. Values set by hooks are kept only in memory, so the hook must restore the password after Deckhouse Platform restarts (for details, refer to “Hooks”).

ServiceAccount token

To show a ServiceAccount token, add a Secret of the `kubernetes.io/service-account-token` type for the ServiceAccount from the example above:

```
apiVersion: v1
kind: Secret
metadata:
  name: d8a-{{ .Application.Instance.Name }}-api-token
  labels:
    packages.deckhouse.io/application-instance: {{ .Application.Instance.Name }}
    packages.deckhouse.io/application-serviceaccount: d8a-{{ .Application.Instance.Name
}}-api
    packages.deckhouse.io/initial-secret: "true"
  annotations:
    kubernetes.io/service-account.name: d8a-{{ .Application.Instance.Name }}-api
type: kubernetes.io/service-account-token
```

Kubernetes fills in the `ca.crt`, `namespace`, and `token` keys of this Secret: the CA certificate of the Kubernetes API, the namespace, and the ServiceAccount token. The web interface shows them as separate fields.

Restrictions

Templates must follow the Application constraints:

- Create only namespaced objects. Don’t set `metadata.namespace`: DP creates the objects in the namespace of the Application, and `d8 package verify` reports an error for objects with this field (the `instance-namespace` rule).
- Don’t create CustomResourceDefinition objects. DP doesn’t install CRDs from the `crds/` directory of the chart.

By default, `d8 package verify` also requires that:

- Every Deployment and StatefulSet has a PodDisruptionBudget whose selector matches the labels of its Pods (the `pdb` rule).
- Every Deployment, StatefulSet, and DaemonSet has a VerticalPodAutoscaler with a policy for each container (the `vpa` rule). The VerticalPodAutoscaler kind is available only if the `vertical-pod-autoscaler` module is enabled, so render it under the `.Capabilities.APIVersions.Has "autoscaling.k8s.io/v1/VerticalPodAutoscaler"` condition, as the package skeleton does.
- Services refer to container ports by name in `targetPort` (the `service-port` rule).

You can lower the severity of these rules in `.pkglint.yaml` (for details, refer to “Linting”).

Replica limits

The user can change the number of replicas of a Deployment, StatefulSet, or ReplicaSet in the `spec.resourceRequests` field of the Application. If the application can’t run with an arbitrary number of replicas, add one of the following annotations to the workload in the templates:

- `packages.deckhouse.io/scale-disabled: "true"`: The number of replicas can’t be changed.
- `packages.deckhouse.io/scale-down-disabled: "true"`: The number of replicas can’t be lower

than the number set in the templates.

The limits are counted from `spec.replicas` of the workload rendered from the templates (`1` if the field isn't set), not from the current number of replicas. For example, if the templates set `replicas: 2` and `scale-down-disabled`, the user can scale the workload to 4 replicas and back to 2, but not to 1. Only the `"true"` value enables a limit.

If a HorizontalPodAutoscaler from the templates manages the replicas of the workload, add the annotation to the HorizontalPodAutoscaler. Deckhouse Platform sets both `minReplicas` and `maxReplicas` of such a HorizontalPodAutoscaler to the requested number of replicas, and the annotations limit this number:

- `scale-disabled`: The number must be equal to both `minReplicas` and `maxReplicas`. If they differ, the number of replicas can't be changed.
- `scale-down-disabled`: The number can't be lower than `minReplicas` (`1` if the field isn't set).

Example:

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: d8a-{{ .Application.Instance.Name }}-web
  annotations:
    packages.deckhouse.io/scale-down-disabled: "true"
spec:
  replicas: 2
  # ...
---
apiVersion: autoscaling/v2
kind: HorizontalPodAutoscaler
metadata:
  name: d8a-{{ .Application.Instance.Name }}-api
  annotations:
    packages.deckhouse.io/scale-down-disabled: "true"
spec:
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: d8a-{{ .Application.Instance.Name }}-api
  minReplicas: 2
  maxReplicas: 10
  # ...
```

If `spec.resourceRequests` requests a forbidden number of replicas, Deckhouse Platform doesn't apply the templates, and the objects of the application stay as they were. The Application itself is accepted, because Deckhouse Platform checks the limits when it renders the templates. The conditions of the Application get the `ScalingForbidden` reason, and the condition message names the workload, for example: `Deployment 'd8a-myapp-web' does not allow its replicas to go below 2`.

Workload health

DP determines whether the application is running from its Deployments and StatefulSets only:

- The `Scaled` condition of the Application becomes `True` when all Deployments and StatefulSets rendered by the templates have rolled out and have the desired number of ready replicas. DaemonSets, Jobs, CronJobs, and Pods are not taken into account.
- A Deployment whose rollout exceeds `spec.progressDeadlineSeconds` sets `Scaled` to `False` with the `Degraded` reason.
- The first installation is considered complete (`Installed=True`) only after the manifests are applied and `Scaled` becomes `True`.

⚠ The package must contain at least one Deployment or StatefulSet. Otherwise, the `Scaled` condition stays `Unknown`, and the application never reaches the `Installed` and `Ready` states.

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Nelm annotations

Application templates are rendered and deployed by Nelm. Nelm extends the standard Helm behavior with annotations that control deployment order, resource lifecycle, readiness tracking, and log output. This page covers the most commonly used annotations.

Deployment stages

Nelm processes a deployment in three stages. Different annotation groups affect different stages.

Render

Templates are evaluated with the current values. Deckhouse Platform (DP) renders the templates with access to the cluster: `.Capabilities` reflects the API server, and `lookup` returns live objects. At this stage:

- Template functions (`include`, `tpl`, `lookup`, and others) are executed.
- All resources are rendered and stored in the release, regardless of `werf.io/deploy-on`.

Plan

Nelm connects to the cluster, reads current resource state, and runs a **dry-run Server-Side Apply** to compute the exact diff. It then builds a **DAG of operations** — which resources to create, update, or delete, and in what order.

At this stage:

- `werf.io/deploy-on` determines for which operations (`install`, `upgrade`, and so on) and in which stage the resource is deployed.
- Order and dependency annotations (`werf.io/weight`, `werf.io/deploy-dependency-*`, `*.external-dependency.werf.io/*`) shape the DAG.
- Lifecycle annotations (`werf.io/ownership`, `werf.io/delete-policy`, `werf.io/delete-propagation`) determine which operations enter the plan.

Dry-run SSA means the diff is computed by the API server — defaulting, admission plugins, and mutating webhooks are all applied.

Apply

The DAG is executed: resources are created, updated, or deleted in dependency order, with parallelism where no dependencies exist. Readiness tracking and log streaming run concurrently.

At this stage:

- Tracking annotations (`werf.io/track-termination-mode`, `werf.io/fail-mode`, `werf.io/failures-allowed-per-replica`, `werf.io/no-activity-timeout`) control waiting behavior.
- Log annotations control what is printed during deployment.

Common use cases

Job that must run before the main application

Database migration before the application starts:

```
apiVersion: batch/v1
kind: Job
metadata:
  name: d8a-{{ .Application.Instance.Name }}-db-migrate
  annotations:
    werf.io/delete-policy: before-creation
spec: ...
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: d8a-{{ .Application.Instance.Name }}-app
  annotations:
    werf.io/deploy-dependency-migrate: state=ready,kind=Job,name=d8a-{{
.Application.Instance.Name }}-db-migrate
spec: ...
```

The annotation `werf.io/delete-policy: before-creation` makes Nelm recreate the Job on every deployment, so the migration runs each time. By default, Nelm recreates a Job only when an immutable field of the Job changes. The Deployment waits for `ready`, that is, for the Job to complete successfully.

Preserve a resource across uninstall or chart removal

A PVC with database data that must not be deleted even when the Application is uninstalled:

```
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
  name: d8a-{{ .Application.Instance.Name }}-postgres-data
  annotations:
    helm.sh/resource-policy: keep
spec:
  accessModes: [ReadWriteOnce]
  resources:
    requests:
      storage: 50Gi
  storageClassName: gp3
```

The annotation `helm.sh/resource-policy: keep` prevents the PVC from being deleted on uninstall or when removed from the chart. It doesn’t protect against `d8 k delete pvc`. To keep the data in this case, use a StorageClass with `reclaimPolicy: Retain`: then the PersistentVolume outlives the PVC.

Resource shared between releases

A TLS Secret used by multiple charts should not disappear when any one of them is uninstalled:

```
apiVersion: v1
kind: Secret
metadata:
  name: d8a-{{ .Application.Instance.Name }}-shared-tls
  annotations:
    werf.io/ownership: anyone
type: kubernetes.io/tls
data: ...
```

The annotation `werf.io/ownership: anyone` tells Nelm it is not the sole owner, so it skips deletion on uninstall. DP still deletes the Secret together with the Application if its kind is listed in `orphanResources`. To keep the Secret, add `helm.sh/resource-policy: keep`.

Wait for a resource created by an operator

Deploy only after `cert-manager` creates the Certificate object:

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: d8a-{{ .Application.Instance.Name }}-app
  annotations:
    cert.external-dependency.werf.io/resource: certificates.v1.cert-manager.io/d8a-{{
.Application.Instance.Name }}-tls
spec: ...
```

Nelm waits until the Certificate object exists before creating the Deployment. Nelm doesn’t wait until the certificate is issued.

Non-critical component that must not fail the deploy

A metrics DaemonSet whose unavailability should not block the release:

```
apiVersion: apps/v1
kind: DaemonSet
metadata:
  name: d8a-{{ .Application.Instance.Name }}-metrics-agent
  annotations:
    werf.io/fail-mode: IgnoreAndContinueDeployProcess
    werf.io/track-termination-mode: NonBlocking
spec: ...
```

Nelm will not wait for readiness and will not fail on timeout.

Resource rendered only on first install

An init Job that runs only during `install`, not `upgrade`:

```
apiVersion: batch/v1
kind: Job
metadata:
  name: d8a-{{ .Application.Instance.Name }}-init-data
  annotations:
    werf.io/deploy-on: install
    werf.io/ownership: anyone   # CRITICAL
spec: ...
```

Without `werf.io/ownership: anyone`, on upgrade the resource renders as absent and the owning release removes it. `anyone` prevents that. Nelm doesn’t delete such a Job on uninstall either. To make DP delete it together with the Application, list `Job` in `orphanResources`.

Slow-starting resource with a large image

StatefulSet with a large Docker image (ML models, Elasticsearch with pre-loaded indices):

```
apiVersion: apps/v1
kind: StatefulSet
metadata:
  name: d8a-{{ .Application.Instance.Name }}-elasticsearch
  annotations:
    werf.io/no-activity-timeout: 20m
    werf.io/failures-allowed-per-replica: "3"
    werf.io/show-service-messages: "true"
spec: ...
```

Used annotations:

- `no-activity-timeout: 20m`: 20 minutes without events before Nelm considers it timed out. Use this for slow image pulls or long initialization.
- `failures-allowed-per-replica: "3"`: Allows up to 3 tracking errors per replica, for example, container restarts or image pull errors, before the deployment fails. Use for flapping init dependencies.
- `show-service-messages: "true"`: Emit Kubernetes Events in deploy output (useful for diagnosing `ImagePullBackOff`, scheduling failures, OOM events).

Ordering and dependencies

Weights

The annotation `werf.io/weight` groups resources: equal weights deploy in parallel; different weights deploy sequentially in ascending order. The weight is ignored for a resource with a `werf.io/deploy-dependency-*` annotation.

```
metadata:
  annotations:
    # Deploys before default-weight (0) resources.
    werf.io/weight: "-10"
```

Direct dependencies

The annotation `werf.io/deploy-dependency-<id>` waits for a specific resource in the same release to reach a specific state before deploying the annotated resource.

```
metadata:
  annotations:
    werf.io/deploy-dependency-db: state=ready,kind=StatefulSet,name=d8a-{{
.Application.Instance.Name }}-postgres
    werf.io/deploy-dependency-migrations: state=present,kind=Job,name=d8a-{{
.Application.Instance.Name }}-db-migrate
```

Dependency states:

- `ready`: Resource is in a ready state (for example, `availableReplicas == replicas` for a Deployment).
- `present`: Resource exists in the cluster.

Full format:

```
werf.io/deploy-dependency-<id>: state=ready|present[,name=<name>][,namespace=<namespace>][,kind=<kind>]
[,group=<group>][,version=<version>]
```

⚠ This annotation has no effect if the dependency resource is in a different deploy stage (pre/main/post). Cross-stage ordering is already enforced by the stage sequence itself.

External dependencies

The annotation `<id>.external-dependency.werf.io/resource` waits until a resource **outside the release** (created by an operator or another release) exists. Nelm doesn't wait for the readiness of the resource:

```
metadata:
  annotations:
    cert.external-dependency.werf.io/resource: certificates.v1.cert-manager.io/d8a-{{
.Application.Instance.Name }}-tls
    cert.external-dependency.werf.io/namespace: myapp-production  # Namespace of the
external resource
```

Full format:

```
<id>.external-dependency.werf.io/resource: <kind>[.<version>.<group>]/<name>
```

Delete dependencies

The annotation `werf.io/delete-dependency-<id>` means that the annotated resource will be deleted only after the referenced resource becomes `absent`:

```
metadata:
  annotations:
    werf.io/delete-dependency-app: state=absent,kind=Deployment,name=d8a-{{
.Application.Instance.Name }}-app
```

Lifecycle annotations

helm.sh/resource-policy

The `keep` value instructs Nelm not to delete the resource on uninstall or when removed from the chart. The resource continues to be updated on install/upgrade as long as it renders. If `werf.io/resource-policy` is set, Nelm ignores `helm.sh/resource-policy`. DP doesn't delete a resource with `helm.sh/resource-policy: keep` as an orphan resource, even if `werf.io/resource-policy` is set: only this annotation protects a resource from such deletion.

werf.io/resource-policy

A list of policies:

- `skip-create`: Do not create the resource if it doesn't exist in the cluster.
- `skip-update`: Do not update the resource if it already exists.
- `skip-recreate`: Do not recreate the resource when a recreation would otherwise be required.
- `skip-delete` (alias: `keep`): Do not delete the resource.

DP deletes a resource with `skip-delete` or `keep` together with the Application if its kind is listed in `orphanResources`. To keep the resource, also set `helm.sh/resource-policy: keep`.

werf.io/ownership

Allowed values:

- `release` (default for regular resources): Resource is deleted on uninstall and when absent from the chart. Release metadata annotations are applied.
- `anyone` (default for hooks): Resource is not deleted on uninstall. Release metadata annotations are not applied.

Use `anyone` for resources shared between releases or for resources that should survive their release (init Jobs with `werf.io/deploy-on: install`).

Resources that stay after uninstall, that is, hooks and resources with `werf.io/ownership: anyone`, are deleted by DP together with the Application if their kind is listed in `orphanResources`. To keep such a resource, set `helm.sh/resource-policy: keep`.

werf.io/deploy-on

Controls on which lifecycle operations the resource is rendered.

```
werf.io/deploy-on: pre-install,upgrade,post-install
```

Allowed values:

- `pre-install`
- `install`
- `post-install`
- `pre-upgrade`
- `upgrade`
- `post-upgrade`
- `pre-rollback`
- `rollback`
- `post-rollback`
- `pre-delete`
- `delete`
- `post-delete`

Default for regular resources: `install,upgrade,rollback`. Hooks are deployed on the events listed in `helm.sh/hook`.

> ⚠ If a resource is rendered for `install` but not `upgrade`, and `werf.io/ownership: release` is set, the resource will be **deleted on upgrade** because it is absent from the upgrade render. Set `werf.io/ownership: anyone` to prevent this.

werf.io/delete-policy

Controls when a resource is deleted relative to the `apply` operation.

Value	When
`before-creation`	Always recreate before `apply` (default for hooks)
`before-creation-if-immutable`	Recreate only on `field is immutable` error (default for Jobs)
`succeeded`	Delete after successful deploy
`failed`	Delete on readiness-check failure

Values can be combined with a comma: `before-creation,succeeded`.

werf.io/delete-propagation

Kubernetes deletion propagation strategy.

Value	Behavior
`Foreground` (default)	Wait for dependent objects to be deleted
`Background`	Delete resource immediately; dependents deleted asynchronously
`Orphan`	Delete resource; leave dependents

Tracking annotations

Annotation	Default	Description
`werf.io/track-termination-mode`	`WaitUntilResourceReady`	`WaitUntilResourceReady` or `NonBlocking`
`werf.io/fail-mode`	`FailWholeDeployProcessImmediately`	`FailWholeDeployProcessImmediately` or `IgnoreAndContinueDeployProcess`
`werf.io/failures-allowed-per-replica`	`1` for Deployment, StatefulSet, and DaemonSet, `0` for other kinds	Number of tracking errors per replica, for example, container restarts or image pull errors, allowed before the deployment fails. Ignored for Jobs
`werf.io/no-activity-timeout`	`4m`	Go duration; timeout on absence of events or status changes
`werf.io/show-service-messages`	`false`	Show Kubernetes Events in deploy output

Log annotations

> **i** DP doesn’t collect pod logs when it deploys Applications, so these annotations don’t affect the deployment.

Annotation	Default	Description
`werf.io/skip-logs`	`false`	Suppress all pod logs
`werf.io/skip-logs-for-containers`	—	Comma-separated list of containers to suppress
`werf.io/show-logs-only-for-containers`	—	Comma-separated list; only show logs for these containers
`werf.io/show-logs-only-for-number-of-replicas`	`1`	Show logs only for the first N replicas
`werf.io/log-regex`	—	RE2 pattern; show only matching lines

Annotation	Default	Description
`werf.io/log-regex-skip`	—	RE2 pattern; suppress matching lines
`werf.io/log-regex-for-<container>`	—	Per-container RE2 filter for showing
`werf.io/log-regex-skip-for-<container>`	—	Per-container RE2 filter for suppressing

Template functions

werf_secret_file

Embed the decrypted content of a file from the `secret/` directory:

```
data:
  config.yaml: {{ werf_secret_file "config.yaml" | b64enc }}
```

⚠ DP doesn’t provide a decryption key for Nelm secrets, so Application packages can’t use `werf_secret_file`, the `secret/` directory, or `secret-values.yaml`.

dump_debug, printf_debug, include_debug, tpl_debug

The functions `dump_debug` and `printf_debug` render nothing, and `include_debug` and `tpl_debug` render the same output as `include` and `tpl`. The functions write to the log only when Nelm debug logging is enabled. DP doesn’t enable it, so in Application packages these functions log nothing.

```
{{ dump_debug $ }}
{{ printf_debug "replicaCount: %d" .Values.replicaCount }}
{{ include_debug "myapp.labels" . | nindent 4 }}
{{ tpl_debug "{{ .Values.template }}" . }}
```

Known issues and troubleshooting

- **`null` values and SSA.** Server-Side Apply frequently fails on fields with a `null` value. If `.Values.foo` is `nil`, the manifest gets `foo: null`. Fix with `{{ if .Values.foo }}` guards or `default`.
- **`lookup` timing.** If cluster resources change between the Plan and Apply stages, the rendered plan may be stale. Avoid `lookup` for critical logic; pass data through values instead.
- **Non-deterministic functions.** `now`, `randAlphaNum`, `uuidv4`, and the unsorted output of `keys` produce different results on every render. DP applies the templates when the rendered manifests change, so such functions cause a redeployment in every reconciliation run.
- **`werf.io/deploy-dependency-*` and stages.** The annotation has no effect across deploy stages (pre/main/post). Cross-stage ordering is implicit in the stage sequence.
- **Resources that disappear after deployment.** DP checks every 4–5 minutes that all regular (non-hook) resources of the release exist and applies the templates again if one is missing (for details, refer to “Resource restoration”). Therefore, a regular Job that is deleted after it completes, for example, because of `werf.io/delete-policy: succeeded` or `ttlSecondsAfterFinished`, runs again after every check, and a deleted resource that is rendered only on install causes a redeployment after every check. Make such Jobs Helm hooks: DP doesn’t check hooks.

Additional resources

- Module `cert-manager` documentation

ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Hooks

Application hooks are written in Go using module-sdk. Deckhouse Platform (DP) runs them at certain stages of the application lifecycle, on changes of Kubernetes objects, and on schedule. Hooks prepare values for templates, create and change objects in the application namespace, and validate settings.

Hooks binary

All hooks of a package are compiled into a single Go binary. In the package skeleton, the sources are located in `hooks/batch/`, and `d8 package build` builds the binary according to `hooks/hooks.yaml` and puts it into the package bundle.

Each hook is registered with `registry.RegisterFunc`, and the `main` function calls `app.Run`:

```
// hooks/batch/main.go
package main

import (
    "github.com/deckhouse/module-sdk/pkg/app"

    "hooks/settings"
    _ "hooks/triggers"
)

func main() {
    app.Run(app.WithSettingsCheck(settings.Check))
}
```

Requirements for the binary:

- The hook source files must be located under a directory named `hooks`: module-sdk builds the hook name from the file path.
- The binary must register at least one hook. DP ignores a binary without hooks, even if it contains a settings validation hook.
- Build a static binary for Linux (`CGO_ENABLED=0`), as the skeleton does.

DP finds hooks by running each executable file without an extension from the `hooks/` directory of the bundle with the `hook list` argument. A binary that fails at this stage, for example, because of an invalid hook configuration, is skipped without an error in the Application status. To make sure that the hooks are registered, check the output of the following commands in CI:

```
cd hooks/batch
CGO_ENABLED=0 go build -o /tmp/hooks .
/tmp/hooks hook list
/tmp/hooks hook config
```

Hook example

```
package state

import (
   "context"

   corev1 "k8s.io/api/core/v1"
   metav1 "k8s.io/apimachinery/pkg/apis/meta/v1"

   "github.com/deckhouse/module-sdk/pkg"
   objectpatch "github.com/deckhouse/module-sdk/pkg/object-patch"
   "github.com/deckhouse/module-sdk/pkg/registry"
)

var _ = registry.RegisterFunc(&pkg.ApplicationHookConfig{
   OnBeforeHelm: &pkg.OrderedConfig{Order: 10},
   Kubernetes: []pkg.ApplicationKubernetesConfig{
      {
         Name:      "credentials",
         APIVersion: "v1",
         Kind:      "Secret",
         LabelSelector: &metav1.LabelSelector{
            MatchLabels: map[string]string{"example.com/credentials": "true"},
         },
         JqFilter: `{"name": .metadata.name}`,
      },
   },
}, handle)

type secret struct {
   Name string `json:"name"`
}

func handle(_ context.Context, input *pkg.ApplicationHookInput) error {
   secrets, err := objectpatch.UnmarshalToStruct[secret](input.Snapshots, "credentials")
   if err != nil {
      return err
   }

   // The path must be declared in openapi/values.yaml.
   input.Values.Set("internal.credentialsCount", len(secrets))

   // The ConfigMap is created as d8a-<INSTANCE_NAME>-state in the application
namespace.
   input.PatchCollector.CreateOrUpdate(&corev1.ConfigMap{
      TypeMeta:   metav1.TypeMeta{APIVersion: "v1", Kind: "ConfigMap"},
      ObjectMeta: metav1.ObjectMeta{Name: "state"},
      Data:      map[string]string{"instance": input.Instance.Name()},
   })

   return nil
}
```

Bindings and execution order

The `pkg.ApplicationHookConfig` structure defines when the hook runs:

Field	When the hook runs
`OnStartup`	Once after the package is loaded: on installation, after the package version changes, and after DP restarts. The hook doesn’t get snapshots
`OnBeforeHelm`	In every reconciliation run, before the templates are applied
`OnAfterHelm`	In every reconciliation run, after the templates are applied. If the hook changes values, DP applies the templates again

Field	When the hook runs
`OnBeforeDeleteHelm`	Before the Helm release is uninstalled: when the Application is deleted or when the package requirements stop being met. The hook doesn’t run when the package version changes
`OnAfterDeleteHelm`	After the Helm release is uninstalled, in the same cases as `OnBeforeDeleteHelm`
`Schedule`	On schedule in the crontab format
`Kubernetes`	When the watched objects in the application namespace change, and during the synchronization of the binding (for details, refer to “Kubernetes bindings”)

Other fields:

- `Queue`: Name of the queue for the `Schedule` and `Kubernetes` bindings of the hook (default: `main`). These bindings run in a queue separate from the lifecycle stages, so they can run at the same time as `OnBeforeHelm` or `OnAfterHelm` hooks.
- `AllowFailure` and `Settings` are not supported for applications.

Hooks with the same binding run in the ascending order of `Order` (the `pkg.OrderedConfig` field). The sequence of lifecycle stages is described in “Lifecycle and debugging”.

A hook can’t combine `OnStartup` with `Kubernetes` bindings: module-sdk panics when such a hook is registered, and DP skips the whole binary.

Error handling

- If a hook fails, the stage that ran it fails and is retried with an increasing delay, from 15 seconds up to 2 hours. The next tasks of the application wait. The error is reported in the Application’s `status.conditions` and `status.summary` fields.
- If an `OnBeforeDeleteHelm` hook fails, DP doesn’t uninstall the Helm release and retries the hook. The Application is not deleted until the hook succeeds.
- If an object operation of the hook fails, the hook run fails, and the values changes made by the run are discarded. The operations that have already been executed are not rolled back.

> ⚠ If a hook handler panics, module-sdk recovers from the panic and considers the hook execution successful. However, the handler results are not applied: changes to values and object operations are ignored. Do not use panic in hook handlers. Return errors instead.

ApplicationHookInput

The hook handler has the `func(ctx context.Context, input *pkg.ApplicationHookInput) error` signature. The `pkg.ApplicationHookInput` structure contains the following fields:

Field	Description
`Instance`	Instance parameters: `Name()` and `Namespace()`
`Snapshots`	Snapshots of the Kubernetes bindings of the hook
`Values`	Application values: reading (`Get`, `GetOk`, `Exists`, `ArrayCount`) and changing (`Set`, `Remove`)
`Settings`	Effective settings of the application, read-only
`PatchCollector`	Operations with objects in the application namespace (for details, refer to “Object operations”)
`DC`	Dependencies: an HTTP client (`GetHTTPClient`), a container registry client (`GetRegistryClient`), and a clock (`GetClock`)
`Logger`	Logger. The output is written to the DP log
`MetricsCollector`	Not supported for applications: DP ignores the metrics

Application hooks don’t get a Kubernetes client. To read objects, use Kubernetes bindings, and to change them, use `PatchCollector`.

The instance name and namespace are the only parameters of the instance available to hooks. The package name, version, and images are available only to templates.

Kubernetes bindings

The `pkg.ApplicationKubernetesConfig` structure describes the objects the hook watches:

Field	Description
`Name`	Binding name, the key in `Snapshots`
`APIVersion`, `Kind`	API version and kind of the objects. Only namespaced kinds are supported
`NameSelector`, `LabelSelector`, `FieldSelector`	Selection of objects
`JqFilter`	jq expression applied to each object. The snapshot contains the results of the expression. Without the expression, the snapshot contains full objects
`ExecuteHookOnEvents`	`false` — update the snapshot without running the hook when the objects change. Default: `true`
`ExecuteHookOnSynchronization`	`false` — don’t run the hook during the synchronization. Default: `true`
`WaitForSynchronization`	`false` — don’t wait for the synchronization of the binding before the next stages. It takes effect only if the `Queue` field of the hook is set. Default: `true`
`AllowFailure`	Ignore errors of the hook during the synchronization

Behavior:

- DP always restricts the bindings to the application namespace, so the structure has no namespace selector.
- On every run, the hook gets the snapshots of all its bindings: the current state of the objects, not the event that triggered the run.
- `OnBeforeHelm`, `OnAfterHelm`, `OnBeforeDeleteHelm`, and `OnAfterDeleteHelm` hooks get the snapshots too.
- DP synchronizes the bindings at the beginning of every reconciliation run: hooks with `ExecuteHookOnSynchronization` enabled run with the full list of objects.
- `NameSelector` matches the actual object names, including the `d8a-<INSTANCE_NAME>-` prefix.

The hook configuration is the same for all instances of the package, so selectors can’t refer to the instance name. If several instances of the package can be installed into the same namespace, add the instance label to the snapshot and compare it with `input.Instance.Name()`. Objects rendered from the templates carry the `packages.deckhouse.io/instance` label:

```
JqFilter: `{"name": .metadata.name, "instance":
.metadata.labels["packages.deckhouse.io/instance"]}`,
```

Object operations

`input.PatchCollector` collects the operations with objects. DP executes them after the hook completes:

Method	Description
`Create`	Create an object. The operation fails if the object exists
`CreateIfNotExists`	Create an object if it doesn’t exist
`CreateOrUpdate`	Create an object or replace the existing one. The fields that the hook doesn’t set are removed from the object
`Delete`, `DeleteInBackground`, `DeleteNonCascading`	Delete an object with foreground, background, or orphan propagation of the deletion. A missing object is ignored
`PatchWithJSON`, `PatchWithMerge`, `PatchWithJQ`	Patch an object with a JSON Patch (RFC 6902), a JSON Merge Patch (RFC 7396), or a jq expression. To patch a subresource, pass the `objectpatch.WithSubresource("status")` option

Behavior:

- module-sdk sets the application namespace in every operation, regardless of the namespace specified in the object.
- Typed objects must have `TypeMeta` with `apiVersion` and `kind` set. Otherwise, the operation is not executed.
- Patching a missing object fails the hook. Check that the object exists, for example, in a snapshot, before patching it.
- Objects created by hooks are not part of the Helm release, and DP doesn't add platform labels to them, so uninstalling the release doesn't delete them. To delete such objects together with the application, set the `packages.deckhouse.io/instance` label to the instance name and list their kind in `orphanResources`. You can also set an owner reference to an object of the release, or delete the objects in `OnBeforeDeleteHelm` or `OnAfterDeleteHelm` hooks.

Object names

DP adds the `d8a-<INSTANCE_NAME>-` prefix to the object name in every operation, unless the name already starts with it. For example, for the `myapp` instance:

- `Create` of the `state` ConfigMap creates `d8a-myapp-state`.
- `PatchWithMerge` of the `server` Deployment changes `d8a-myapp-server`, that is, the Deployment named `d8a-<INSTANCE_NAME>-server` in the templates.

As a result, a hook can change only the objects of its own instance. Objects with the `d8a-` prefix are protected from changes by users (for details, refer to "Templates").

Values

`input.Values` contains the application values: the same document the templates get as `.Values`. The settings are located at the root of the document, without the package name key.

- `Set(path, value)` and `Remove(path)` accept a path with dot-separated keys, for example, `internal.credentialsCount`. The parent object of the path must exist, so declare intermediate objects in `openapi/values.yaml` with `default: {}`.
- After the hook completes, DP validates the values against `openapi/values.yaml`. The schema must include the settings schema with `x-extend` (for details, refer to "Application settings"): the settings are located at the root of the values, and undeclared fields fail the validation.
- The values changes are kept in memory. After DP restarts or the package version changes, they are lost until the hooks run again.

What happens after the values change depends on the binding:

Binding	Result
`Kubernetes`, `Schedule`	DP starts a new reconciliation run
`OnAfterHelm`	DP applies the templates again
`OnStartup`, `OnBeforeHelm`, synchronization	The values are used when the templates are applied in the same run

`input.Settings` is read-only: hooks can't change the application settings.

Settings validation hook

Applications can include a settings validation hook for checks that the OpenAPI schema can't express, for example, business logic constraints across multiple settings fields.

The hook implements a `Check` function with the signature:

```
func Check(_ context.Context, input settingscheck.Input) settingscheck.Result
```

`settingscheck.Input` provides access to the settings (`input.Settings`) with the default values from `openapi/settings.yaml` applied, as well as to a logger (`input.Logger`).

`settingscheck.Result` is one of:

- `settingscheck.Allow(warnings...)` — settings are valid; optionally attach warning messages.
- `settingscheck.Reject(reason)` — settings are invalid.

Example:

```
func Check(_ context.Context, input settingscheck.Input) settingscheck.Result {
   replicas := input.Settings.Get("replicas").Int()
   if replicas == 0 {
      return settingscheck.Reject("replicas cannot be 0")
   }

   var warnings []string
   if replicas == 2 {
      warnings = append(warnings, "an even number of replicas may cause split-brain in
some configurations")
   }

   if replicas > 3 {
      return settingscheck.Reject("replicas cannot be greater than 3")
   }

   return settingscheck.Allow(warnings...)
}
```

To register the check, pass it to `app.Run` in the hooks binary: `app.Run(app.WithSettingsCheck(Check))`. A package can contain only one settings validation hook.

DP calls the check in the following cases:

- When the settings of an installed application are changed, and `spec.packageVersion` matches the installed version, the check runs in the validating webhook. A rejection denies the request with the specified reason. Warnings are returned to the client, for example, `d8 k` prints them.
- When DP applies changed settings. A rejection leaves the new settings unapplied, and the error is reported in the Application conditions. Warnings are ignored.

The check doesn't run in the validating webhook when an Application is created or `spec.packageVersion` changes: in these cases, the request is checked against the settings schema only. Describe critical constraints in the schema, for example, with CEL rules, to reject invalid settings before installation.

Restrictions

- Kubernetes bindings and object operations are limited to the application namespace, and object operations are also limited to the objects with the `d8a-<INSTANCE_NAME>-` name prefix.
- Hooks can't create or change cluster-wide objects.
- Readiness probes (`app.WithReadiness`) are intended for modules. Don't use them in applications: DP determines the application health from its workloads.
- Metrics of hooks are not collected.

Additional resources

- Global custom resources

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Lifecycle and debugging

This page describes how Deckhouse Platform (DP) runs an application instance and which tools help to debug a package.

Admission checks

When an Application is created or changed, the DP validating webhook checks that:

- The Application name is at most 24 characters long.
- The ApplicationPackage exists, and the ApplicationPackageVersion for the specified repository, package, and version exists and has its metadata loaded.
- The settings match the settings schema of the package version (for details, refer to "Application settings").
- The cluster meets the package requirements: the Kubernetes and DP versions and the module dependencies. The rejection message names the unmet requirement, the required value, and the value

in the cluster.

Installation pipeline

DP processes each application instance in a separate queue, step by step:

1. **Download.** DP downloads the package bundle of the specified version from the repository.
2. **Load.** DP reads `package.yaml`, the schemas, and `images_digests.json`, and discovers the hooks.
3. **Scheduling.** DP waits until the package requirements are met: the cluster bootstrap is complete, the Kubernetes and DP versions match the constraints, and the modules from `requirements.modules` are enabled. While DP waits for the modules the application depends on, the Application's `status.summary` field reports it.
4. **Configuration.** DP validates and applies the settings.
5. **Hook initialization.** DP enables the `schedule` bindings and the Kubernetes monitors of the hooks and runs the `Synchronization` of the Kubernetes bindings. The first time after the package is loaded, DP also runs `onStartup` hooks.
6. **Apply.** DP runs `beforeHelm` hooks, renders the templates and applies them with Nelm, and then runs `afterHelm` hooks. If `afterHelm` hooks change values, DP applies the templates again.

Steps 4–6 form a reconciliation run. In the apply step, DP upgrades the Helm release only if it is needed: on the first installation, if the last release revision is not deployed, if the rendered manifests have changed, or if some resources are missing in the cluster.

The order of hook bindings and the handling of hook errors are described in "Hooks".

Events and reactions

Event	Reaction of DP
The `spec.settings` or `spec.maintenance` field of the Application changes	A new reconciliation run
A `schedule` or Kubernetes hook changes values	A new reconciliation run
The `spec.packageVersion` field changes	DP stops the hooks of the current version while keeping its resources, and then goes through all steps with the new version. The templates of the new version are applied as an upgrade of the same Helm release
DP restarts	DP loads the package again and goes through all steps, including `onStartup` hooks
A resource of the application is deleted from the cluster	DP restores it (for details, refer to "Resource restoration")
The package requirements stop being met, for example, a module from `requirements.modules.mandatory` is disabled	DP uninstalls the application but keeps the Application (for details, refer to "Suspension")
The Application is deleted	DP uninstalls the application, deletes its orphan resources, and then removes the Application (for details, refer to "Deletion")

Suspension

DP checks the package requirements not only on admission but all the time. If the requirements of an installed application stop being met, DP does the following:

1. Runs `beforeDeleteHelm` hooks.
2. Uninstalls the Helm release, which deletes the resources of the application.
3. Runs `afterDeleteHelm` hooks.

The Application stays in the cluster in the `Suspended` state, and the orphan resources of the application are not deleted. When the requirements are met again, DP installs the application again with the same settings.

⚠ The resources are deleted together with the Helm release, including PersistentVolumeClaims. To keep the data, add the `helm.sh/resource-policy: keep` annotation to PersistentVolumeClaims (for details, refer to "Nelm annotations").

Deletion

When an Application is deleted, DP does the following:

1. Runs `beforeDeleteHelm` hooks.
2. Uninstalls the Helm release and waits until its resources are deleted.
3. Runs `afterDeleteHelm` hooks and stops the hooks: disables the `schedule` bindings and the Kubernetes monitors.
4. Deletes the orphan resources of the application.
5. Removes the Application.

If a step fails, DP retries it with an increasing delay, from 15 seconds up to 2 hours. The Application stays in the cluster until all steps succeed.

Orphan resources

Uninstalling the Helm release deletes only the objects of the release. The following objects stay in the namespace:

- Objects that the workloads or hooks of the application create at runtime.
- Objects of the templates that Nelm doesn't delete when it uninstalls a release, if they are still in the cluster (for details, refer to "Nelm annotations"):
  - Helm hooks, that is, objects with the `helm.sh/hook` annotation.
  - Objects with the `werf.io/ownership: anyone` annotation, for example, a Job that is deployed only on install.
  - Objects with the `helm.sh/resource-policy: keep` annotation and objects whose `werf.io/resource-policy` annotation contains `keep` or `skip-delete`.

To make DP delete such objects together with the Application, list their kinds in the `orphanResources` field of the values, as the default value of the field in `openapi/values.yaml`. For example:

```
x-extend:
  schema: settings.yaml
type: object
properties:
  orphanResources:
    type: array
    default:
      - kind: Job
        version: batch/v1
      - kind: ConfigMap
        version: v1
    items:
      type: object
      required: [kind, version]
      properties:
        kind:
          type: string
        version:
          type: string
```

Each item of the list contains the following fields:

- `kind`: Kind of the objects, for example, `Job`.
- `version`: API version of the kind: `<GROUP>/<VERSION>`, for example, `batch/v1`, or only `<VERSION>`, for example, `v1`. A version without a group matches the kind in every API group that serves it at this version, so `kind: Job` with `version: v1` matches the `batch/v1` Jobs too. To match the kind in one group only, specify the group.

Declare the field in `openapi/values.yaml` rather than in `openapi/settings.yaml`, so that users can't change the list in `spec.settings`. DP reads the list from the values of the current package version when the Application is deleted. If earlier versions of the package created objects of other kinds, keep these kinds in the list.

DP deletes the objects of the listed kinds that are located in the namespace of the Application and carry the `packages.deckhouse.io/instance: <INSTANCE_NAME>` label. The object names don't matter. DP adds the label to every object rendered from the templates, including Helm hooks (for details, refer to "Templates"). Objects created by workloads and hooks don't get the label automatically, so set it yourself. For example, a hook sets the label to the instance name:

```
input.PatchCollector.CreateOrUpdate(&corev1.ConfigMap{
   TypeMeta: metav1.TypeMeta{APIVersion: "v1", Kind: "ConfigMap"},
   ObjectMeta: metav1.ObjectMeta{
      Name:  "state",
      Labels: map[string]string{"packages.deckhouse.io/instance":
input.Instance.Name()},
   },
   Data: map[string]string{"instance": input.Instance.Name()},
})
```

A workload can get the instance name from the templates (`.Application.Instance.Name`), for example, in an environment variable.

DP deletes the objects after the Helm release is uninstalled and the hooks are stopped, so that the application can't create them again. Dependent objects are deleted in the background: for example, the Kubernetes garbage collector deletes the Pods of a deleted Job, so their kind doesn't need to be listed. DP doesn't wait until the objects are gone: an object with finalizers stays in the cluster until its finalizers are removed, even after the Application is deleted.

DP doesn't delete:

- Objects with the `helm.sh/resource-policy: keep` annotation, even if the `werf.io/resource-policy` annotation is set. Other annotations don't protect an object: DP deletes objects whose `werf.io/resource-policy` annotation contains `keep` or `skip-delete` and objects with the `werf.io/ownership: anyone` annotation, for example, the Job from "Resource rendered only on first install".
- Objects that are already being deleted.
- Objects of cluster-wide kinds and of kinds that the cluster doesn't serve, for example, custom resources whose CustomResourceDefinition is not installed. DP skips such kinds and writes a warning to its log.

DP deletes orphan resources only when the Application is deleted. When the application is suspended or its package version changes, the objects stay, because the application can use them again. If the package of the application isn't loaded when the Application is deleted, for example, because DP failed to download the package bundle, DP uninstalls the Helm release but doesn't delete orphan resources.

If DP fails to list or delete the objects, for example, when the API server is unavailable, DP deletes the rest of the objects and retries the step. If the `orphanResources` value is not a list of kinds, DP writes an error to its log and removes the Application without deleting orphan resources.

DP writes every deleted object, every object with the `helm.sh/resource-policy: keep` annotation and every skipped kind to its log: search the log for `orphan`. While DP retries the step, the queue of the application contains the `Purge` task with the error (for details, refer to "State in DP").

Resource restoration

DP remembers the resources rendered from the templates and checks every 4–5 minutes that all of them exist in the cluster. If a resource is missing, DP starts a reconciliation run, and the resource is created again.

DP checks only whether the resources exist, not their contents. The check is paused while hooks run and is disabled in maintenance mode.

Deployment tracking

When DP applies the templates, Nelm waits until the resources become ready. The waiting is controlled by the tracking annotations. Pod logs are not collected, so the log annotations have no effect.

The progress of the current apply is published in the `status.tracking` field of the Application: a list of Nelm operations with their states and dependencies.

One apply is limited to 30 minutes. When the limit is exceeded, DP cancels the apply, and the condition message names up to five resources DP was waiting for, for example:

```
install nelm release 'my-namespace.myapp': apply timed out after 30m0s, waiting for Job/d8a-myapp-migrate
```

Whether the application is running after the apply is determined from its Deployments and StatefulSets (see Workload health).

Maintenance mode

To debug or tweak an installed application manually, switch it to maintenance mode:

```
spec:
  maintenance: NoResourceReconciliation
```

In maintenance mode:

- DP stops applying the templates: changes of settings and values are not reflected in the resources. Hooks keep running.
- Deleted resources are not restored.
- DP labels the resources rendered from the templates with `maintenance.deckhouse.io/no-resource-reconciliation`, and the admission policies stop protecting them, so the resources can be changed manually. To add the label, DP applies the templates once when the mode is enabled.
- The `ApplicationIsInMaintenanceMode` alert fires.

To return the application to normal operation, remove the `spec.maintenance` field. DP applies the templates, which restores the managed state of the resources and removes the label.

Debugging

Application status

The following fields of the Application status are useful when you develop a package:

Field	Description
`status.summary`	High-level state of the application, the reason, and a hint on what to do
`status.conditions`	Detailed conditions (for details, refer to “Installing and managing applications”)
`status.currentVersion.version`	Installed package version
`status.lastAppliedConfiguration`	Effective settings of the last successful apply
`status.urls`	Application endpoints
`status.tracking`	Nelm progress report of the current or the last apply

Example:

```
d8 k -n <NAMESPACE> get applications <INSTANCE_NAME> -o jsonpath='{.status.summary}'
```

State in DP

The `deckhouse-controller packages` command shows the state of the application in DP. The package name in this command is formatted as `<NAMESPACE>.<INSTANCE_NAME>`. Run the command in the `deckhouse` container of the DP leader pod.

> ⚠ The output contains values and container registry credentials. Only cluster administrators should have access to it.

- To render the templates with the current values, run the following command:

  ```
  d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller packages render <NAMESPACE>.<INSTANCE_NAME>
  ```

- To show the loaded package (path, definition, image digests, repository, values, hooks, and internal conditions), run the following command:

  ```
  d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller packages dump --name <NAMESPACE>.<INSTANCE_NAME>
  ```

- To show the snapshots of the hook Kubernetes bindings, run the following command:

  ```
  d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller packages snapshots <NAMESPACE>.<INSTANCE_NAME>
  ```

- To show the task queues of the application, run the following command:

```
d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller packages queue dump --name <NAMESPACE>.<INSTANCE_NAME>
```

- To show the scheduler state of the application (for example, which requirement is not met), run the following command:

```
d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-controller packages scheduler dump --name <NAMESPACE>.<INSTANCE_NAME>
```

Logs

DP writes the application processing events, including the output of hooks, to its log:

```
d8 k -n d8-system logs svc/deckhouse-leader -c deckhouse | grep '<NAMESPACE>.<INSTANCE_NAME>'
```

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Disaster resilience

Disaster resilience is the ability of infrastructure based on Deckhouse Platform (DP) to remain operational in the event of large-scale failures. It is achieved through distributed deployment, automatic traffic switching, and replication of critical components.

DP implements two approaches to disaster resilience:

- Geo-distribution, which is a distribution of infrastructure components across different availability zones (Multi-AZ) or regions (Multi-Region). This approach helps reduce the impact of infrastructure failures on application availability. For details, refer to Geo-distribution.
- Geo-reserving, which is based on using multiple independent clusters combined into a multi-cluster system. If one of the clusters becomes unavailable, traffic can be automatically redirected to another. For details, refer to Geo-reserving.

Both approaches require configuring network connectivity between nodes and regions, traffic balancing, and proper storage organization. The choice of an architecture depends on the specifics of applications and infrastructure constraints.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Geo-distribution

Geo-distribution, in the context of disaster resilience in Deckhouse Platform (DP), is an architectural approach that ensures continuous cluster operation by distributing its components across multiple availability zones (Multi-AZ) or regions (Multi-Region). This approach minimizes the risks of incidents of various scales.

> ⚠ When implementing geo-distribution, it’s important to ensure network connectivity between cluster nodes. This is the responsibility of the platform administrator.

Using multiple availability zones (Multi-AZ)

DP lets you distribute cluster nodes across availability zones. This approach increases application resilience to infrastructure-wide failures and ensures the applications remain functional even if one of the zones in a data center or cloud becomes unavailable.

An **availability zone (AZ)** is the basic unit of a disaster-resilient architecture. It represents a logical group of one or several data centers located within a few kilometers of each other. An AZ can be viewed as an isolated unit (a virtual data center), even though it's a physically distributed infrastructure. Availability zones are part of regions.

Availability zone features

Availability zones are defined by the following features:

- Sufficient physical separation between data centers within the same AZ (usually ≤10 km) to protect from localized incidents (such as floods or fires), while maintaining low network latency.
- Independent power supply for components within the zone (different substations, diesel generators, etc.).
- Use of different providers and network routes by components within the zone.
- Relatively low latency within the zone.

Distributing nodes across zones

With most cloud providers, zone distribution happens automatically. In non-cloud environments, administrators must manually label nodes to indicate the target zone.

For the node labeling process and how to add nodes to groups, refer to "Node management".

Using multiple regions (Multi-Region)

DP supports distributing cluster nodes across different regions. This approach allows applications to continue running even in the event of a complete outage of a data center or cloud provider.

A **region** is an independent geographic area that includes several (typically at least three) isolated availability zones (AZs). All zones within a region are united into a single logical infrastructure unit with shared management services. A region is a key element in the global distributed architecture used by cloud providers.

> **i** Using multiple regions (Multi-Region) is usually appropriate only when applications can work independently in each region (without reaching out to others). This is due to the relatively high latency between regions. Typical use cases include hosting CDN cache servers or distributed monitoring nodes.

Region features

Regions are defined by the following features:

- Latency differences within a region and between regions. Within a region, latency between AZs can be around 5 ms. Between regions, it can be between 50 and 200 ms.
- Geographic distance. Regions may be widely dispersed. For example, the distance between `europe-west3` (Frankfurt) and `us-east-1` (Virginia) is around 6500 km.
- Physical safety. Providers try to place regions outside of seismically or politically unstable areas.
- Energy redundancy. Regions are usually connected to multiple national power grids (for example, `me-central-1` (UAE) uses 4 independent power sources).

Distributing nodes across regions

Distributing nodes across regions requires the following:

- Labeling each node to indicate the region it belongs to.
- Providing stable communication channels between regions.

For the node labeling process and how to add nodes to groups, refer to "Node management".

Balancing incoming traffic

In a geo-distributed cluster, traffic balancing can be handled either by the cloud provider or by internal load balancers (such as MetalLB). The specific implementation depends on the infrastructure and must be configured by the administrator. For details on traffic balancing options and configuration, refer to Network.

Storage organization

Storage system organization and configuration in a geo-distributed cluster are handled by the administrator. DP supports various storage options and the choice depends on the specific project needs. For details on

supported storage systems, their features and configuration, refer to Storage.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Geo-reserving

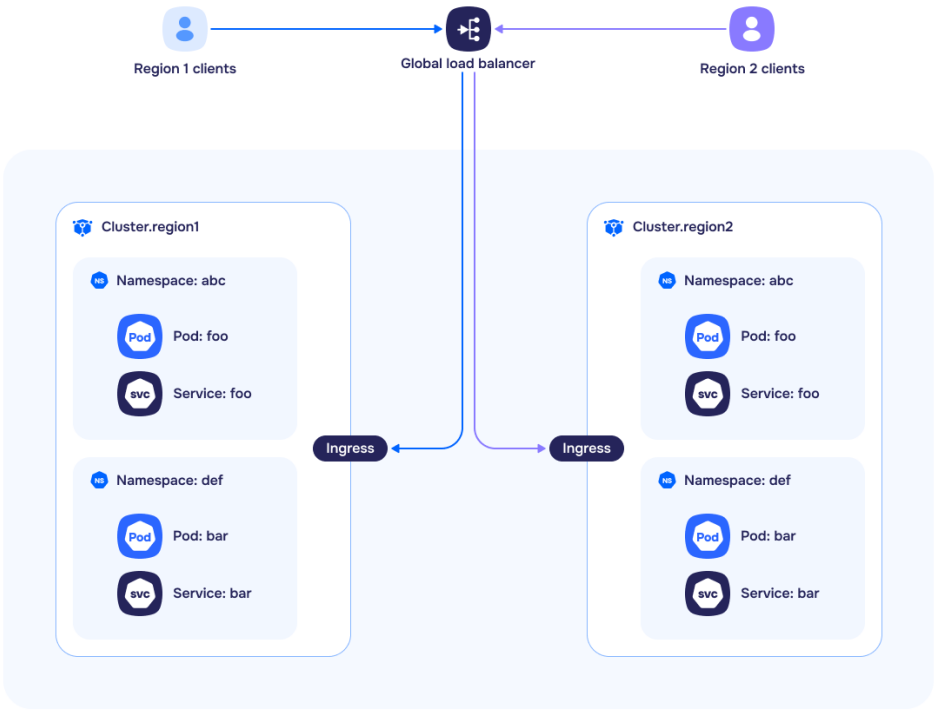
Geo-reserving, in the context of disaster resilience in Deckhouse Platform (DP), is a method of increasing fault tolerance by combining multiple independent Kubernetes clusters into a single multi-cluster system (multi-cluster) distributed across different geographic locations.

DP offers several tools to unite multiple clusters into a multi-cluster. This approach ensures automatic routing of both external and internal traffic to another cluster with an available copy of the application, in case it becomes unavailable in the original cluster.

Clusters can be combined using:

- The built-in Istio-based Service Mesh.
- DP's networking features powered by Cilium.

Enabling multi-cluster functionality requires deploying one DP cluster per region and then connecting them using a declarative API. It is important that the application can run in parallel across different regions, and that there is a stable network connection between the regions. A properly configured system ensures global disaster resilience for the application, guaranteeing uninterrupted operation even if an entire region or cloud becomes unavailable.



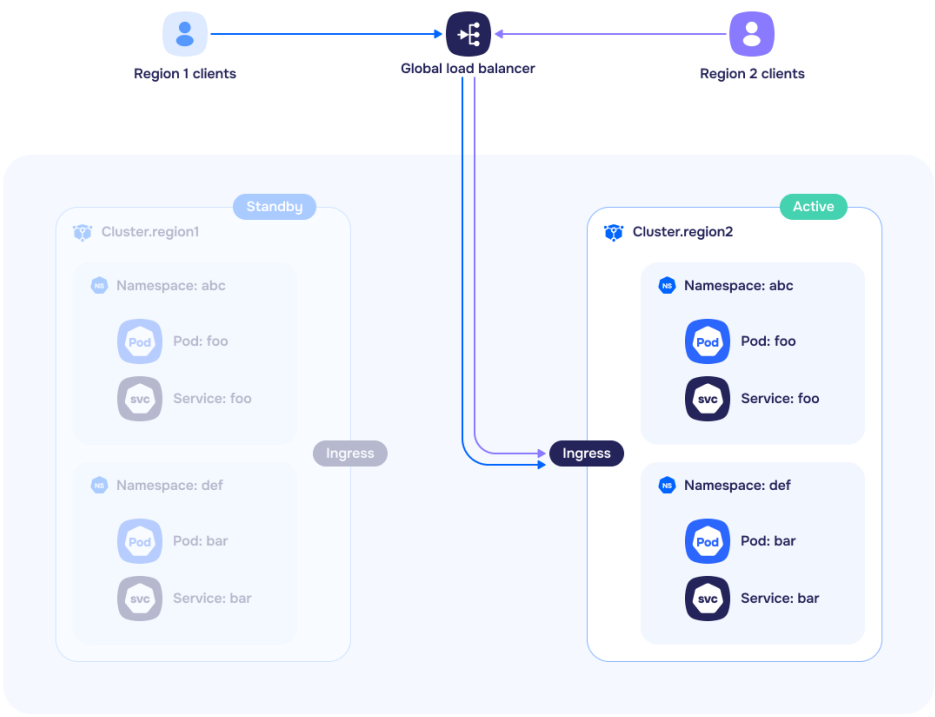
For the process of joining multiple clusters into a multi-cluster, refer to Inter-cluster cooperation.

Balancing incoming traffic in a multi-cluster

To ensure disaster resilience in a multi-cluster, incoming traffic can be balanced by an external load balancer using one of the following methods: `active-active` or `active-standby`. The balancing configuration is handled by the cluster administrator.

Balancing traffic via active-active method

Following the `active-active` method, the external load balancer distributes traffic across multiple active clusters, for example, based on geographic proximity or current workload.



Key aspects of `active-active` balancing:

- All clusters in the multi-cluster process traffic simultaneously.
- Traffic is routed to the nearest and least loaded cluster, or according to other defined rules.
- Shared data is replicated across clusters.
- In the event of a failure in one cluster, traffic is automatically rerouted to the others (automatic failover).

Balancing traffic via active-standby method

Following the `active-standby` method, the external load balancer routes traffic only to the currently active cluster. The standby cluster remains idle and receives traffic only if the primary cluster becomes unavailable.

Key aspects of `active-standby` balancing:

- The active cluster receives all traffic.
- The standby cluster remains idle until the primary cluster fails.
- Traffic failover to the standby cluster is performed automatically upon detection of issues.

Storage organization in a multi-cluster

Storage system organization and configuration in a multi-cluster are handled by the administrator. DP supports various storage systems. The choice of a suitable solution depends on requirements of performance, fault tolerance, and data synchronization methods. For details on supported storage systems, their features and configuration, refer to Storage.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Updating

Releases

A release is any published version of Deckhouse Platform (DP). Each release is distributed through release channels with defined delays. DP publishes two types of releases:

- **Patch version** (for example, from `0.0.1` to `0.0.2`): Includes bug fixes and is published when needed.
- **Minor version** (for example, from `0.0.1` to `0.1.0`): Includes new features and is published every 3–4 weeks.

Release channels

> **i** Up-to-date information about DP versions available on different release channels is available at releases.deckhouse.io.

DP uses **five release channels** to gradually roll out new versions. Each new DP version is first published to the **Alpha** channel and then gradually moves to **Rock Solid**. Updates in less stable channels are made available to a limited number of users, which allows to detect and resolve potential issues before they affect production environments.

- **Rock Solid**: The most stable release channel. Ideal for clusters requiring maximum reliability. Updates are published at least 30 days after the release.
- **Stable**: A stable channel suitable for production clusters. Updates are published at least 14 days after the release.
- **Early Access**: The recommended release channel if you're unsure which one to choose. Suitable for actively evolving clusters (for example, those launching or refining new applications). Updates are published at least 7 days after the release.
- **Beta**: Intended for development clusters, similar to the Alpha channel. Receives versions that have already been tested in Alpha.
- **Alpha**: The least stable channel with the most frequent updates. Targeted at development clusters with a small number of developers. Versions appear immediately after release.

Switching to a more stable channel

When switching to a more stable channel (for example, from `Alpha` to `EarlyAccess`):

1. DP fetches release data from the `EarlyAccess` channel.
2. It compares this data with existing DeckhouseRelease custom resources in the cluster.
   - If the cluster contains newer releases with `Pending` status (not yet applied), they will be **removed**, since they haven't been published to the new channel.
   - If newer releases have already been marked as `Deployed` (installed successfully), the switch won't take effect immediately. DP will remain on the current release until a newer version becomes available in the `EarlyAccess` channel.

Switching to a less stable channel

When switching to a less stable channel (for example, from `EarlyAccess` to `Alpha`):

1. DP fetches release data from the `Alpha` channel.
2. It compares this data with existing DeckhouseRelease custom resources.
3. It applies the update according to the configured update parameters.

Control plane updates

In DP, the control plane update process is highly automated and safe for both single-master and multi-master clusters. While brief interruptions in API server availability may occur, they do not affect the operation of applications running in the cluster. In most cases, no additional maintenance window is required.

DP supports the latest five minor Kubernetes versions. A full list of supported versions is available in the corresponding table.

Patch version updates

Patch updates to control plane components (within the same minor version, for example, from `1.35.3` to `1.35.5`) are applied automatically together with DP updates. Users cannot manage patch updates manually. The process is fully automated by the platform.

Automatic minor version updates

To automatically update the control plane to a new minor version (for example, from `1.34.*` to `1.35.*`), specify `kubernetesVersion: Default` in the `control-plane-manager` ModuleConfig. DP will select the default Kubernetes version at the time of the update.

Manual minor version updates

To manually update the control plane to a new minor version (for example, from `1.34.*` to `1.35.*`), specify the target version in the `kubernetesVersion` parameter of the `control-plane-manager` module. For example, `kubernetesVersion: 1.35`.

```
d8 k edit mc control-plane-manager
```

The command opens the `control-plane-manager` ModuleConfig for editing. After the change is saved, DP starts the upgrade to the specified version. To track the upgrade progress, check the Kubernetes version in

the output of the node description command:

```
d8 k get nodes
```

Process of control plane component updates

1. The control-plane-manager module modifies the manifests of core components (`apiserver`, `controller-manager`, `scheduler`, etc.).
2. The updated components are deployed on all master nodes.

When performing a minor version upgrade:

- If bumping for more than one minor version (for example, from `1.33` to `1.35`), the update happens in stages: `1.33` → `1.34` → `1.35`.
- At each step, the control plane is updated first, followed by the kubelet upgrade on the nodes.

When performing a downgrade:

- Only a single minor version downgrade is supported from the highest version ever used in the cluster.
- The downgrade occurs in reverse order. Kubelet components on the nodes are downgraded first, followed by the control plane components.

After the control plane has been updated, node updates begin:

1. The Bashible API Server updates the kubelet version in the scripts for all NodeGroups.
2. Nodes in different NodeGroups are updated in parallel, but within each NodeGroup, they are updated sequentially (one by one).
3. Each NodeGroup's update settings are taken into account:
   - Manual or automatic update mode.
   - Update windows.
   - Whether Pods should be evicted before updating, etc.
4. One or more candidate nodes that meet all update conditions are selected and updated.
5. The process repeats until all nodes in all groups are updated.
6. When all nodes are updated, the update process is complete.

Retrieving the changelog

Each new version of DP includes a *changelog*, which is a detailed list of changes, including new features, bug fixes, component updates, and important compatibility notes.

You can find the changelog for a specific DP version in the Deckhouse release list on GitHub.

A summary of key changes, component version updates, and which cluster components will be restarted is included in the description of the zero patch release: example for DP v1.68.

Changelog contents

The changelog includes four sections:

- **Know before update**: Critical information to consider before updating. Includes compatibility requirements, pre-update actions, and possible cluster impacts.
- **Features**: Highlights of key improvements and new features introduced in the release.
- **Fixes**: Minor changes, security updates, and performance improvements.
- **Chore**: Technical updates, such as dependency updates, refactoring, build and test pipeline changes, and vulnerability fixes.

Minor versions and zero patch releases

All major changes are listed in the **zero patch release** (for example, `v1.68.0` for the DP `v1.68`). Before updating to a new minor version (for example, `v1.68`):

1. Review the changelog for the corresponding version.
2. Check if the changes affect your infrastructure.
3. Adjust the cluster configuration if needed.

Checking dependencies before update

Before applying a new release, DP checks the cluster for potential issues. If any of the following incompatibilities are detected, the update is aborted:

- Unsupported Kubernetes version.
- When `kubernetesVersion: Automatic` is enabled, the update is aborted if:
  - The release introduces a new default Kubernetes version;
  - Monitoring is enabled;
  - The cluster contains resources that are deprecated in the new version.
- The installed Ingress controller version is incompatible with the new release.

- Nodes are running outdated or unsupported operating systems.
- The cluster has an enabled module that is `deprecated` or has been removed in the new release.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Deckhouse subsystem

This subsection describes the architecture of the modules that are part of the Deckhouse subsystem of Deckhouse Platform (DP).

The Deckhouse subsystem includes the following modules:

- `deckhouse`: Deckhouse controller.
- `console`: Deckhouse web UI.
- `deckhouse-tools`: Provides a web interface for downloading the `d8` CLI utility.
- `documentation`: Provides a web interface with documentation corresponding to the running DP version.
- `registry`: Manages the configuration of DP components responsible for working with the container registry and provides an internal image storage.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

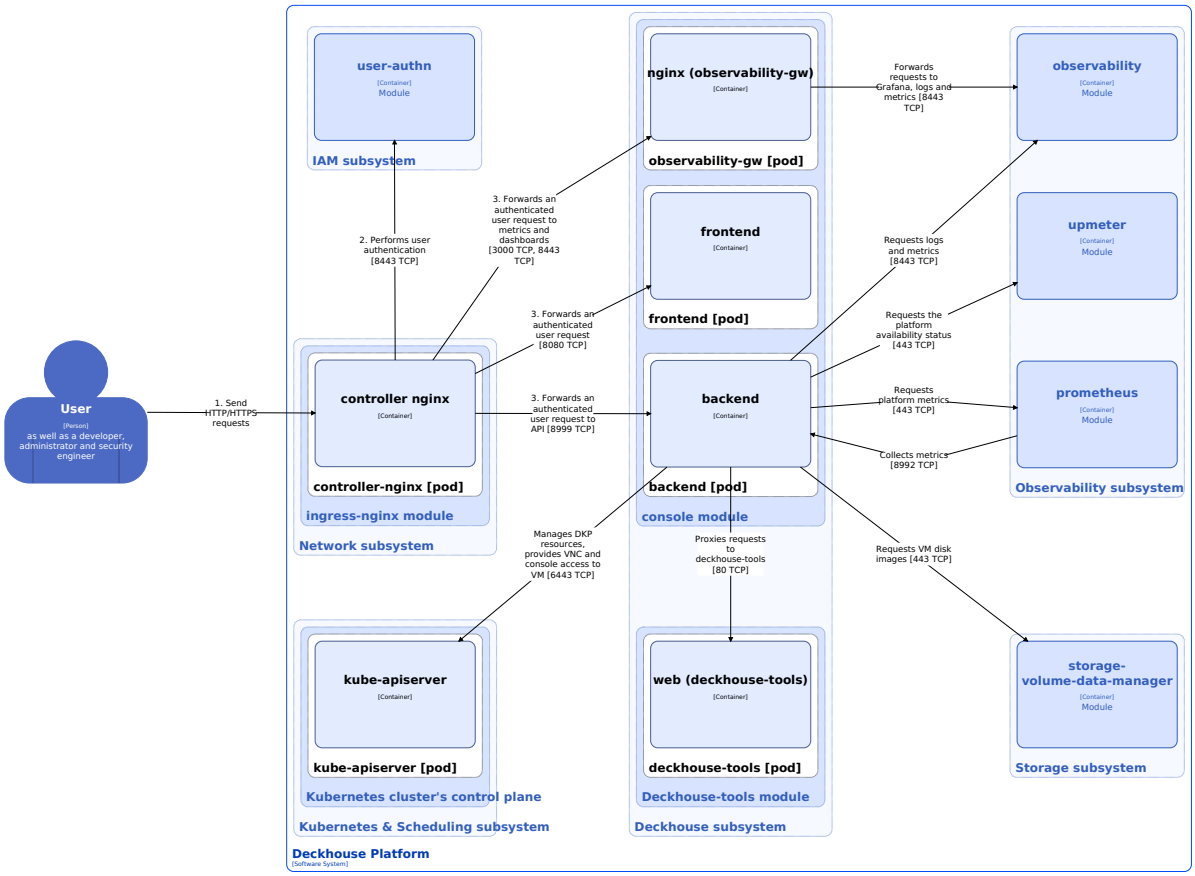
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Web interface modules



Console module

The `console` module implements the web interface of Deckhouse Platform (DP), simplifying platform management and enabling the system state monitoring.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `console` module and its interaction with other DP components are shown in the following diagram:

> **i** The numbers in the diagram indicate the order in which the user's request passes through the `frontend`, `backend`, and `nginx` components.
>
> At steps 1, 2, and 3, the request passes through the Ingress NGINX Controller, where mandatory user authentication is performed by the `user-authn` module. For more information about the architecture of the `user-authn` module, refer to the corresponding documentation section.

Module components

The module consists of the following components:

1. **Frontend**: Consists of a single **frontend** container and provides the web interface for DP users and administrators.
2. **Backend**: Consists of a single **backend** container and implements an API interface that provides the following capabilities:
   - Retrieving, creating, deleting, and modifying DP resources according to the user's permissions.
   - Generating a kubeconfig with the user's profile.
   - Determining the environment in which the DP cluster is deployed.
   - Detecting DP and Kubernetes versions.
   - Loading metrics and logs.
   - Loading platform availability information.
   - Downloading VM disks (when the `virtualization` and `storage-volume-data-manager` modules are enabled).
3. **Observability-gw**: Consists of a single **nginx** container and proxies requests to Grafana to embed dashboards into the platform's main web UI, as well as to work with metrics and logs for the selected project.

Module interactions

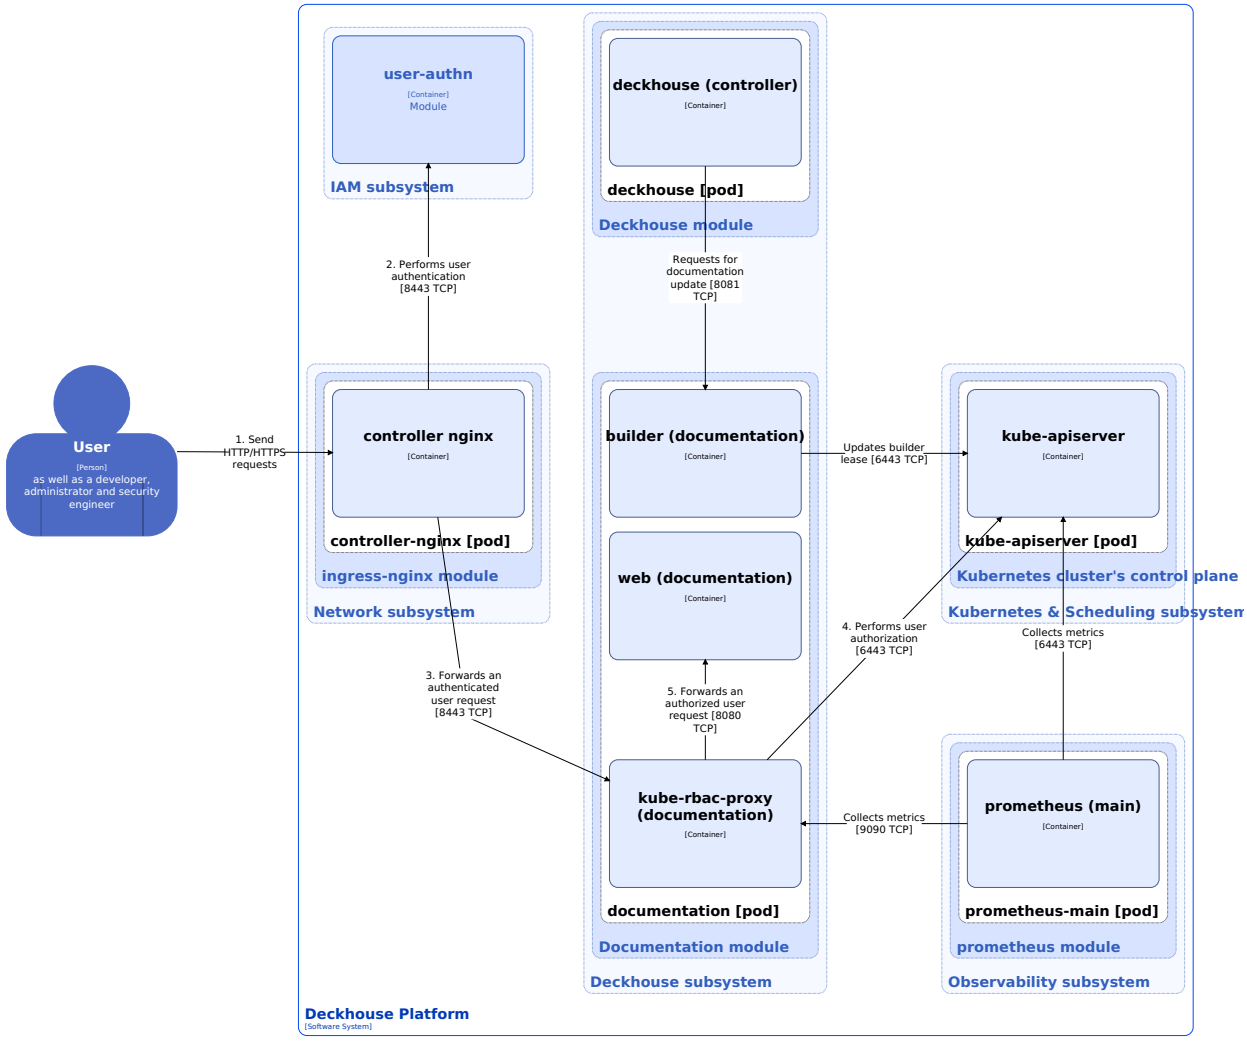
The module interacts with the following components:

1. **Kube-apiserver**:
   - Establishing VM connections via console and VNC.
   - Creating, deleting, modifying, and tracking DP resources.
2. **Upmeter**: Retrieves DP availability information.

3. **Deckhouse-tools**: Forwards requests to download the Deckhouse CLI utility.
4. **Prometheus**: Retrieves system metrics for the platform, such as CPU and RAM usage.
5. **Observability**: Retrieves metrics and logs for the selected project.
6. **Storage-volume-data-manager**: Exports VM disk images.

The following external component interacts with the module:

- **Controller nginx**: Forwards external user requests to the module web interface.



Documentation module

The `documentation` module provides a web interface for documentation corresponding to the running version of DP.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `documentation` module and its interaction with other DP components are shown in the following diagram:

> **i** The numbers in the diagram indicate the order in which the user's request passes through the `web` component:
>
> - At steps 1, 2, and 3, the request passes through the Ingress NGINX Controller, where mandatory user authentication is performed by the `user-authn` module.
> - At steps 4 and 5, user authorization based on the Kubernetes RBAC is performed to provide secure access.

Module components

The module consists of the following component:

- **Documentation**: A component that provides the documentation web interface.

  It consists of the following containers:

  - **web**: Main container.
  - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the main container. It is an open source project.
  - **builder**: Sidecar container that dynamically extends the documentation when new DP modules are installed. The Hugo static site generator is used to render and generate the up-to-date site content.

    The **builder** container automatically creates and updates a Kubernetes Lease resource, placing an endpoint for documentation updates. This endpoint is used by the `deckhouse` module controller to initiate documentation updates when modules are updated or installed. This ensures that changes are promptly rendered in the web interface.

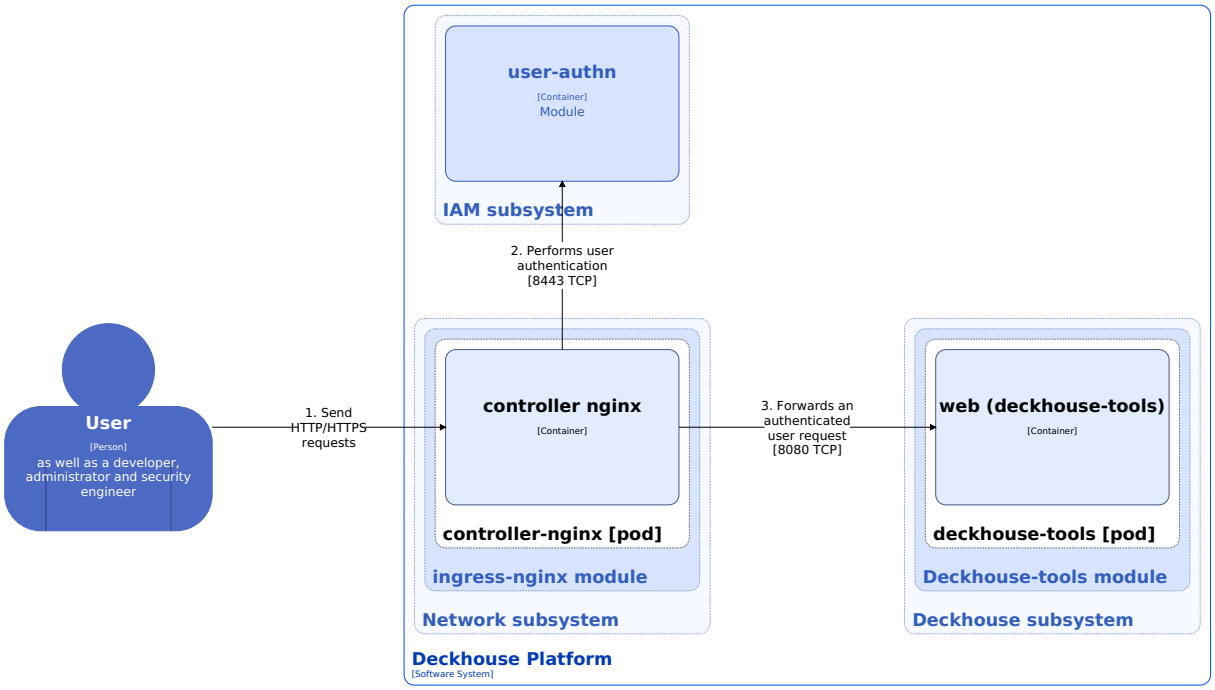
Module interactions

The module interacts with the following components:

- **Kube-apiserver**:
  - Creates and updates the Lease resource.
  - Authorizes requests to the documentation web interface.

The following external components interact with the module:

1. **Deckhouse**: Sends requests to update the documentation when the set of modules changes.
2. **Prometheus**: Collects module metrics.
3. **Controller nginx**: Forwards external user requests to the module web interface.



Deckhouse-tools module

The `deckhouse-tools` module provides a web interface with links to download the Deckhouse CLI utility for various operating systems.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `deckhouse-tools` module and its interaction with other DP components are shown in the following diagram:

> **i** The numbers in the diagram indicate the order in which the user's request passes through the `web` component.
>
> At steps 1, 2, and 3, the request passes through the Ingress NGINX Controller, where mandatory user authentication is performed by the `user-authn` module.

Module components

The module consists of the following component:

- **Deckhouse-tools**: Consists of a single **web** container and provides a web interface with links to download the Deckhouse CLI utility.

Module interactions

The following external component interacts with the module:

- **Controller nginx**: Forwards external user requests to the module web interface.

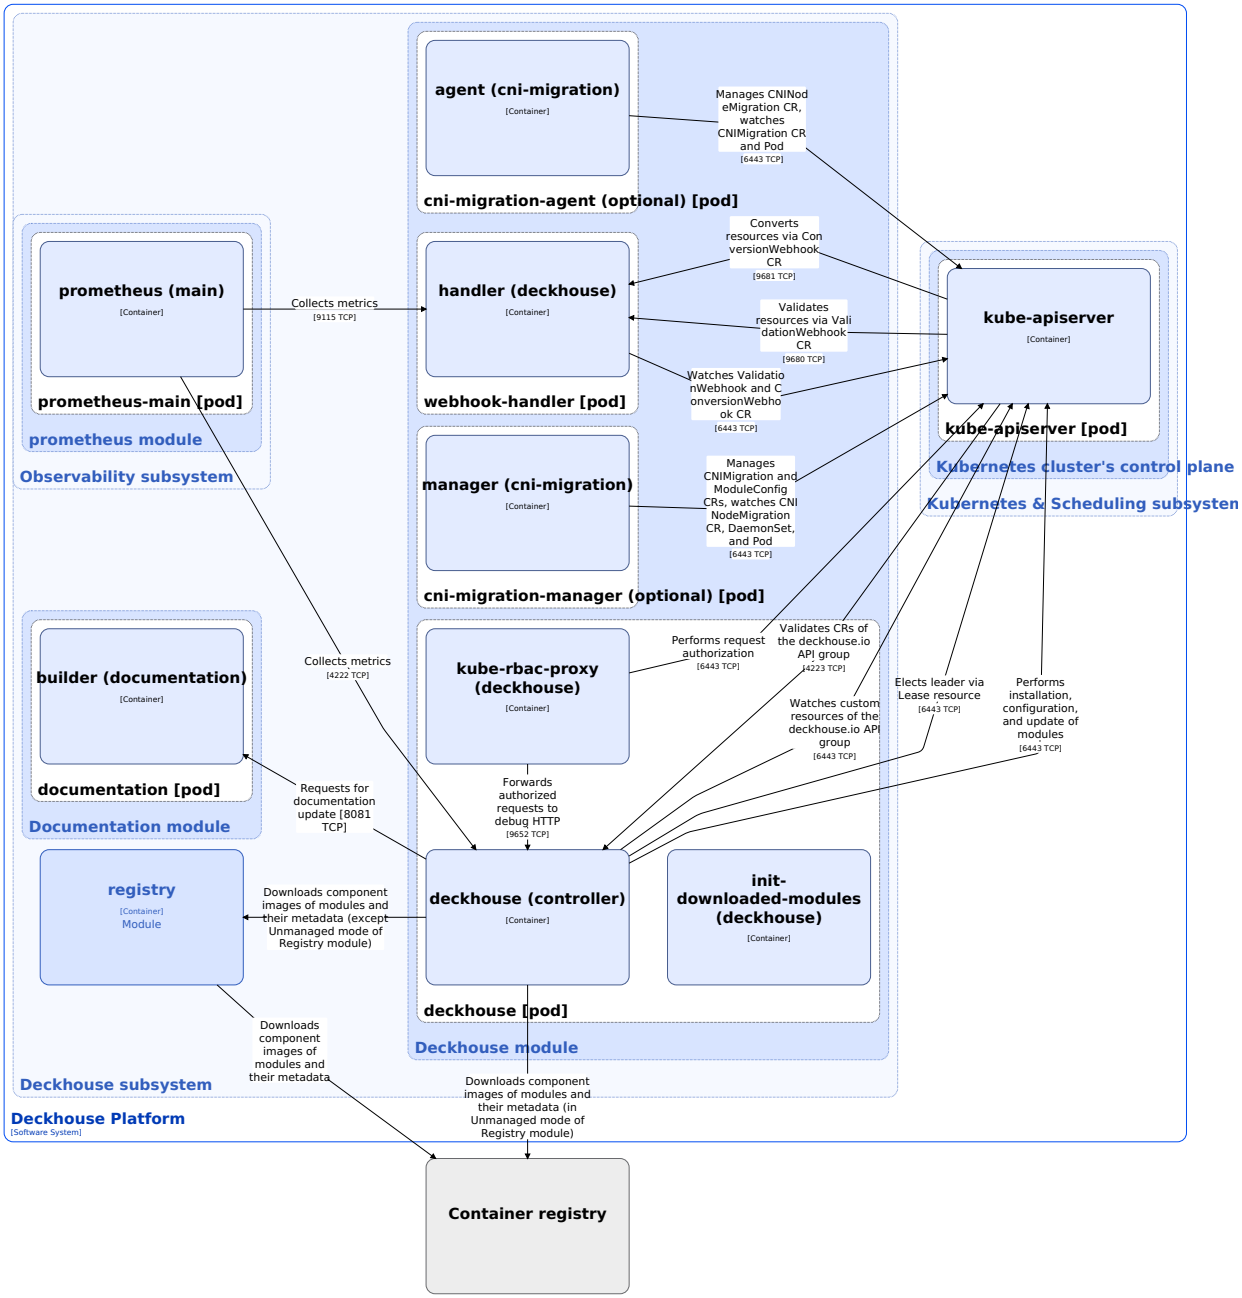
Deckhouse module

The `deckhouse` module implements the core of Deckhouse Platform (DP), performing the following operations:

- Platform updates
- Module configuration management
- Module installation and updates

- Module documentation build triggering
- Validation of custom resources managed by DP modules



The module manages the following custom resources in the `deckhouse.io` API group:

- Module management:
  - Module: Description, status, and publication of module information.
  - ModuleConfig: Description of user-defined module settings.
  - ModulePullOverride: Description of module version selection overrides.
  - ModuleRelease: Description, publication, and tracking of module releases.
  - ModuleSettingsDefinition: Schema, versions, and transformation rules for module settings.
  - ModuleSource: Description of a module source, repository, or storage.
  - ModuleUpdatePolicy: Rules for module updates and version transition automation.
- Platform management:
  - DeckhouseRelease: An object that defines the DP release (version) and platform update policy.
- Package management (Marketplace):
  - Application: An installed instance of an application package and its settings.
  - ApplicationPackage: Aggregated information about a package: the repositories that provide it, the versions the release channels point to, and the applications that use it.
  - ApplicationPackageVersion: A discovered package version: its metadata, OpenAPI schemas, and requirements.
  - PackageRepository: Connection to a container registry with packages and the scan schedule.
  - PackageRepositoryOperation: A scan operation that discovers package versions in a repository.
- Utility management:
  - CNIMigration: Container Network Interface (CNI) migration process, including migration parameters and status.
  - CNINodeMigration: Status and management of CNI migration at the individual node level.
  - ObjectKeeper: A resource that links Kubernetes resources using `ownerReference`.
- Management of custom resources controlled by DP modules:
  - ConversionWebhook: Settings and handlers for resource conversion webhooks.
  - ValidationWebhook: Settings and handlers for resource validation webhooks.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `deckhouse` module and its interaction with other DP components are shown in the following diagram:

Module components

The module consists of the following components:

1. **Deckhouse** (Deployment): A controller that implements platform management operations.

   The controller coordinates platform management tasks using the queueing mechanism.

   The Deckhouse controller can run in standard mode or in hook isolation mode. To enable it, create the `chroot-mode` ConfigMap in the `d8-system` namespace. In isolation mode, shell hooks and module enable scripts run in a chroot environment with a limited set of mounted directories, isolating them from the controller container file system.

   If High Availability (HA) mode is enabled, multiple Deckhouse controller instances are started. To ensure correct behavior, Deckhouse controllers perform leader election using the `deckhouse-leader-election` Lease resource. The controller elected as leader performs all platform management operations.

   In addition, you can set the following parameters using the Deckhouse controller:

Module configuration parameter	Description
`logLevel`	Logging level
`bundle`	Set of modules enabled by default
`releaseChannel`	Release channel

Module configuration parameter	Description
`update.mode`	Update mode
`update.windows.days`	Update windows

For details about module settings, refer to the module documentation section.

It consists of the following containers:

- **init-downloaded-modules**: Init container that prepares the directory structure required for module operations.
- **deckhouse**: Main container.
- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the main container component debug interface.

2. **Webhook-handler** (Deployment): Consists of a single **handler** container and implements a generic webhook for conversion and validation of custom resources managed by DP.

   The component watches ConversionWebhook and ValidationWebhook custom resources and, based on them, generates hook Python files for shell-operator from templates. When `kube-apiserver` sends resource validation or conversion requests, shell-operator runs the required hook and returns the processing result.

3. **Cni-migration-manager** (Deployment): An optional component running on control plane nodes, consisting of a single **manager** container. The component manages the network plugin (CNI) switching process in the DP cluster and records the current state in the CNIMigration custom resource. Migration to Flannel, Simple bridge, and Cilium is supported. For details on switching CNI in the cluster, refer to the corresponding guide.

   > **i** The component is created by the `detect-cni-migration` global hook when the CNIMigration custom resource exists. The CNIMigration resource is created manually by an administrator or by running the `d8 network cni-migration switch --to-cni <target cni>` command.

4. **Cni-migration-agent** (DaemonSet): An optional component running on all cluster nodes, consisting of a single **agent** container. The component watches the CNIMigration custom resource and manages the CNINodeMigration custom resource that reflects migration state for a specific node.

   > **i** The component is created by the `detect-cni-migration` global hook when the CNIMigration custom resource exists. The CNIMigration resource is created manually by an administrator or by running the `d8 network cni-migration switch --to-cni <target cni>` command.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Working with custom resources in the `deckhouse.io` API group.
   - Watching Pod and DaemonSet resources, as well as restarting Pods when the network plugin is changed.
   - Watching resources described in the ObjectKeeper custom resource.
   - Creating and updating Lease resources.
   - Creating, deleting, modifying, and watching resources described in DP modules.
   - Authorizing requests.
2. **Documentation**: Updating documentation when a DP module is added or updated.
3. **Container registry**: Retrieving module component images along with metadata when the `registry` module is installed in `Unmanaged` mode.
4. **`registry` module**: Retrieving module component images along with metadata when the `registry` module is installed in one of the following modes: `Direct`, `Proxy`, or `Local`.

The module is interacted with by the following external components:

- **Kube-apiserver**: Validation and conversion of DP custom resources.
- **Prometheus-main**: Collecting metrics from the `deckhouse` and `webhook-handler` containers.

Queuing mechanism

The `deckhouse` module implements the core of Deckhouse Platform (DP), performing various platform management operations using a queueing mechanism. For more information about the module architecture, refer to the corresponding documentation section.

The Deckhouse controller implements addon-operator and marketplace queues.

Addon-operator queues

The **addon-operator queues** are the primary processing mechanism for built-in and external DP modules. The queue is implemented in shell-operator and extended with addon-operator task types. The Deckhouse controller synchronizes ModuleConfig custom resources and updates global or module values for addon-operator.

Task types:

Task	Function
GlobalHookRun	Runs global hooks (`onStartup`, `beforeAll`, `afterAll`, `kubernetes`, `schedule`)
GlobalHookEnableKubernetesBindings	Enables Kubernetes monitors from global hooks
GlobalHookWaitKubernetesSynchronization	Blocks the queue until global hooks with `executeHookOnSynchronization: true` complete
GlobalHookEnableScheduleBindings	Registers cron tasks in the addon-operator scheduler
DiscoverHelmReleases	Finds “extra” Helm releases after the first `converge`
ApplyKubeConfigValues	Applies changes from ModuleConfig
ConvergeModules	Full `converge` cycle for all modules
ModuleRun	Configures or updates a module, including subtasks: `onStartup` -> `sync` -> `beforeHelm` -> `helm` -> `afterHelm`
ParallelModuleRun	Launches modules in batch and in parallel
ModuleDelete	Removes a module (`helm delete`, `afterDeleteHelm`)
ModuleHookRun	Runs a module hook on event
ModuleEnsureCRDs	Installs module CRDs
ModulePurge	Removes unknown Helm release

Addon-operator queue types:

Queue	Name	Purpose
Main	`main`	Runs global hooks at startup, installs critical modules, configures and deletes modules
Parallel	`parallel_queue_0` ... `parallel_queue_19`	Parallel ModuleRun with module dependencies taken into account (20 queues)
Hook queues	From task config (hook)	Tasks for a specific module and global hooks

Each queue is a separate pipeline with one worker. The queue has the following properties:

- Tasks can be inserted both at the tail (`AddLast`) and at the head (`AddFirst`) of the queue.
- Tasks are executed from the head of the queue.
- Multiphase operations are supported with the following operations:
  - `AddHeadTasks`: Insert subtasks before the current task.
  - `AddTailTasks`: Insert a subtask at the end of the queue after the current task succeeds.
  - `AddAfterTasks`: Insert a subtask right after the current task.
- A task is executed until success unless `allowFailure: true` is set in task parameters.
- On error, exponential restart (backoff) is applied, starting with a 5-second delay between retries.

> ⚠ If a task cannot complete successfully and `allowFailure: true` is not set in its parameters, that task blocks the queue it runs in. Tasks in different processing queues do not block each other.

At startup, the Deckhouse controller creates `main` and `parallel_queue_0..19` queues and adds the following tasks to `main` in this order:

- GlobalHookRun (onStartup): For each global hook.
- GlobalHookEnableScheduleBindings: To enable cron scheduling.
- GlobalHookEnableKubernetesBindings: To enable global tasks that watch Kubernetes resources.
- GlobalHookWaitKubernetesSynchronization.
- ConvergeModules (OperatorStartup): First converge of all modules.

After ConvergeModules, the controller adds the DiscoverHelmReleases task to clean up unknown Helm releases.

The module processing order in the ConvergeModules task is determined by several attributes:

- Module criticality: The `critical` parameter in the module `module.yaml` configuration.
- Module *weight*: Numeric module processing order. The higher the number, the later the module is processed. The weight is taken from the `weight` parameter in module `module.yaml`; if missing or set to 0, the default weight 900 is used. If no module config file exists, the weight is taken from the numeric prefix of the module directory name (for example, `040-node-manager` means weight 40). If the weight cannot be obtained from the directory name, weight 100 is used.
- Module dependencies: A list of modules that must be installed before the current module.

Based on these attributes, the Deckhouse controller scheduler defines processing order according to the following principles:

- For critical modules, module weight is considered in ascending order and tasks are put into the `main` queue.
- For non-critical modules, module weight is not considered and tasks are put into `parallel_queue_0..19`.
- For all modules, dependencies on other modules are considered.

If critical modules can be processed in parallel, the Deckhouse controller scheduler places the ParallelModuleRun task into the `main` queue with the list of modules. The ParallelModuleRun task starts a ModuleRun task for each module in `parallel_queue_0..19` and waits for completion, thereby blocking the `main` queue. If an error occurs while processing a ModuleRun task, the scheduler moves this task to the end of the queue and starts the next queue task.

The process of installing critical modules is shown in the following diagram:

The process of installing non-critical (functional) modules is shown in the following diagram:

If more than one identical task is added to a queue, all duplicates are removed when such a task starts, as part of deduplication.

To view addon-operator queues, use the `d8 system queue list` command.

Marketplace queues

The **Marketplace queues** are a queue implementation used by Marketplace functionality.

Each queue served by the Deckhouse controller for Marketplace has the following properties:

- FIFO (First In First Out): Defines strict task execution order. The first task in queue is executed first.
- Strict sequential execution of tasks, one task at a time.
- Tasks are started only on events (event-driven), without polling any resources.
- Restart on errors with exponential backoff between retries, starting at 15 seconds and capped at 1 minute, with no limit on retry attempts.
- Supports cascading task cancellation on version changes or package deletion.

Queue types:

Name	Purpose
`{packageName}`	Lifecycle: Deploy, Load, Configure, Enable, Run, Disable, Undeploy
`{packageName}/{hookQueue}`	Running hooks triggered by Kubernetes or schedule events (queue from hook binding)
`{packageName}/{hookQueue}/sync`	Hook synchronization at startup (WaitForSynchronization)

Task types:

Task	Function
Deploy	Downloads or mounts the package image
Load	Parses configuration, creates Application or Module, registers in scheduler
Configure	Applies Application or Module settings using the parameter store
Enable	Enables hooks, performs parameter synchronization, runs OnStartup hook
Run	Runs subtasks when installing Application or Module: `BeforeHelm` -> `helm Upgrade` -> `AfterHelm`
HookRun	Runs a hook on event
HookSync	Performs initial synchronization of Kubernetes binding
Disable	Removes Helm, disables hooks, clears hook queues
Undeploy	Removes the package from disk

Task execution in one queue does not block task execution in another queue.

To view Marketplace queues, run the following command:

⚠ When performing module installation or configuration tasks in addon-operator, the Deckhouse controller pauses Marketplace queue processing.

Additional resources

- Global custom resources
- Module `deckhouse` documentation

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Registry module

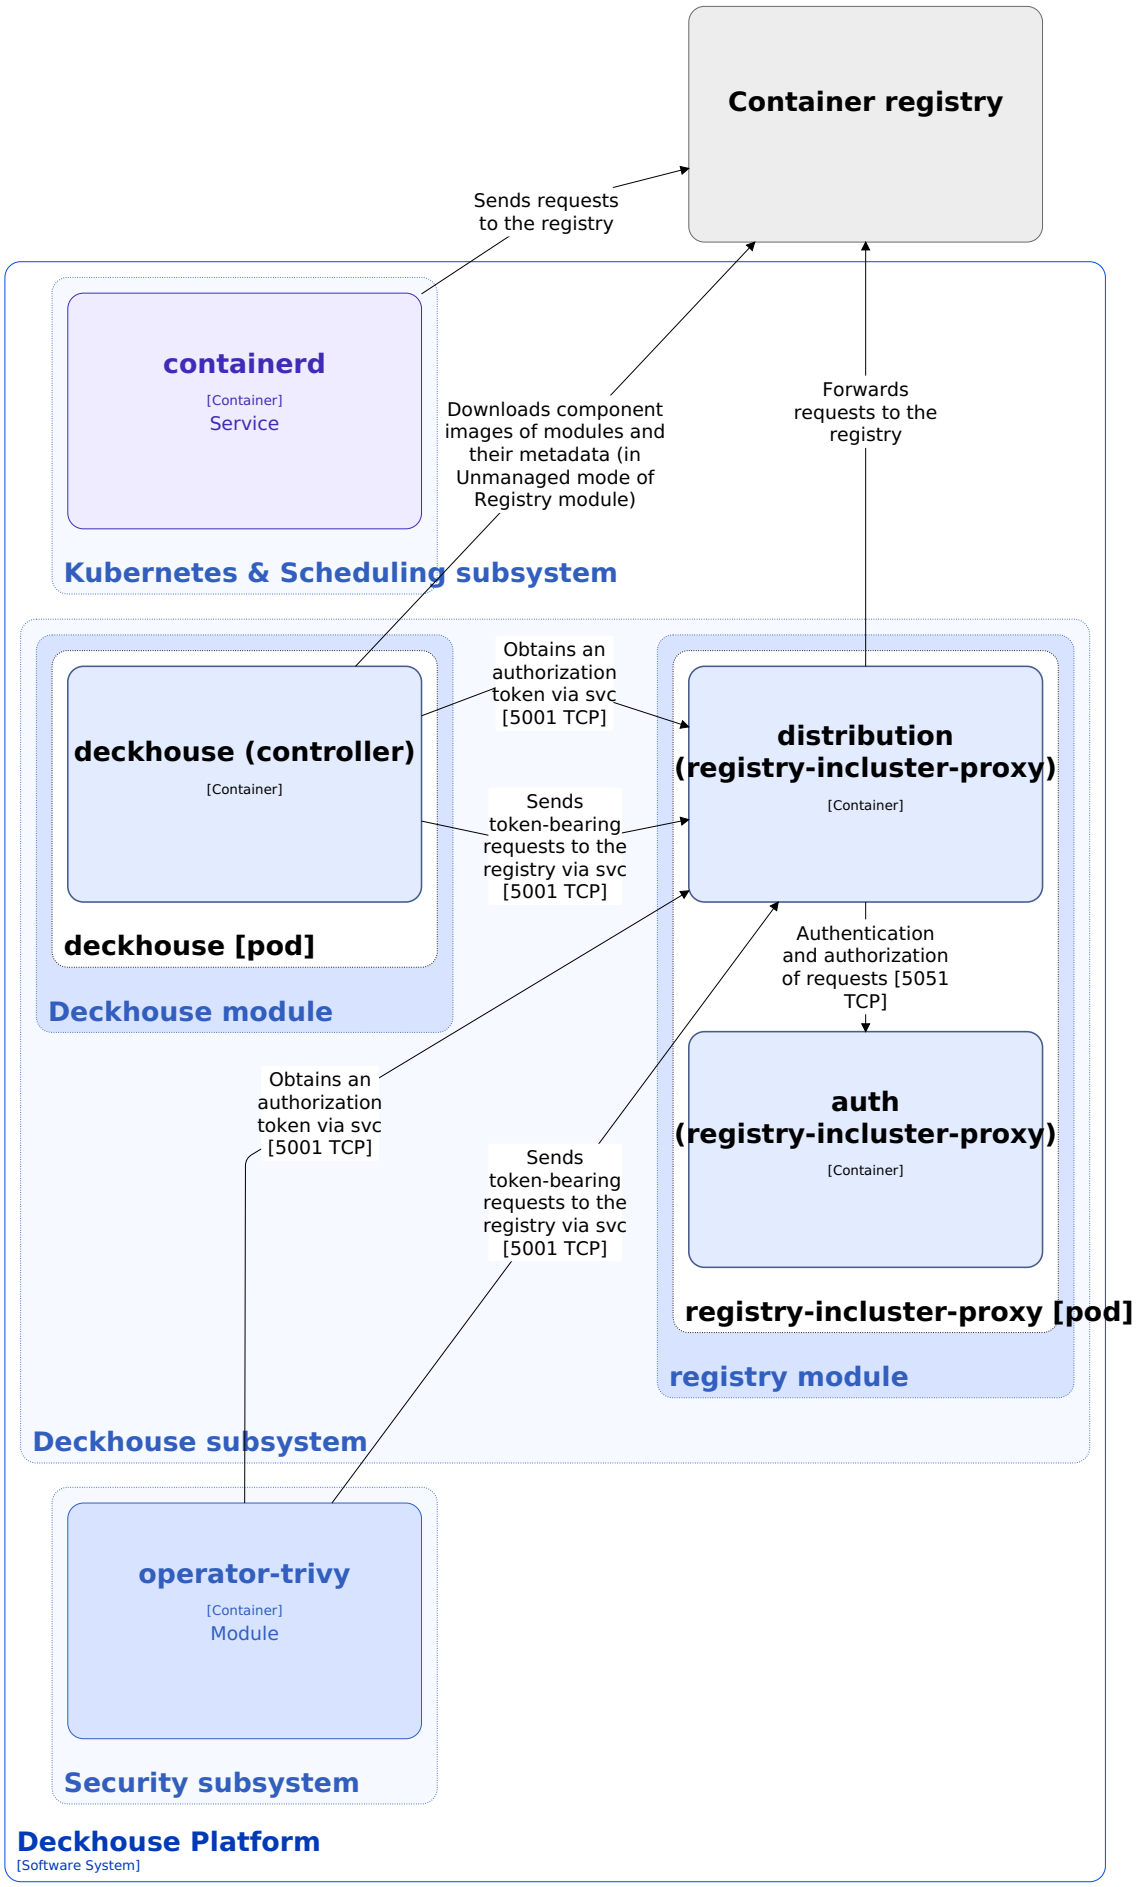
The `registry` module manages the registry settings for Deckhouse Platform (DP) components.

The module can operate in the following modes:

- `Direct`: Provides direct access to an external registry via the fixed address `registry.d8-system.svc:5001/system/deckhouse`. This fixed address prevents Deckhouse images from being re-downloaded and components from being restarted when registry parameters are changed. The fixed address is replaced by the actual address of the external registry when sending requests by configuring `mirroring/rewrite` section in the configuration of the containerd component and by using the internal registry-incluster-proxy component that proxies requests to the external registry.
- `Proxy`: Using an internal caching proxy registry that accesses an external registry, with the caching proxy registry running on control-plane (master) nodes. This mode reduces the number of requests to the external registry by caching images. Cached data is stored on the control-plane (master) nodes.

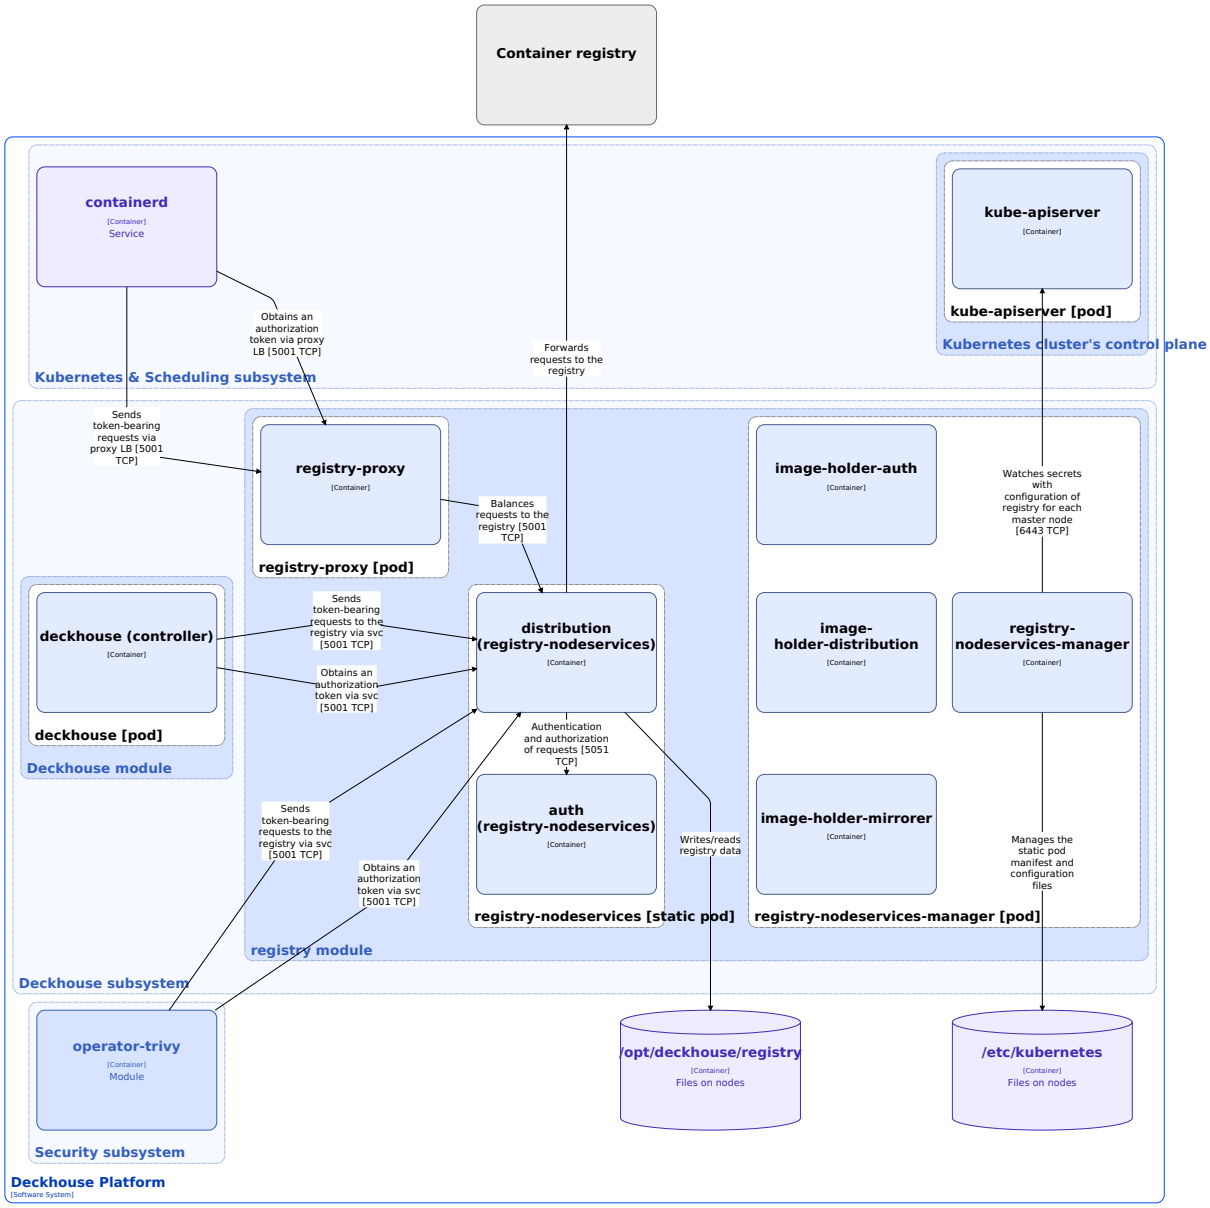
Access to the internal registry is via the fixed address `registry.d8-system.svc:5001/system/deckhouse`, similar to the `Direct` mode.

- `Local`: Using a local internal registry, with the registry running on control-plane (master) nodes. This mode allows the cluster to operate in an isolated environment. All data is stored on the control-plane (master) nodes. Access to the internal registry is via the fixed address `registry.d8-system.svc:5001/system/deckhouse`, similar to the `Direct` and `Proxy` modes.
- `Unmanaged`: Operation without using the internal registry. Access within the cluster is performed directly to the external registry.



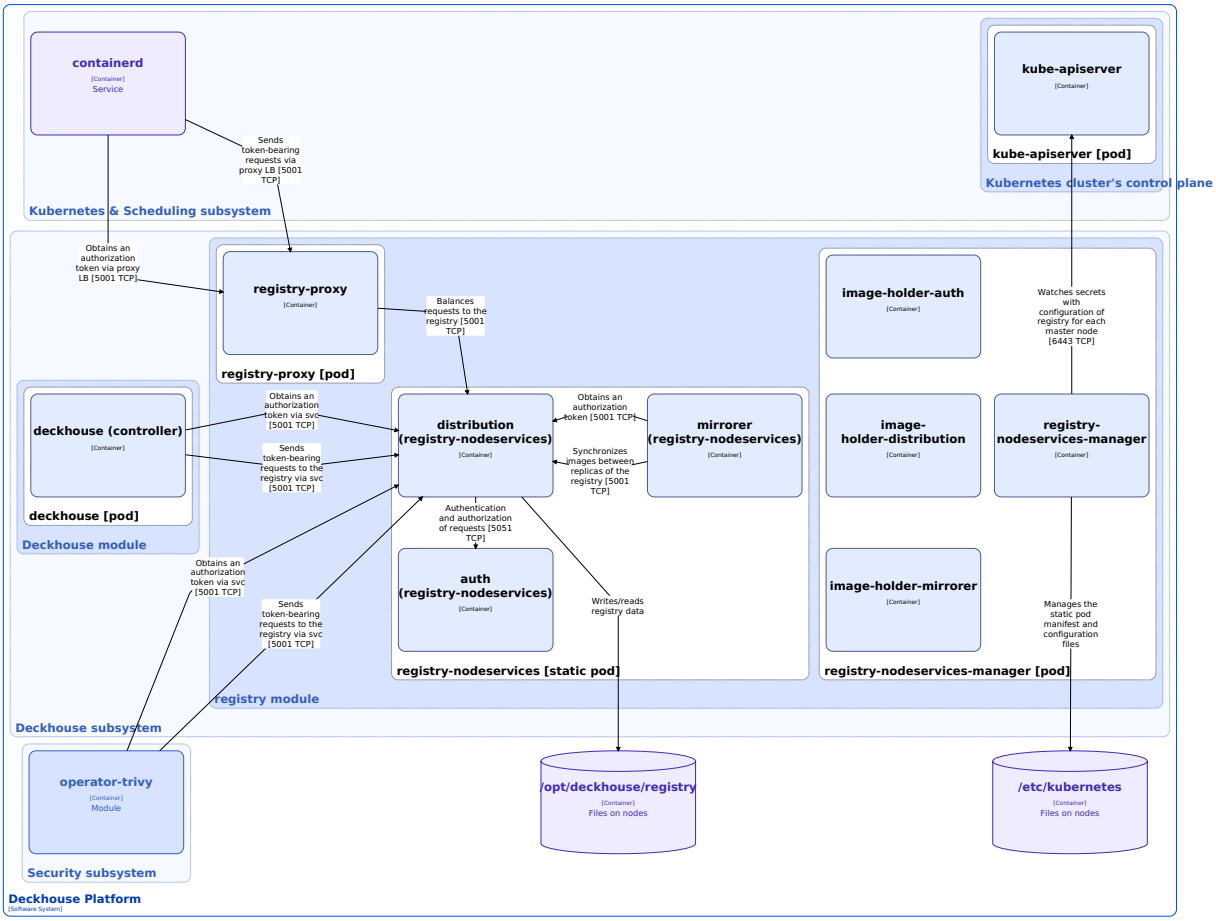
For more details about the configuration and usage examples of the module, refer to the module documentation.

Module architecture



> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `registry` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:



The `registry` module in `Direct` mode:

The `registry` module in `Proxy` mode:

The `registry` module in `Local` mode:

Module components

The module consists of the following components:

1. **Registry-incluster-proxy** (`Direct` mode): A container registry based on Distribution. Distribution is an open-source project that provides a framework for storing and distributing container images and other content using the OCI Distribution Specification. Registry-inclusion-proxy is installed in the cluster as a Deployment, does not store or cache images, but forwards requests to the external registry specified in Direct mode settings in `deckhouse` ModuleConfig.

   Registry-incluster-proxy consists of the following containers:

   - **distribution**: Main container.
   - **auth**: Sidecar container that implements authentication and authorization when accessing the registry. It is an open-source project.

     The principle of operation:

     1. **Request to the authentication service**. When the client tries to access the registry, distribution returns a `401 Unauthorized` HTTP response with the `WWW-Authenticate` header indicating how to authenticate.
     2. **Getting a token**. The client sends a request to the authentication service via the distribution service (for example, `registry.d8-system.svc:5051/auth`) using the values `service` and `scope` from the header `WWW-Authenticate`. The auth service returns an opaque Bearer token that represents authorized client access.
     3. **Token usage**. After receiving the token, the client resends the original request to distribution, including the token in the `Authorization` header.
     4. **Access verification**. Distribution validates the token and the `claims` contained in it, and then begins the image download session.

2. **Registry-nodeservices** (`Proxy` or `Local` modes): A container registry based on Distribution running on control plane (master) nodes. The registry is launched as a static pod, and its lifecycle is managed by the registry-nodeservices-manager component. The data is stored in the directory `/opt/deckhouse/registry` on the control plane (master) nodes.

   Registry-nodeservices consists of the following containers:

    - **distribution**: Main container.
    - **auth**: Sidecar container for authentication and authorization (described above).
    - **mirrorer** (`Local` mode): Sidecar container that synchronizes images between distribution replicas running on control plane (master) nodes.

3. **Registry-proxy** (`Proxy` or `Local` modes): A load balancer installed on each cluster node that provides high availability for registry. The CRI accesses the registry via the load balancer. The settings to access the load balancer are specified in the containerd configuration.

   It consists of a single container:

    - **registry-proxy**: A container built based on a standard NGINX image. The registry-proxy-reloader process is also running in the container and restarts the NGINX load balancer processes when its configuration changes.

4. **Registry-nodeservices-manager** (`Proxy` or `Local` modes): A controller that manages the lifecycle of registry-nodeservices components. Registry-nodeservices-manager performs the following operations:

    - Renders the manifest of the registry-nodeservices static pod from templates and saves it in the `/etc/kubernetes` directory on the control plane (master) nodes. Kubelet detects created manifests and runs registry-nodeservices static pod.
    - Saves configuration files necessary for the operation of registry-nodeservices components in the `/etc/kubernetes/registry` directory on control plane (master) nodes.
    - Deletes the static pod manifest in the `/etc/kubernetes` directory and configuration files in the `/etc/kubernetes/registry` directory, thereby deleting the local container registry, in case the module switches to the `Direct` or `Unmanaged` mode.

   Registry-nodeservices-manager consists of the following containers:

    - **registry-nodeservices-manager**: Main container.
    - A set of sidecar containers used to pre-pull images of registry-nodeservices components. These containers remain paused and serve only as image holders:
        - **image-holder-auth**
        - **image-holder-distribution**
        - **image-holder-mirrorer**

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
    - Checks that the current node is the master.
    - Checks that all containers of the registry-nodeservices static pod are pulled and status of registry-nodeservices pod is `Ready`.
    - Applies configuration changes from `registry-node-config-<Node Name>` Secret to the registry-nodeservices static pod.
2. **External container registry**: The module forwards internal requests to the external container registry.

The following external components interact with the module:

1. **Containerd**: Sends requests to the registry to pull images used to create containers.
2. **Deckhouse-controller**: Sends requests to the registry to pull images used to install modules.
3. **Operator-trivy (as well as other components that access the registry directly)**: Sends requests to the registry to download images, for example, to perform security tests (in case of operator-trivy).

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

DP cluster management

The `commander` and `commander-agent` modules are used to implement cluster management in Deckhouse Platform (DP).

A DP cluster with the `commander` module installed is a *managing* cluster. A DP cluster with the `commander-agent` module installed is a *managed* cluster.

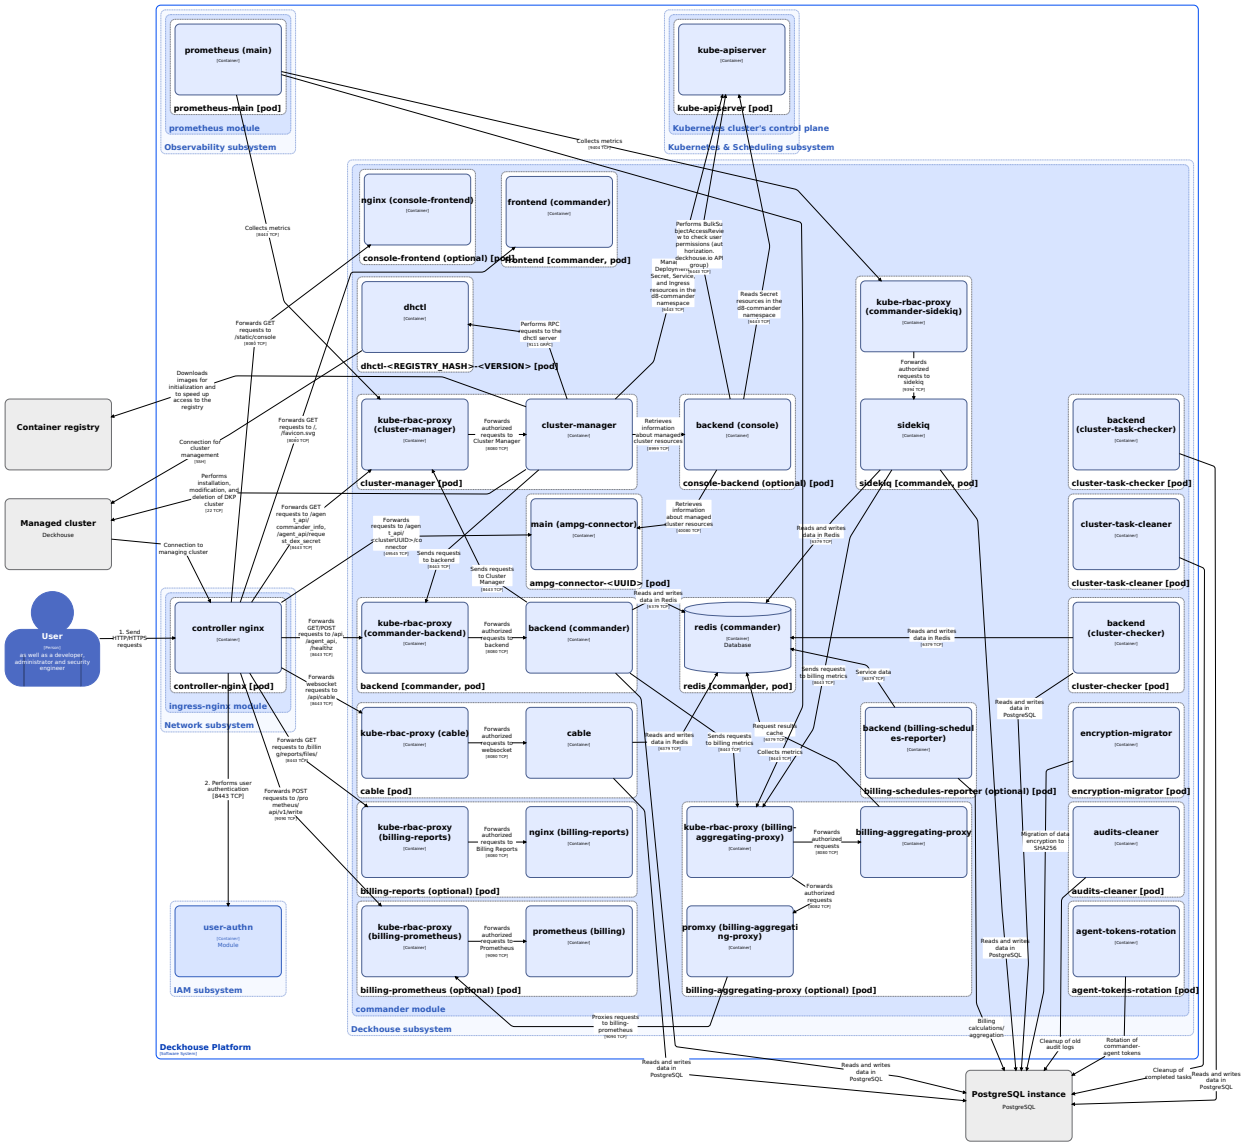
Commander module

The `commander` module implements a web application that allows you to create standardized DP clusters and manage their configurations and lifecycle.

To install the `commander` module, you need a PostgreSQL instance. It can be deployed inside or outside the cluster by using the `managed-postgresql` module.

⚠ For `commander` in production environments, using a dedicated PostgreSQL instance is recommended.

When `commander` is installed, a PostgreSQL data encryption key is generated. This key is stored in the `d8-commander` namespace in the `commander-envs` Secret.



For details about features, configuration, and usage examples, see the module documentation section.

Commander module architecture

i The following simplifications are made in the diagram:

- The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the context. Otherwise, the Service name is shown above the arrow.
- Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.
- The diagram shows only the main containers of each component.

The Level 2 C4 architecture of the `commander` module and its interaction with other DP components are shown in the following diagram:

Commander module components

The module consists of core, service, and optional components.

Core components

Core components of the `commander` module include:

1. **Frontend** (Deployment): Provides a web interface for cluster management.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **frontend**: The main container.

2. **Backend** (Deployment): The main component that implements the following APIs:

   - UI API: Manages cluster, template, and workspace settings.
   - External API for integrations and automation: Operates on clusters, tasks, templates, projects, roles, and more.
   - API for cluster-manager: Exchanges cluster task states and processes deployment and configuration phases of managed clusters.
   - API for `commander-agent`: Authorizes and receives agent metrics, and provides target configuration for a managed cluster.

   Backend provides the following capabilities:

   - Cluster lifecycle management: Creates, modifies, or deletes a cluster (through cluster-manager), restarts failed tasks, and runs related checks.
   - Cluster RBAC management and API operation access restrictions.
   - Template management and storage of target and current cluster settings.
   - Container registry management.

- Project and project template management.
- Billing settings management (if this component is enabled).

The component stores the target system state in a PostgreSQL instance. It also uses a Redis instance to publish tasks to managed clusters and receive task processing results.

Contains the following containers:

- **wait-postgres**: An init container that checks PostgreSQL instance availability.
- **wait-migrations**: An init container that waits for all database migrations to complete.
- **backend**: The main container.
- **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

3. **Cable** (Deployment): Provides WebSocket support for real-time UI updates.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **cable**: The main container.
   - **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

4. **Sidekiq** (Deployment): A component based on the Sidekiq library that provides queue processing in Ruby on Rails.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **sidekiq**: The main container.
   - **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

5. **Cluster-manager** (Deployment): Executes tasks requested by backend to deploy managed DP clusters and manage their configuration.

   When a new cluster is created, cluster-manager creates the following resources in the `d8-commander` namespace of the managing cluster:

   - Deployment and Secret named `dhctl-<REGISTRY_HASH>-<VERSION>`: Runs dhctl in gRPC server mode. Cluster-manager uses RPC calls to install and configure a DP cluster.
   - To process incoming `commander-agent` connections and implement a reverse interaction channel with the control plane of the corresponding cluster:
     - Deployment (`ampg-connector-<UUID>`)
     - Service:
       - `ampg-connector-<UUID>`
       - `ampg-console-backend-<UUID>`
       - `ampg-api-server-<UUID>`
       - `ampg-deckhouse-tools-<UUID>`
       - `ampg-aggregating-proxy-<UUID>`
       - `ampg-upmeter-<UUID>`
       - `ampg-label-proxy-<UUID>`
     - Secret (`ampg-console-backend-<UUID>`)
     - Ingress (`ampg-agent-api-connector-<UUID>`, `ampg-console-backend-<UUID>`)
   - DexClient (`cluster-<UUID>`): Configures the authentication service for a managed cluster using the capabilities of the `user-authn` module.

   During cluster bootstrap, cluster-manager also performs the following actions in the managed cluster:

   - Installs the `commander-agent` module.
   - Disables the `terraform-manager` module.
   - Configures authentication based on the Dex controller of the `user-authn` module. As a Dex provider, cluster-manager sets `cluster-<UUID>` DexClient from the managing cluster.
   - Configures the managed cluster connection to a container registry.
   - If billing is enabled, creates a PrometheusRemoteWrite custom resource to send metrics to the billing-prometheus component in the managing cluster.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **cluster-manager**: The main container.
   - **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

6. **Dhctl-<REGISTRY_HASH>-<VERSION>** (Deployment): A component with a single **dhctl** container. It runs the dhctl utility in gRPC server mode. Cluster-manager uses RPC calls to the `dhctl` server to

install or configure a managed DP cluster.

7. **Ampg-connector-<UUID>** (Deployment): A component with a single **main** container that establishes a tunnel and proxies requests to the control plane of a managed DP cluster through the incoming `commander-agent` connection.

   The component is created by cluster-manager for each managed DP cluster.

8. **Cluster-checker** (Deployment): Periodically starts cluster verification tasks.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **backend**: The main container.

9. **Cluster-task-checker** (Deployment): Periodically searches for running tasks that have not reported their status for a long time and moves them to `lost` or `lost_in_critical`.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **backend**: The main container.

10. **Redis** (Deployment): A component with a single **redis** container that provides a dedicated Redis database instance for storing task queue data and commander session states.

11. **Console-frontend** (Deployment): Provides the managed DP cluster administration web interface.

    Contains the following containers:

    - **wait-postgres**: An init container that checks PostgreSQL instance availability.
    - **wait-migrations**: An init container that waits for all database migrations to complete.
    - **nginx**: The main container.

12. **Console-backend** (Deployment): An administration API backend for the managed DP cluster that serves requests from the cluster-manager component.

    Console-backend uses Secret and Service resources created by cluster-manager to connect to the control plane of a managed DP cluster.

    Contains the following containers:

    - **wait-postgres**: An init container that checks PostgreSQL instance availability.
    - **wait-migrations**: An init container that waits for all database migrations to complete.
    - **backend**: The main container.

Service components

Service components of the `commander` module include:

1. **Cluster-task-cleaner** (CronJob): Runs once a day and removes completed tasks created more than 30 days ago.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **cluster-task-cleaner**: The main container.

2. **Agent-tokens-rotation** (CronJob): Regularly rotates `commander-agent` tokens.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **agent-tokens-rotation**: The main container.

3. **Encryption-migrator** (CronJob): Runs once a day and migrates encrypted data from SHA-1 to SHA-256. Not all data may be processed in a single run. In addition, after restoring from backup or due to delayed migrations, SHA-1 records may appear.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **encryption-migrator**: The main container.

4. **Audits-cleaner** (CronJob): Runs once a day and deletes old audit logs.

The Deckhouse controller of the `deckhouse` module creates audits-cleaner if the `settings.featureFlags.auditsRetentionDays` module parameter is set and defines the audit log retention period.

Contains the following containers:

- **wait-postgres**: An init container that checks PostgreSQL instance availability.
- **wait-migrations**: An init container that waits for all database migrations to complete.
- **audits-cleaner**: The main container.

Optional components

Optional components of the `commander` module include:

1. **Billing-prometheus** (StatefulSet): Runs Deckhouse Prom++ in metrics ingestion mode over the Prometheus Remote Write protocol.

   The `prometheus` module in a managed DP cluster sends metrics. The component stores resource usage history for all managed clusters, which is an important data source for billing reports.

   Contains the following containers:

   - **prometheus**: The main container.
   - **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

2. **Billing-reports** (StatefulSet): A component that runs the nginx web server as billing report storage. Reports are uploaded to nginx over Web-based Distributed Authoring and Versioning (WebDAV).

   Contains the following containers:

   - **nginx**: The main container.
   - **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

3. **Billing-schedules-reporter** (Deployment): Implements a scheduler that starts and controls tasks for generating required billing reports.

   The billing-schedules-reporter component saves generated reports to billing-reports over WebDAV.

   Contains the following containers:

   - **wait-postgres**: An init container that checks PostgreSQL instance availability.
   - **wait-migrations**: An init container that waits for all database migrations to complete.
   - **backend**: The main container.

4. **Billing-aggregating-proxy** (Deployment): Aggregates PromQL queries, proxies them to billing-prometheus, and returns query results.

   Contains the following containers:

   - **billing-aggregating-proxy**: A sidecar container based on Grafana Mimir. It provides query optimization and data caching. If data is missing in the cache, Grafana Mimir forwards the request to billing-prometheus via the promxy sidecar container.
   - **promxy**: A sidecar container based on Promxy. It proxies requests to billing-prometheus and provides a single endpoint for accessing data from multiple Deckhouse Prom++ instances.
   - **kube-rbac-proxy**: A sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the main container.

> **i** The billing-prometheus, billing-reports, billing-schedules-reporter, and billing-aggregating-proxy components are created by the Deckhouse controller of the `deckhouse` module if `settings.featureFlags.billingEnabled` is set to `true`.

Module interactions

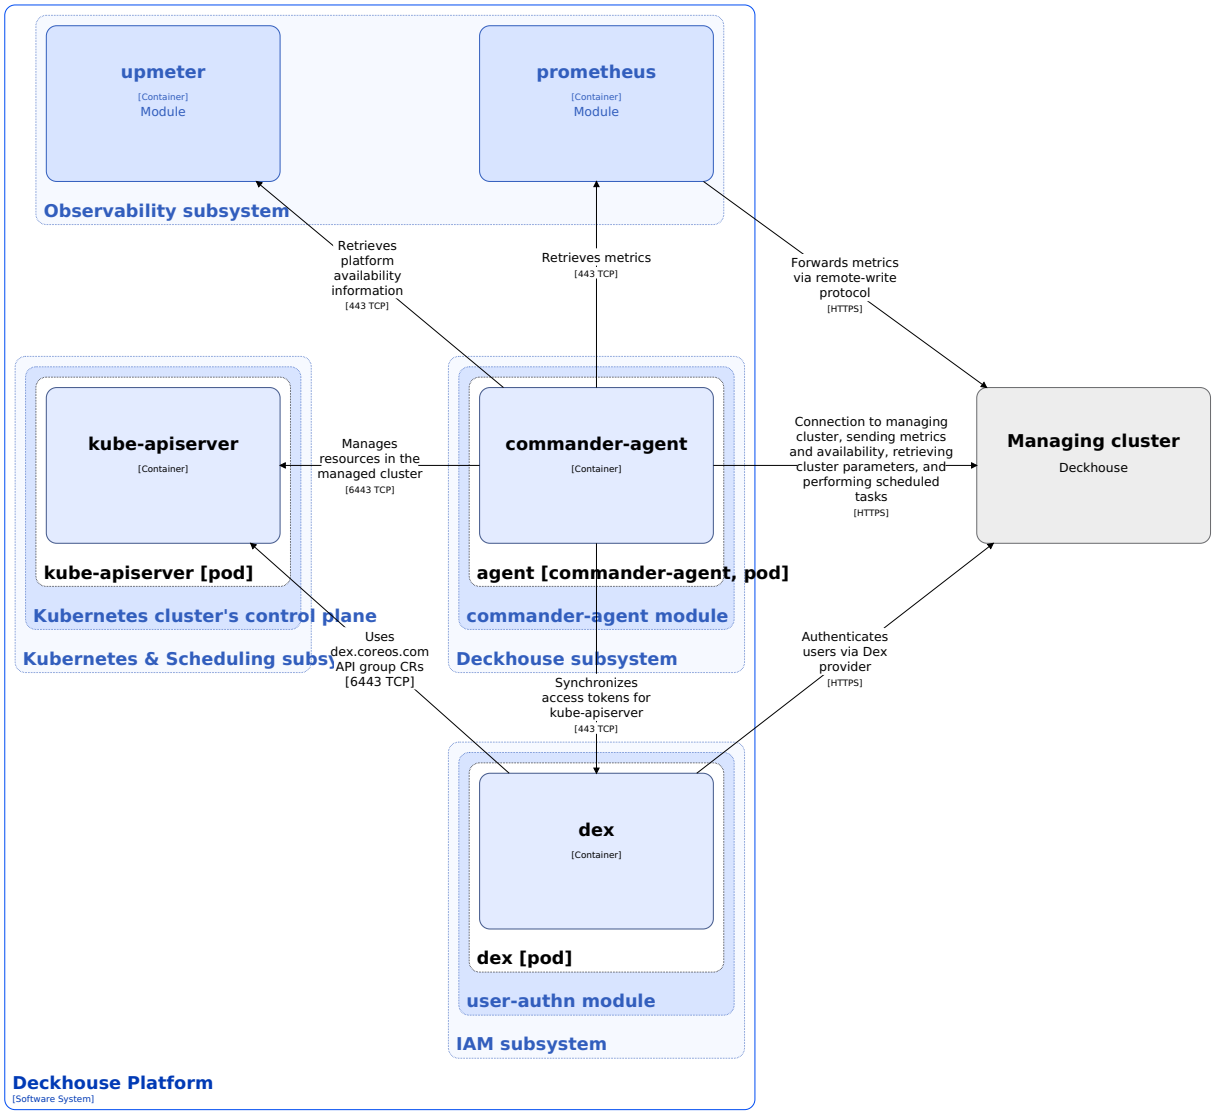
The module interacts with the following components:

1. **Kube-apiserver**:
   - Works with Deployment, Service, Secret, and Ingress resources in the `d8-commander` namespace.
   - Authorizes requests.
2. **Container registry**: Retrieves available DP releases by release channels.
3. **PostgreSQL instance**: Stores cluster states and metadata, tasks, tokens, projects, billing parameters, and reports.

4. **Managed cluster**: Creates, modifies, or deletes DP clusters.

The following external components interact with the module:

- **Controller-nginx**: Forwards external requests to module component endpoints.
- **Prometheus-main**: Collects metrics from module components.



Commander-agent module

The `commander-agent` module establishes a service connection to a managing DP cluster.

For details about module settings, see the module documentation section.

Commander-agent module architecture

The Level 2 C4 architecture of the `commander-agent` module and its interaction with other DP components are shown in the following diagram:

Commander-agent module components

The module consists of one **agent** component and one **commander-agent** container.

Agent performs the following actions:

- Brings managed cluster configuration in line with target configuration received from `commander` module backend.
- Collects managed cluster metrics:
  - `CPU cores`: Number of node CPU cores.
  - `Memory`: Total node memory in GiB.
  - `Filesystem`: Total size of node root disks in GiB.
  - `PVC`: Total size of attached disks in GiB.
  - `Nodes`: Total number of nodes.

- Collects cluster availability information.
- Establishes a secure connection to the managing DP cluster.
- Sends metrics and cluster availability information to the managing DP cluster.
- Configures user authentication via the Dex provider of the managing cluster.
- If billing is enabled in the managing cluster, creates a PrometheusRemoteWrite custom resource to send metrics to the billing service of the managing DP cluster.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**: Manages resources of the managed cluster.
2. **Prometheus**: Retrieves metrics from the managed cluster.
3. **Upmeter**: Retrieves availability information of the managed cluster.
4. **Dex**: Synchronizes access tokens for Kubernetes API requests from the managing cluster to the managed cluster.
5. **Managing cluster**:
   - Organizes a proxy connection to the managing cluster.
   - Receives target cluster configuration.
   - Sends metrics to the billing service.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Delivery subsystem

This section describes the architecture of the Delivery subsystem in Deckhouse Platform (DP).

The Delivery subsystem includes the following modules:

- `operator-argo`: Manages Argo CD installations in DP.
- `operator-helm`: Declaratively manages Helm chart deployments.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

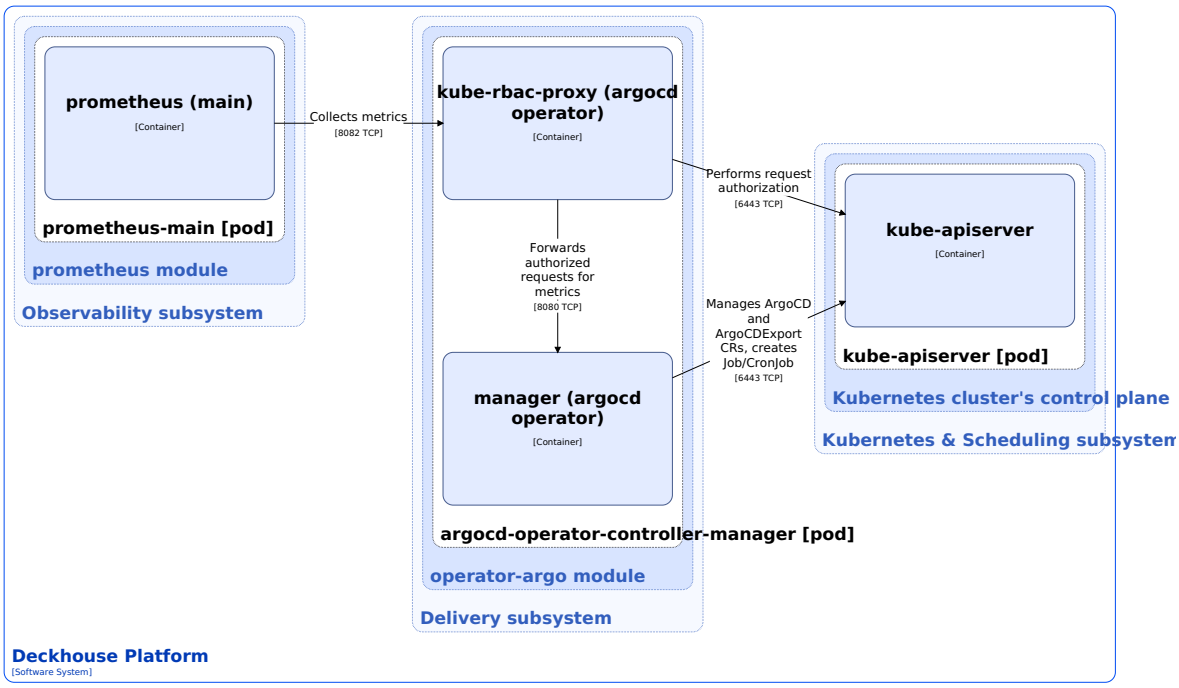
Operator-argo module

The `operator-argo` module deploys Argo CD Operator in a Deckhouse Platform (DP) cluster. The module enables to install Argo CD in a DP cluster using the ArgoCD resource.

The module works with the following custom resources:

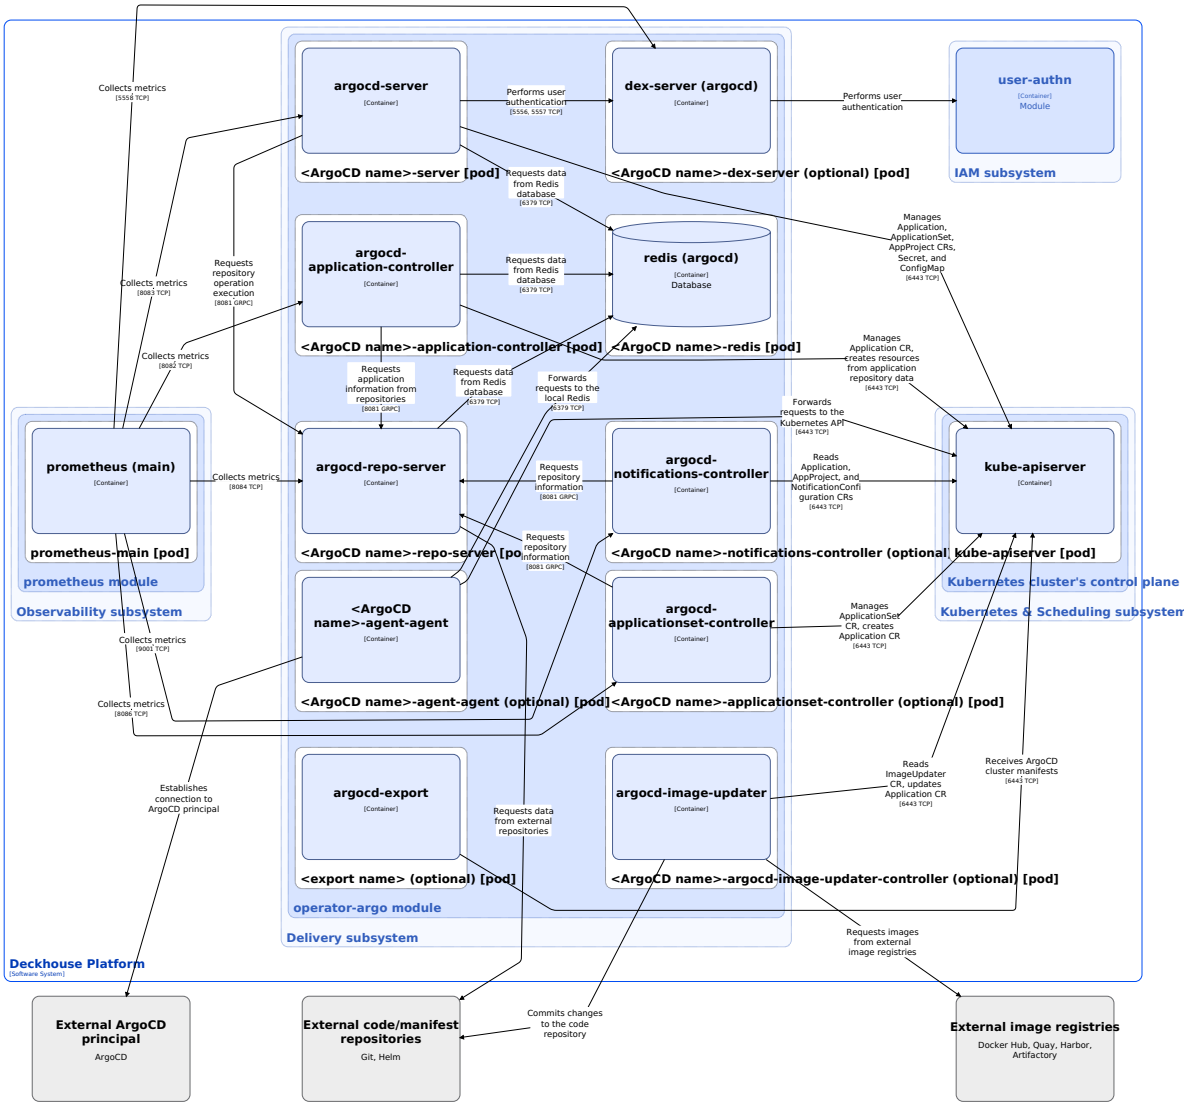
- Application: Describes application deployment and its management.
- ApplicationSet: Provides templating and mass application creation according to defined rules.
- AppProject: Defines a set of applications and application access policies.
- ArgoCD: Main resource for deploying and configuring an Argo CD instance.
- ArgoCDExport: Exports Argo CD configuration and state for backup or migration.
- ImageUpdater: Automatically updates application container images.
- NamespaceManagement: Defines namespace management rules for an Argo CD instance.

- NotificationsConfiguration: Defines notification settings for events in Argo CD and applications.



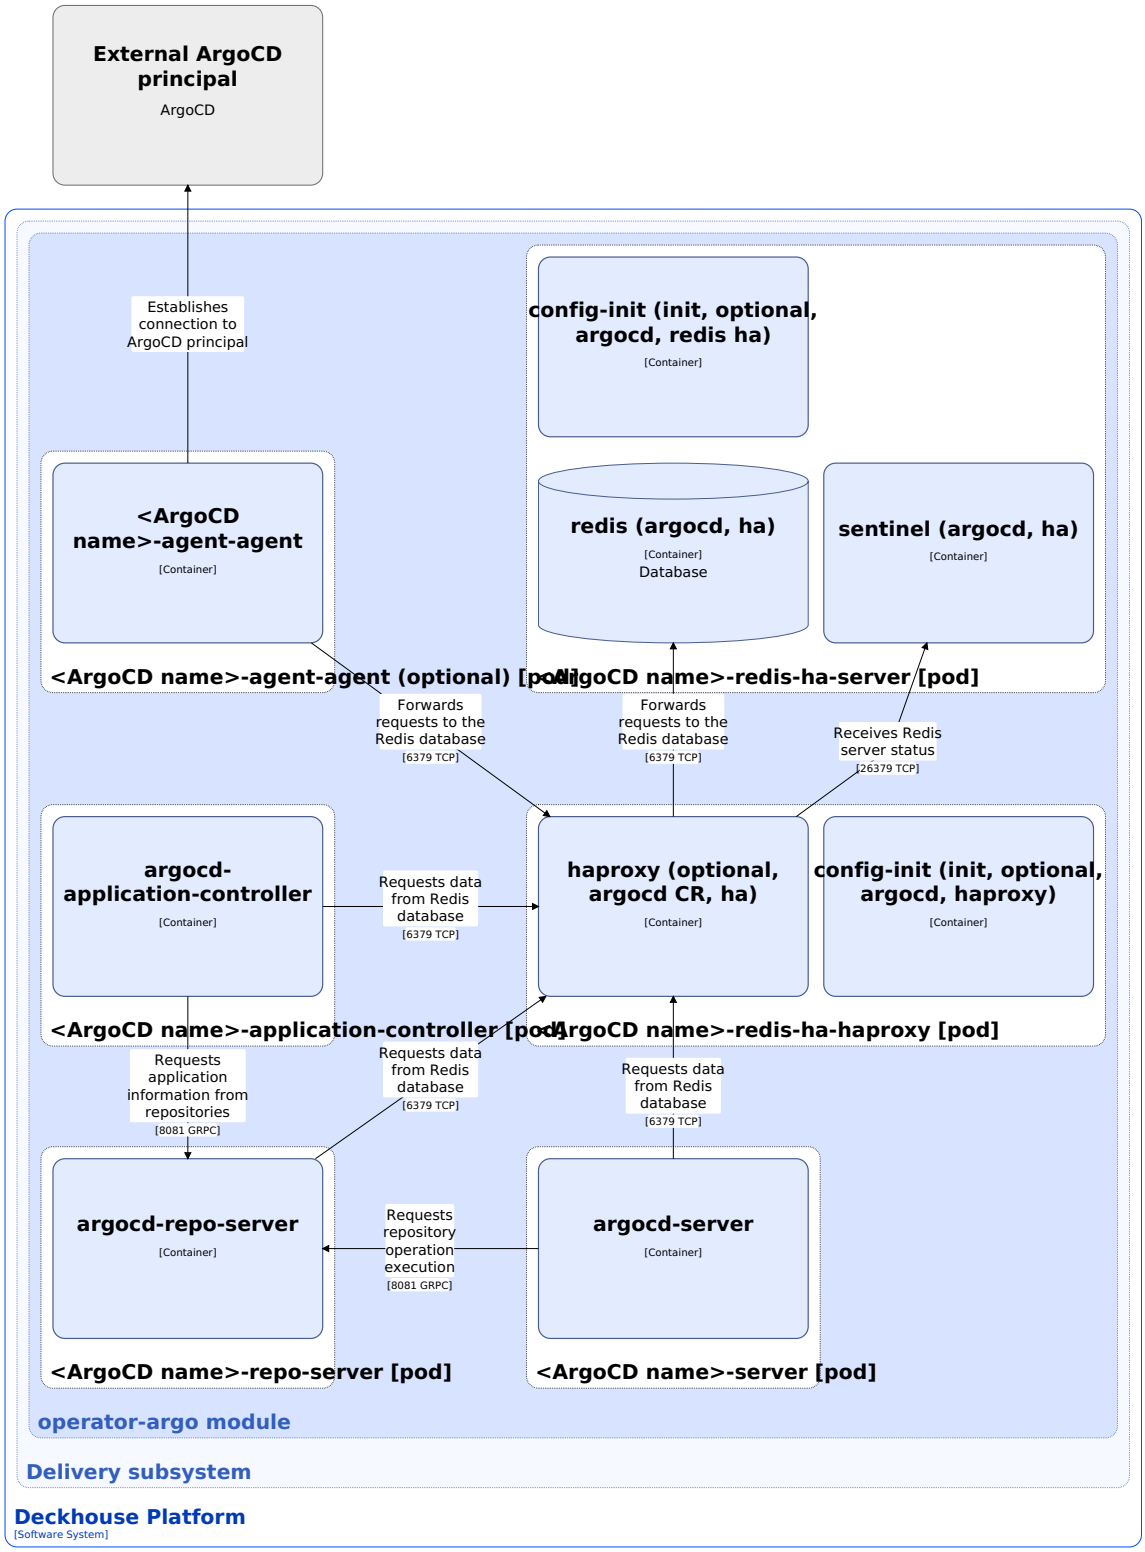
For more details on module settings and usage examples, refer to the module documentation.

Module architecture

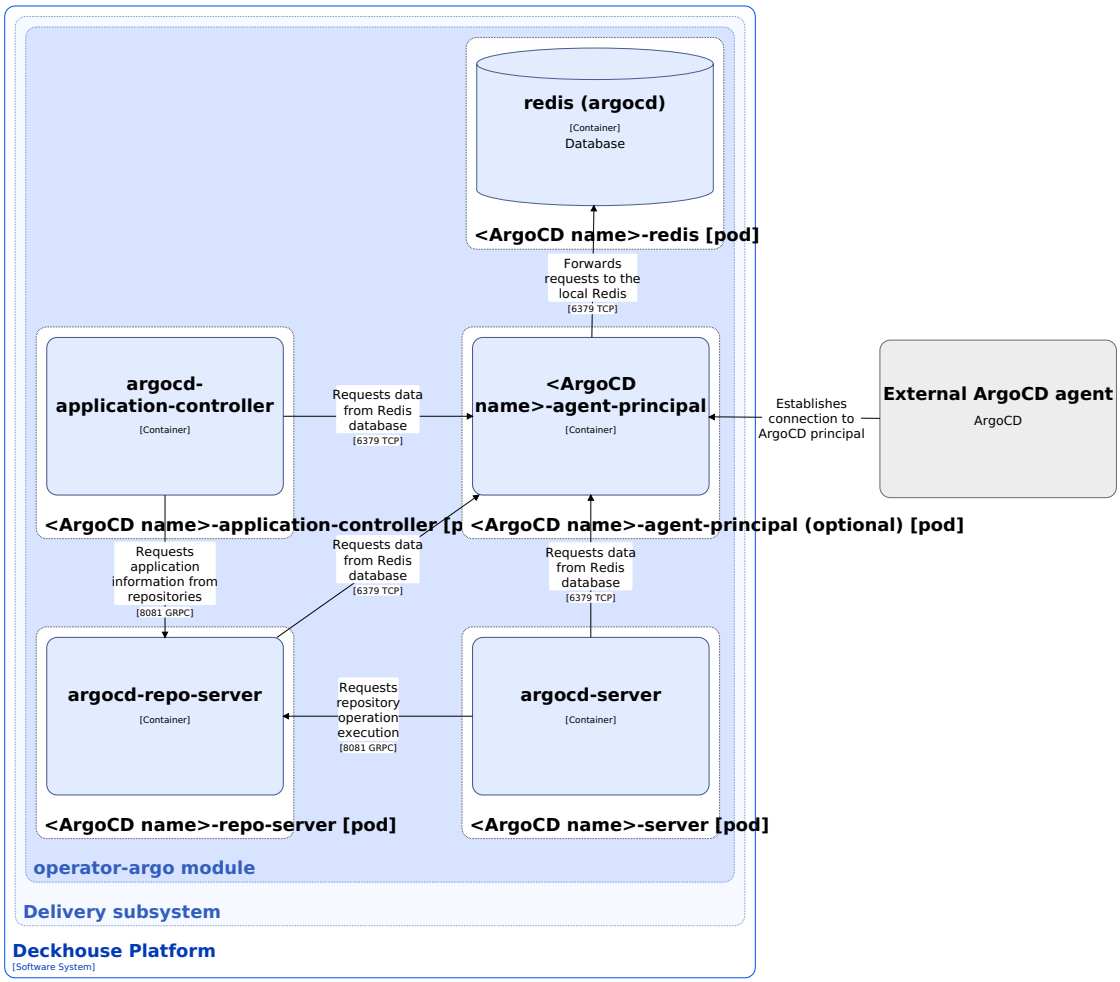


> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.
> - Only the main containers of each component are shown in the diagram.

The Level 2 C4 architecture of the `operator-argo` module and its interactions with other DP components are shown in the following diagrams:



- Main module operator:



- Argo CD instance deployment scenario with Redis in a non-HA configuration:

- Argo CD instance deployment scenario with Redis in an HA configuration (the diagram shows only differences from the primary deployment scenario):

- Argo CD instance deployment scenario in a principal cluster for a multicluster setup (the diagram shows only differences from the primary deployment scenario):

Module components

The module consists of the following components:

1. **Argocd-operator-controller-manager** (Deployment): Implementation of Argo CD Operator that allows deploying Argo CD instances in a DP cluster. The component works with the following custom resources:
   - ArgoCD: Main resource for deploying and configuring an Argo CD instance.
   - ArgoCDExport: Exports Argo CD configuration and state for backup or migration. The operator reads the ArgoCDExport custom resource and creates a Job/CronJob with the same name as the ArgoCDExport resource. The created Job/CronJob performs backup of the Argo CD instance configuration.
   - NamespaceManagement: Defines namespace management rules for an Argo CD instance. The operator watches the NamespaceManagement custom resource and updates the `argocd-cmd-params-cm` ConfigMap accordingly.
   - NotificationsConfiguration: Defines notification settings for events in Argo CD and applications. The operator reads NotificationsConfiguration custom resources and updates configuration in the `argocd-notifications-cm` ConfigMap based on them.

   Argocd-operator-controller-manager creates Deployment, Secret, ConfigMap, StatefulSet, and other resources for each ArgoCD custom resource, adding that resource name as a prefix to the created resources.

   It consists of the following containers:

   - **manager**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to `manager` metrics.

   > **i** The following components describe resources created by argocd-operator-controller-manager based on configuration defined in the ArgoCD custom resource. The `<ArgoCD name>` prefix is used in descriptions and is replaced by the controller with the ArgoCD resource name.

2. **<ArgoCD name>-server** (Deployment): Argocd-server. Main component for interacting with an Argo

CD instance. Argocd-server provides REST/gRPC API and a web UI for Argo CD management. The component allows managing Application, ApplicationSet, and AppProject custom resources through the provided interfaces (web UI, API, CLI).

The operator creates this component if the `.spec.server.enabled` parameter of the ArgoCD custom resource is set to `true` (default value is `true`).

It consists of the following containers:

- **argocd-server-init**: Optional set of init containers defined by the user in the `.spec.server.initContainers` parameter of the ArgoCD custom resource.
- **rollout-extension**: Optional init container that loads the UI extension for the Rollout custom resource. The module does not provide a controller for this custom resource. Such controller must be installed and configured separately. Argocd-operator-controller-manager adds rollout-extension if `.spec.server.enableRolloutsUI` is set to `true`.
- **argocd-server**: Main container.
- **argocd-server-sidecar**: Optional set of sidecar containers defined by the user in the `.spec.server.sidecarContainers` parameter of the ArgoCD custom resource.

3. **<ArgoCD name>-repo-server** (Deployment): Argocd-repo-server. Component responsible for template rendering, application manifest generation, and working with external repositories used by Argo CD. Argocd-repo-server synchronizes application manifests from configured repositories and passes them to the corresponding components for further deployment.

   The operator creates this component if the `.spec.repo.enabled` parameter of the ArgoCD custom resource is set to `true` (default value is `true`).

   It consists of the following containers:

   - **copyutil**: Init container that copies executables for use by the main container.
   - **argocd-repo-server-init**: Optional set of init containers configured through the `.spec.repo.initContainers` parameter of the ArgoCD custom resource to prepare the environment.
   - **argocd-repo-server**: Main container that generates and processes manifests and works with remote application Git repositories.
   - **argocd-repo-server-sidecar**: Optional set of sidecar containers defined by the user in the `.spec.repo.sidecarContainers` parameter of the ArgoCD custom resource and used to extend repo-server functionality.

4. **<ArgoCD name>-application-controller** (StatefulSet): Argocd-application-controller. Component responsible for synchronization and state management of applications defined in Argo CD. Argocd-application-controller provides idempotent application of Kubernetes manifests, manages deployment, rollback, and self-healing workflows, and monitors resource state in the cluster.

   The operator creates this component if the `.spec.controller.enabled` parameter of the ArgoCD custom resource is set to `true` (default value is `true`).

   It consists of the following containers:

   - **application-controller-init**: Optional set of init containers configured through the `.spec.controller.initContainers` parameter of the ArgoCD custom resource to prepare the environment.
   - **argocd-application-controller**: Main container implementing synchronization logic for Application custom resources and resources created from them.
   - **application-controller-sidecar**: Optional set of sidecar containers defined by the user in the `.spec.controller.sidecarContainers` parameter of the ArgoCD custom resource and used to extend controller capabilities.

5. **<ArgoCD name>-applicationset-controller** (Deployment): Argocd-applicationset-controller. Optional component consisting of a single **applicationset-controller** container and responsible for managing the ApplicationSet custom resource in Argo CD. It allows automatic creation, update, and deletion of Application resources based on configured templates and generators (for example, Git, List, Matrix, and Cluster generators). This simplifies mass management of similar applications that must be deployed across different environments or clusters.

   The operator creates this component if the `.spec.applicationSet.enabled` parameter of the ArgoCD custom resource is set to `true` (default value is `true`).

   For more details about the component, refer to the applicationset-controller documentation.

6. **<ArgoCD name>-argocd-image-updater-controller** (Deployment): Argocd-image-updater-controller. Optional component consisting of a single **argocd-image-updater** container and intended for automatic container image updates in Argo CD applications when new versions appear in image registries. The component tracks image tag changes and, when a new version is found, updates corresponding Application resources in Argo CD (for example, image tags in manifests or Helm values) via a pull request to a Git repository or directly, depending on the selected workflow.

   Argocd-image-updater-controller performs the following functions:

- Manages the ImageUpdater custom resource that defines settings for automatic updates of application container images.
- Periodically checks application container images in supported registries (Docker Hub, Quay.io, Harbor, and others).
- Supports filtering image tags by patterns and update strategies (`semver`, `latest`, and others).
- When a new image version is found, automatically performs write-back (writes the new image tag value) to Argo CD Application or a Git repository depending on the configured method.

For correct operation, the component requires access to Git repositories and, if needed, private image registries. Credentials for accessing image registries can be stored in Kubernetes Secrets.

To enable the component, set `.spec.imageUpdater.enabled` to `true` in the ArgoCD custom resource.

For more details about the component, refer to the argocd-image-updater documentation.

7. **<ArgoCD name>-notifications-controller** (Deployment): Optional controller consisting of a single **argocd-notifications-controller** container that sends notifications about Argo CD events (for example, successful application sync, deployment failures, status changes, and others) to external notification systems, including email, Slack, Microsoft Teams, Telegram, OpsGenie, Webhook, and others.

   The main module operator argocd-operator-controller-manager generates notification settings based on NotificationsConfiguration custom resources and stores them in the `argocd-notifications-cm` ConfigMap and `argocd-notifications-secret` Secret used by the controller to generate and send notifications.

   To enable the component, set `.spec.notifications.enabled` to `true` in the ArgoCD custom resource.

   For more details on operation, refer to the Argo CD Notifications documentation.

8. **<ArgoCD name>-dex-server** (Deployment): Argocd-dex-server. Optional component for user authentication in Argo CD, acting as an OIDC provider (OpenID Connect) based on Dex. The component enables user login through various external authentication providers (LDAP, GitHub, GitLab, SAML, Azure AD, and others) and supports static users defined in Dex configuration.

   It consists of the following containers:

   - **copyutil**: Init container that copies executables for use by the main container.
   - **dex**: Main container.

   To enable the component, define parameters in `.spec.sso.dex` section of the ArgoCD custom resource.

   > ⚠ For Argo CD user authentication in DP, the `operator-argo` module supports integration with the `user-authn` module (built-in DP authentication). Other external providers via Dex are not used in this configuration.
   >
   > For more details about module usage examples, refer to the corresponding documentation section.

9. **<ArgoCD name>-redis** (Deployment): Argocd-regis. Mandatory component consisting of a single **redis** container and responsible for storing task queue data and session state in Argo CD. Argocd-regis provides a dedicated Redis database instance.

   Argocd-operator-controller-manager deploys this component if `.spec.ha.enabled` in the ArgoCD custom resource is `false`.

10. **<ArgoCD name>-redis-ha-server** (StatefulSet): Argocd-redis-ha-server. Mandatory component for deploying Redis in high availability (HA) mode in Argo CD. It provides a fault-tolerant Redis cluster with replication and automatic failover using Redis Sentinel.

    It consists of the following containers:

    - **config-init**: Init container that prepares configuration for Redis and Sentinel before main containers start.
    - **redis**: Main container implementing a Redis server instance.
    - **sentinel**: Auxiliary container running Redis Sentinel to monitor Redis instance health and automatically switch to a replica if the primary instance fails.

    Argocd-operator-controller-manager deploys this component if `.spec.ha.enabled` in the ArgoCD custom resource is `true`.

11. **<ArgoCD name>-redis-ha-haproxy** (Deployment): Argocd-redis-ha-proxy. Additional component for load balancing and distributing traffic to Redis cluster instances (redis-ha-server) based on the HAProxy load balancer/reverse proxy server.

It consists of the following containers:

- **config-init**: Init container that prepares HAProxy configuration before the main container starts.
- **haproxy**: Container acting as a proxy server and providing transparent routing of client requests to available Redis master/replica instances, as well as automatic switching between them on failover.

Argocd-operator-controller-manager deploys this component if `.spec.ha.enabled` in the ArgoCD custom resource is `true`.

> **i**
>
> The following components are used to implement a secure and scalable multicluster setup in Argo CD:
>
> - Principal: The central control point. It stores state and distributes tasks.
> - Agent: The executor in each target cluster. It applies manifests and reports back.
>
> This approach allows you to manage multiple clusters without direct access from the central Argo CD to the Kubernetes API of each cluster, which reduces the number of required open inbound connections, provides isolation, and ensures fault tolerance.

12. **<ArgoCD name>-agent-agent** (Deployment): Argocd-agent-agent. Optional component consisting of a single **<ArgoCD name>-agent-agent** container and responsible for executing operations on managed Kubernetes cluster resources based on requests from Argo CD. The component establishes connection to Argo CD Principal, synchronizes applications, and manages their state based on commands received from Argo CD Principal.

    For details on Argo CD multicluster architecture, refer to the Argo CD documentation.

    Argocd-operator-controller-manager deploys this component if `.spec.argoCDAgent.agent.enabled` in the ArgoCD custom resource is `true`. Argo CD Agent and Argo CD Principal cannot be enabled simultaneously in a single ArgoCD resource.

13. **<ArgoCD name>-agent-principal** (Deployment): Argocd-agent-principal. Optional component consisting of a single **<ArgoCD name>-agent-principal** container and enabling Argo CD operation in a multicluster setup.

    When this component is enabled, argocd-operator-controller-manager reconfigures all components that use Redis connection to use Redis proxy instead. The Argocd-agent-principal component provides this Redis proxy and routes database requests by analyzing Redis keys: depending on key values, a request is sent either to a local Redis instance or to one of remote Argo CD Agents.

    Argocd-operator-controller-manager deploys this component if `.spec.argoCDAgent.principal.enabled` in the ArgoCD custom resource is `true`. Argo CD Agent and Argo CD Principal cannot be enabled simultaneously in a single ArgoCD resource.

14. **<Export name>** (Job/CronJob): Argocd-export. Optional component implemented as Job or CronJob that creates a pod with a single **argocd-export** container. The component creates backup of Argo CD instance configuration and state.

Module interactions

The module interacts with the following components:

1. **External image registries**: Receives image lists.
2. **External code repositories**:
   - Receives application deployment manifests from repositories.
   - Updates `image` in Helm chart source code.
3. **External Argo CD Principal**:
   - Connects to Argo CD principal cluster.
   - Receives processing requests.
   - Sends back processing results.
4. **Kube-apiserver**:
   - Manages Application, ApplicationSet, AppProject, ArgoCD, ArgoCDExport, ImageUpdater, NamespaceManagement, NotificationsConfiguration custom resources, as well as Secret and ConfigMap.
   - Manages resources created during deployment of user applications described in the Application custom resource.
   - Authorizes requests for metrics retrieval.
5. **`user-authn` module**: Redirects user for authentication.

The following external components interact with the module:

1. **Prometheus-main**: Collects metrics provided by the operator and Argo CD instances.
2. **External Argo CD Agent**:
   - Connects to Argo CD principal cluster.
   - Receives processing requests.

- Sends back processing results.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Kubernetes & Scheduling subsystem

This subsection describes the architecture of the modules that are part of the Kubernetes & Scheduling subsystem of Deckhouse Platform (DP).

The Kubernetes & Scheduling subsystem includes the following modules:

- `control-plane-manager`: Main module of the subsystem, responsible for managing cluster control plane components.
- `descheduler`: Analyzes the cluster state and evicts pods in accordance with the active strategies.
- `pod-reloader`: Allows you to automatically restart the workload if certain ConfigMap or Secret changes.
- `vertical-pod-autoscaler`: Automatically adjusts container resource requests and limits in pods based on actual consumption. The module architecture is described on the corresponding page.
- `adaptive-resource-management`: Automatically selects optimal resource requests and limits for containers using VPA (Vertical Pod Autoscaler) recommendations.

This subsection also describes the architecture of the control plane and the kubelet agent.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Cluster control plane

Deckhouse Platform (DP) uses a standard (“vanilla”) Kubernetes cluster. The cluster control plane includes the following core components:

1. **kube-apiserver**: Kubernetes API server. It processes REST requests, provides access to the overall cluster state through which all other components interact, validates Kubernetes API resources, and stores them in **etcd** storage. It includes the following containers:
   - **kube-apiserver**: Main container.
   - **kube-apiserver-healthcheck**: Sidecar container that enables health checks of **kube-apiserver** without enabling anonymous authentication and without exposing an unauthenticated port. It uses a client certificate to authenticate to the API server. It is an open source project.
2. **etcd**: Distributed key-value storage that holds all configuration data and Kubernetes cluster resources.
3. **kube-scheduler**: Kubernetes scheduler. It analyzes node resources and assigns pods based on constraints and rules such as affinity and taints.
4. **kube-controller-manager**: Kubernetes controller manager. It runs controller loops that monitor and reconcile the state of standard Kubernetes resources to match the desired state. Examples of controllers shipped with Kubernetes: replication controller, endpoints controller, namespace controller, and ServiceAccount controller.

Interactions between the Kubernetes control plane components are shown in the architecture diagram of the `control-plane-manager` module.

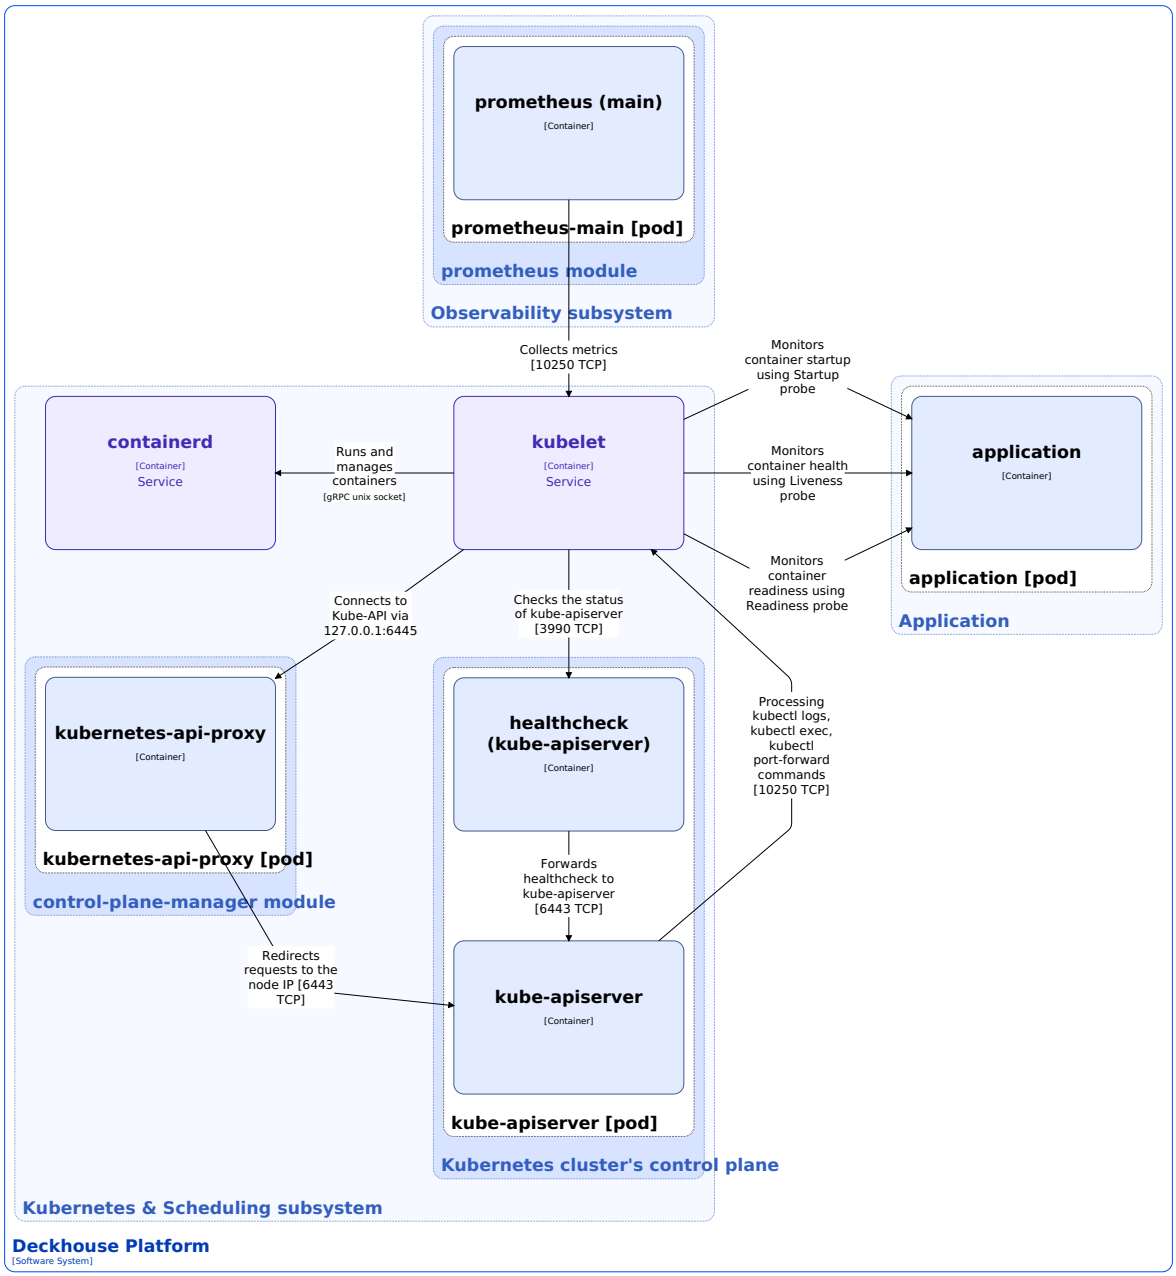
> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Kubelet

Kubelet is not a control plane component, but it plays a key role in the operation of a Kubernetes cluster.

Kubelet is an agent that runs on every node in a Kubernetes cluster. It ensures that containers in pods are started and run according to their specifications. Kubelet continuously interacts with kube-apiserver to verify and maintain the state of nodes and containers. It is also responsible for starting control plane components.

Static pod manifests



Kubelet starts control plane components from static pod manifests located in the `/etc/kubernetes/manifests` directory. In Deckhouse Platform, kubelet processes only files with the `.yaml` or `.yml` extension in this directory.

Files with other extensions, such as `kube-apiserver.backup`, `kube-apiserver.yaml.bak`, editor swap files, or other temporary files, are ignored. This prevents accidental processing of backup or non-manifest files as static pod manifests.

Kubelet interactions

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.
> - The diagram shows an `application` pod, which represents any pod in the cluster, both system and user-managed.

Kubelet interactions are shown in the following diagram:

Kubelet monitors the state of containers in all pods running on the node, including both user workloads and DP components, by performing Startup, Liveness, and Readiness probes according to the pod specification. For more information about probes, see the Kubernetes documentation.

Kubelet also interacts with the following components:

1. **Containerd**: Receives commands from kubelet to manage the container lifecycle on the node via the Container Runtime Interface (CRI).
2. **Kubernetes-api-proxy**: Proxies requests to kube-apiserver that are sent to the `localhost` address. It is part of the `control-plane-manager` module.
3. **Kube-apiserver-healthcheck**: Checks the health of kube-apiserver.

The following components interact with kubelet:

1. **Kube-apiserver**:
   - Retrieving pod logs (the `kubectl logs` command).
   - Executing commands in running pods (the `kubectl exec` command).
   - Port forwarding (the `kubectl port-forward` command).
2. **Prometheus-main**: Collects kubelet metrics.

Cluster control plane management

Control-plane-manager module

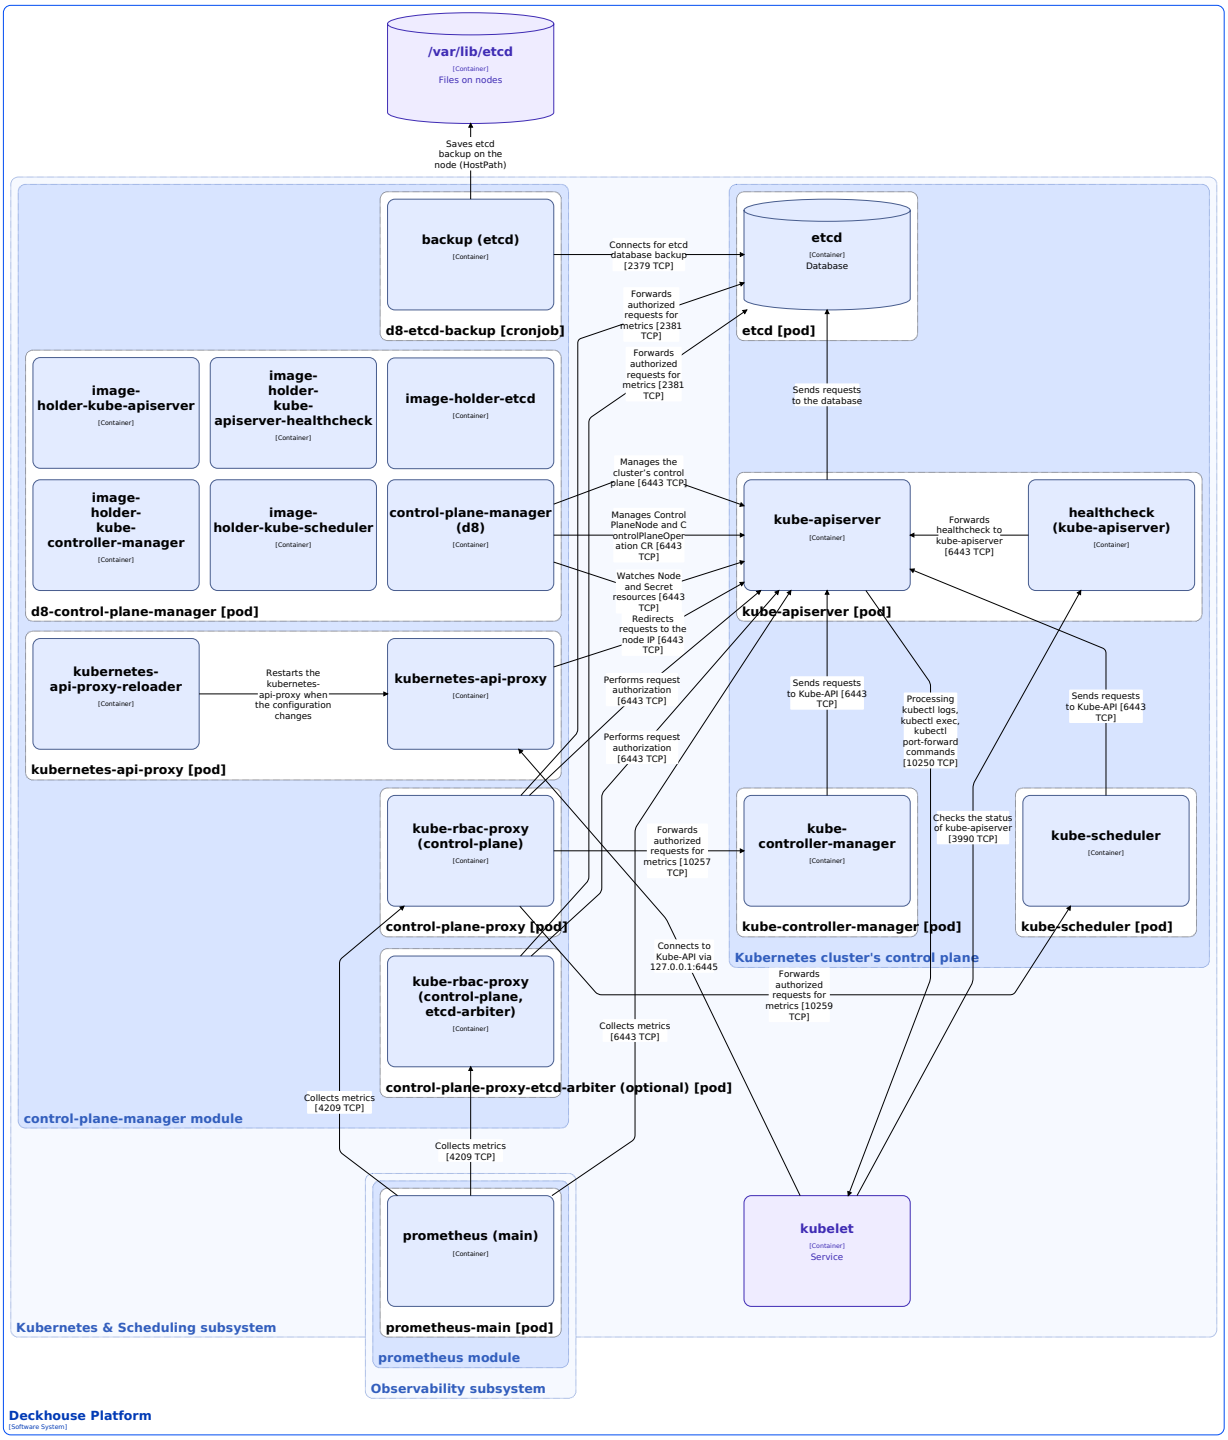
Cluster control plane components are managed by the `control-plane-manager` module, which runs on all master nodes (nodes labeled with `node-role.kubernetes.io/control-plane: ""`).

The module operates with the following custom resources:

- ControlPlaneNode: Describes the parameters and state of control plane nodes (master nodes) in the cluster. It's used for managing the lifecycle and configuration of each control plane component.
- ControlPlaneOperation: Defines operations on control plane components (upgrade, downgrade, addition, or removal of components), and allows tracking and managing the execution of these operations at the cluster level.
- KubeSchedulerWebhookConfiguration: Describes the parameters and logic for connecting external webhooks to the `kube-scheduler` component to extend its functionality.

> ⚠ The ControlPlaneNode and ControlPlaneOperation custom resources are available to users in read-only mode. Full lifecycle management of these resources is performed exclusively by the `control-plane-manager` module.

Control plane management functions:



- **Certificate management**: Issuing, renewing, and rotating certificates required for control plane operation. Ensures automatic and secure control plane configuration and allows additional Subject Alternative Names (SAN) to be added for secure access to the Kubernetes API.
- **Component configuration**: Automatic generation of the required configuration files and manifests for control plane components.
- **Component upgrade and downgrade**: Maintains consistent component versions across the cluster.
- **Management of etcd cluster configuration**: Scaling master nodes and migrating between single-master and multi-master configurations.
- **Management of kubeconfig**: Maintains an up-to-date configuration for using `kubectl` on cluster nodes. Generates, renews, and updates the kubeconfig with *cluster-admin* privileges and creates a symbolic link for the `root` user so that the kubeconfig is used by default.
- **Scheduler extension**: Enables external plugins via webhooks using the KubeSchedulerWebhookConfiguration resource. This allows advanced scheduling logic when planning cluster loads, for example:
  - Placing data-intensive application pods closer to their data.
  - Prioritizing nodes based on their state (network load, storage subsystem health, etc.).
  - Dividing nodes into zones, etc.
- **Periodic etcd defragmentation**. In clusters with three or more etcd members, this feature is enabled by default. For more details, see the `control-plane-manager` module documentation.

For detailed configuration options and usage examples, refer to the `control-plane-manager` module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `control-plane-manager` module and its interactions with other platform components are shown in the following diagram:

Module components

The module consists of the following components:

1. **d8-control-plane-manager** (DaemonSet): Manages cluster control plane components and runs on all master nodes.

   The **d8-control-plane-manager** controller performs the following actions:

   - Monitors the `d8-control-plane-manager-config` and `d8-pki` Secrets and, based on their information, creates or updates the ControlPlaneNode custom resource for each master node.
   - If the required node configuration differs from the current one, creates a ControlPlaneOperation resource to perform operations to update the node's configuration.
   - Determines the order in which to execute the requested ControlPlaneOperation operations to maintain the required cluster fault tolerance during updates.
   - Monitors the execution of operations specified in the ControlPlaneOperation resource.
   - After the requested operations are completed, updates the current state of the master node in the ControlPlaneNode resource.

It consists of the following containers:

- **control-plane-manager**: Main container. Developed by Flant.
- A set of sidecar containers used to pre-pull images of control plane components. These containers remain paused and serve only as image holders:
  - **image-holder-kube-apiserver**
  - **image-holder-kube-apiserver-healthcheck**
  - **image-holder-kube-controller-manager**
  - **image-holder-kube-scheduler**
  - **image-holder-etcd**

2. **kubernetes-api-proxy** (static pods): Additional proxy server configured on each master node to handle requests to `localhost`. By default, it proxies requests to the local **kube-apiserver** instance. If the latter is unavailable, it sequentially queries the remaining **kube-apiserver** instances. It includes the following containers:
   - **kubernetes-api-proxy**: NGINX-based proxy server.
   - **kubernetes-api-proxy-reloader**: Sidecar container that restarts the proxy server when its configuration changes. Developed by Flant.
3. **control-plane-proxy** (DaemonSet): Component that is installed in the cluster when the [`prometheus`] module(/modules/prometheus/) is enabled. In this case, the control-plane-proxy runs on all master nodes and forwards authorized requests for metrics of the following components of the cluster control plane:
   - **kube-controller-manager**;
   - **kube-scheduler**;
   - **etcd**.

   It consists of a single container:
   - **kube-rbac-proxy***: Container with an authorization proxy based on Kubernetes RBAC, providing secure access for metrics of the components of the cluster control plane. It is an open source project.
4. **control-plane-proxy-etcd-arbiter** (DaemonSet): Optional component that is installed in the cluster when the `prometheus` module is enabled, if the cluster operates in HA mode with two master nodes and an arbiter node. In this case, Control-plane-proxy-etcd-arbiter runs on the arbiter node and forwards authorized requests for metrics to the etcd instance running on it.

   It consists of a single container:
   - **kube-rbac-proxy***: Container with an authorization proxy based on Kubernetes RBAC, providing secure access for metrics of the etcd instance (described above).
5. **d8-etcd-backup** (CronJob): Periodically performs backups of the cluster's **etcd** database. It consists of the following container:
   - **backup**: Container running a shell script that creates an etcd snapshot using `etcdctl` and stores it in `/var/lib/etcd` on the master node (default directory, configurable via the module parameters).

Module interactions

The module interacts with the following components:

1. **kube-apiserver**:
   - Manages cluster control plane components.
   - Reconciles ControlPlaneNode and ControlPlaneOperation custom resources.
   - Watches `d8-control-plane-manager-config` and `d8-pki` Secrets.
   - Proxies and load-balances requests to **kube-apiserver** sent to `localhost`.
   - Authorizes the requests for metrics.
2. **etcd**:
   - Manages etcd cluster configuration and membership.
   - Performs periodic database backups.

The following external components interact with the module:

- **kubelet**: Requests to **kube-apiserver** sent to `localhost` are proxied by the module's **kubernetes-api-proxy** component.
- **Prometheus-main**: Collects metrics of the control plane components.

Cluster control plane monitoring

The `control-plane-manager` module provides control plane monitoring, ensuring secure metrics collection and providing a basic set of monitoring rules for the following cluster components:

- **kube-apiserver**
- **kube-controller-manager**
- **kube-scheduler**
- **etcd**

Metrics from **kube-apiserver** are collected directly by **prometheus-main**. Metrics of the other control-plane components are collected by **prometheus-main** with authorization in kube-apiserver via the control-plane-proxy component. The `control-plane-manager` module adds the corresponding metric collection rules to the **prometheus-main** configuration.

>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Vertical Pod Autoscaler

The `vertical-pod-autoscaler` module provides Vertical Pod Autoscaler (VPA) in Deckhouse Platform (DP).

For details on module configuration and usage examples, refer to the relevant documentation section.

VPA operating modes

VPA can operate in two modes:

- Automatic resource adjustment:
  - **InPlaceOrRecreate** (the default, available in Kubernetes 1.33 and later): VPA attempts to update resources without recreating Pods. If in-place resource updates are not possible, VPA falls back to behavior similar to the **Recreate** mode: the Pod for which the resources cannot be updated is evicted, and the controller creates a new Pod with updated resources.

    > **i** To use the **InPlaceOrRecreate** mode in Kubernetes versions earlier than 1.33, enable the `InPlacePodVerticalScaling` feature gate in the `control-plane-manager` configuration.

  - **Recreate**: VPA adjusts the resources of running Pods by restarting them. For a single Pod (`replicas: 1`), this will result in service unavailability during the restart. VPA does not restart Pods that were created without a controller.
  - **Auto**: A deprecated mode. It will no longer be supported in future DP versions. Use one of the supported operating modes instead.
- Recommendations only, without modifying resources:
  - **Initial**: Pod resources are adjusted only when Pods are created and not during the runtime.
  - **Off**: VPA does not change resources automatically. However, it still provides resource recommendations, which can be viewed using the `d8 k describe vpa` command.

When VPA is enabled and configured, resource requests are set automatically based on Prometheus data. You can also configure the system to only provide recommendations without applying any changes. For details on enabling and configuring the VPA, refer to Administration.

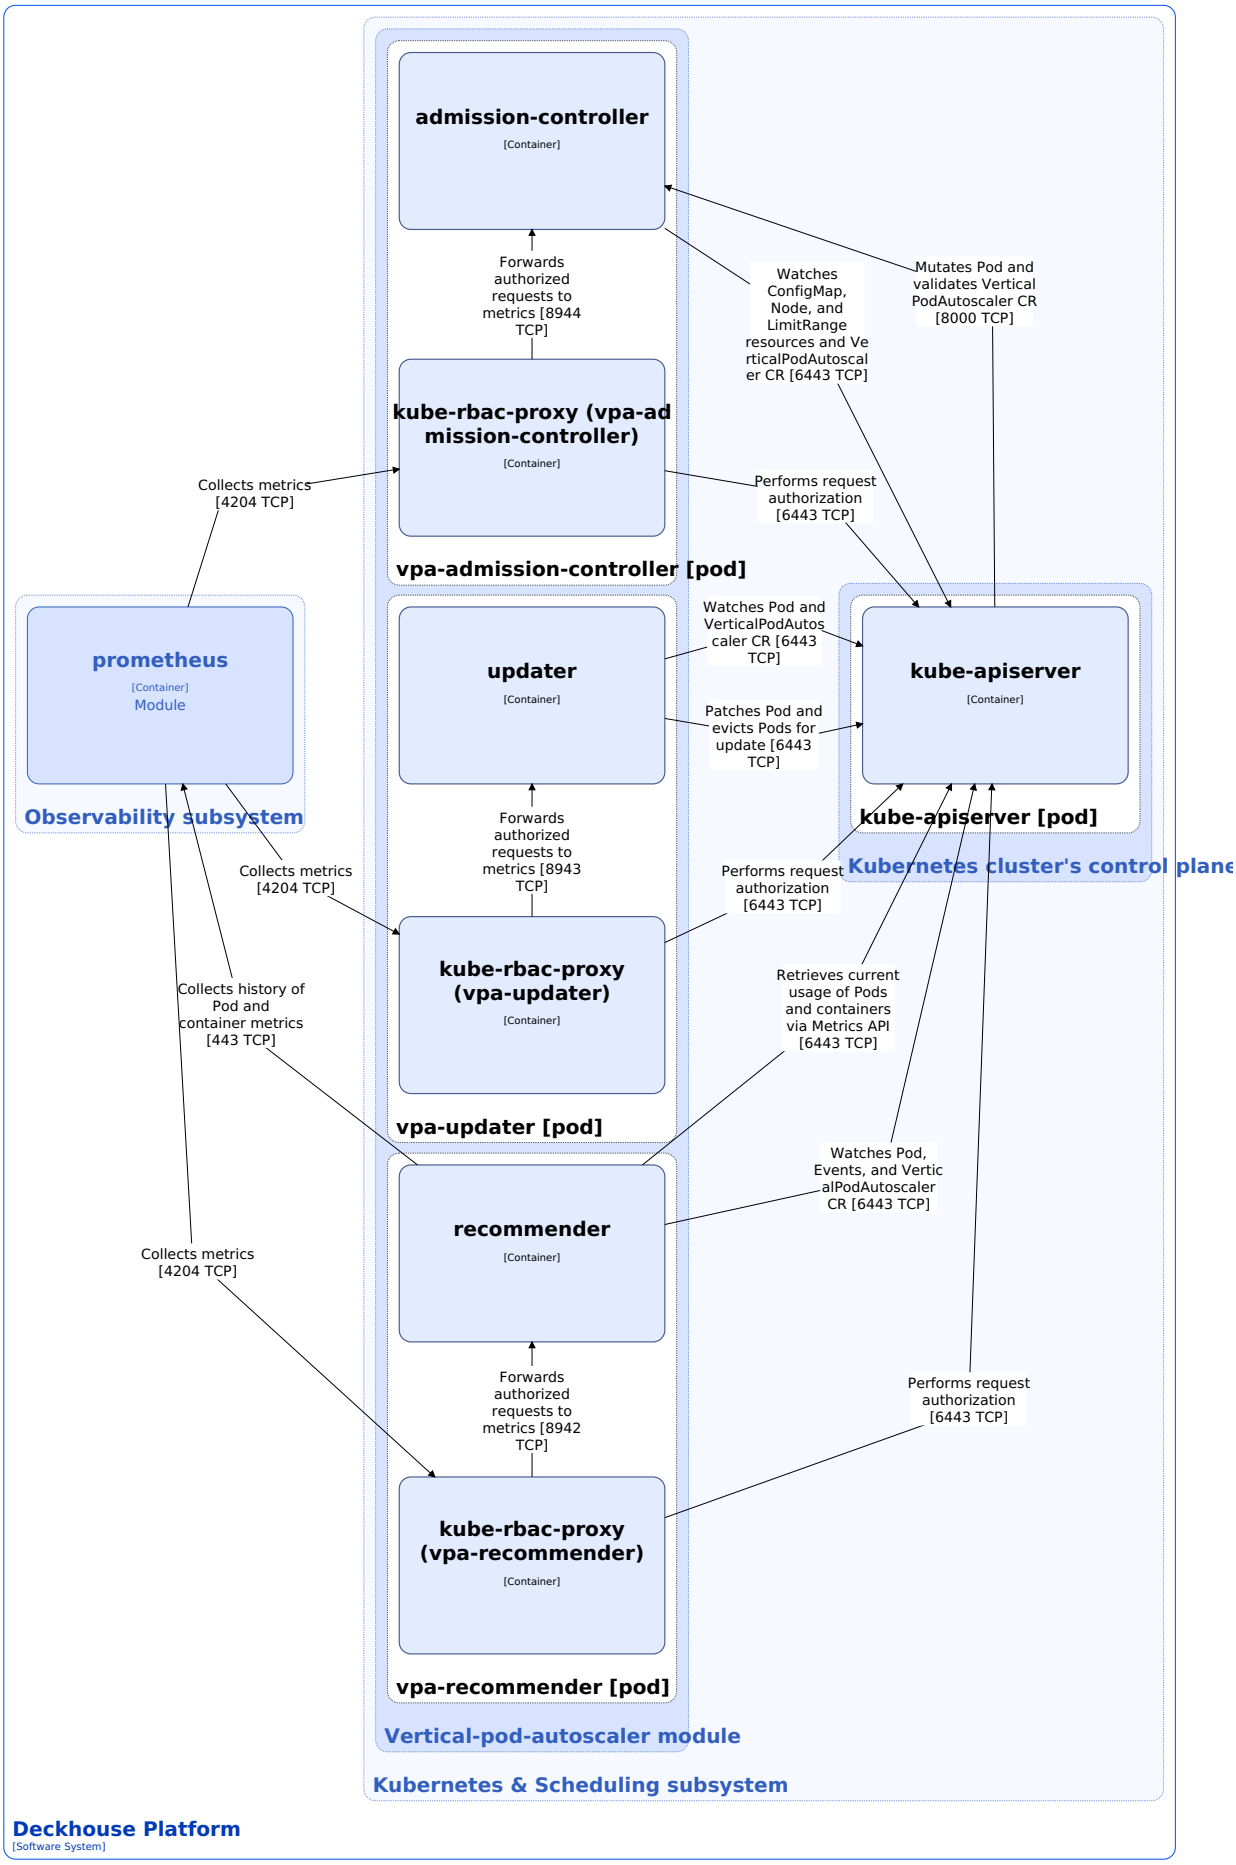
VPA limitations

Before using the vertical pod autoscaler (VPA), you need to consider several limitations:

- Pod restarts when resources are changed:
  - When using modes that allow Pod recreation, VPA may recreate a Pod if requested resources cannot be updated in place.
  - The new Pod can be scheduled on a different node.
- Compatibility with Horizontal Pod Autoscaler (HPA):
  - It is not recommended to use VPA together with HPA that is set for scaling based on CPU and

    memory.
  - VPA can be used with HPA that is set for scaling based on custom or external metrics.

- Issues in large clusters: VPA can work in large clusters, but the load on VPA increases as the number of pods grows.
- Issues with Pending pods: VPA may recommend resources that exceed those available in the cluster, causing pods to get stuck in the `Pending` state.
- Problems when deleting VPA: If you delete or disable VPA (Off mode), the resources will remain at the last modified values. This can cause confusion when resource values differ between the Helm charts, the controller, and the pods themselves.
- Using multiple VPA resources for a single pod: This can lead to unpredictable behavior.



⚠ When using VPA, it is recommended to configure a Pod Disruption Budget.

Module architecture

i The following simplifications are made in the diagram:

- The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
- Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `vertical-pod-autoscaler` module and its interactions with other DP components are shown in the following diagram:

Module components

The `vertical-pod-autoscaler` module consists of the following components:

1. **Vpa-admission-controller** (Deployment): A VPA controller that handles the VerticalPodAutoscaler

custom resource.

The vpa-admission-controller component performs the following actions:

- Validates VerticalPodAutoscaler custom resources.
- When a Pod is created and the VPA mode is not Off, the controller automatically sets or updates `requests` and `limits` in containers, optimizing them according to the current recommendations. The controller updates `limits` values only if the `spec.resourcePolicy.containerPolicies.controlledValues` parameter in the resource management policy is set to `RequestsAndLimits`.

It consists of the following containers:

- **admission-controller**: Main container.
- **kube-rbac-proxy**: Sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to admission-controller metrics. It is an open source project.

2. **Vpa-updater** (Deployment): A VPA component that checks whether pods with VPA have the correct resource settings. Vpa-updater performs in-place resource updates through the `pods/resize` Kubernetes subresource; if that is not possible or does not fit the resource management policy, it evicts the Pod.

   It consists of the following containers:

   - **updater**: Main container.
   - **kube-rbac-proxy**: Sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to updater metrics. It is an open source project.

3. **Vpa-recommender** (Deployment): A VPA component that calculates recommendations for `requests` based on past and current pod resource consumption.

   Vpa-admission-controller and vpa-updater recalculate `limits` values proportionally to `requests` values if the `spec.resourcePolicy.containerPolicies.controlledValues` parameter in resource management policy is set to `RequestsAndLimits`.

   It consists of the following containers:

   - **recommender**: Main container.
   - **kube-rbac-proxy**: Sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to recommender metrics. It is an open source project.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches standard resources such as ConfigMap, Node, LimitRange, and Pod, as well as VerticalPodAutoscaler and VerticalPodAutoscalerCheckpoint custom resources.
   - Retrieves current resource consumption through the Metrics API.
   - Evicts running pods when their resource specifications do not match the recommended values.
   - Authorizes requests for metrics.
2. **Prometheus**: Retrieves the history of pod resource consumption metrics.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Validates VerticalPodAutoscaler custom resources.
   - Changes `requests` and `limits` in the Pod specification.
2. **Prometheus**: Collects module metrics.

Additional resources

- Module `vertical-pod-autoscaler` documentation

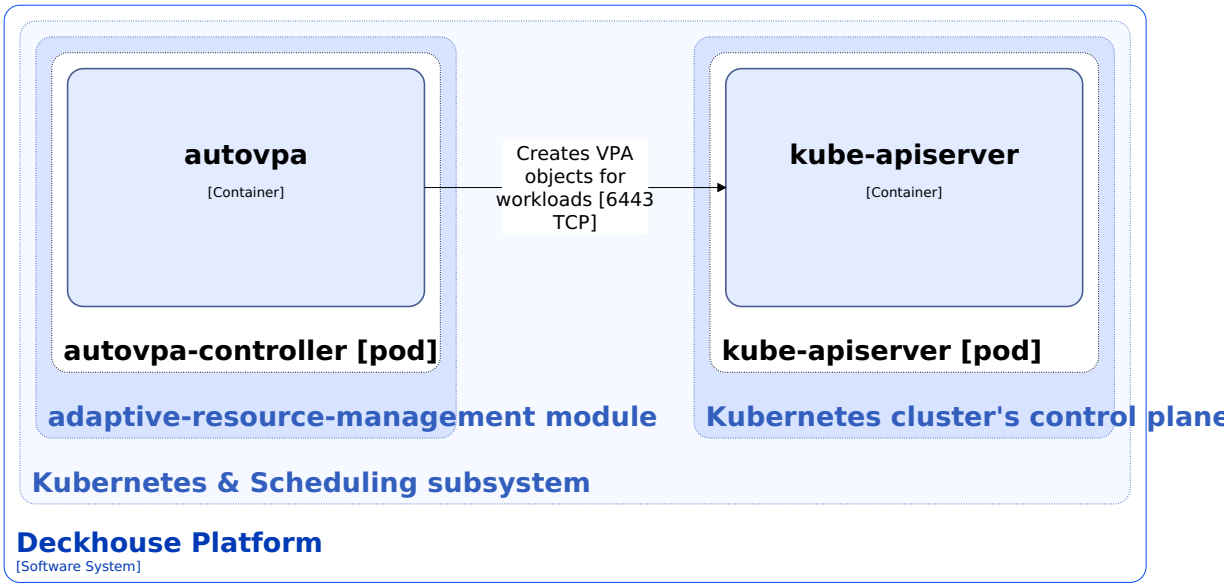
> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Adaptive-resource-management module

The `adaptive-resource-management` module lets you automate the selection of resource requests and limits for workloads by leveraging the Vertical Pod Autoscaler (VPA) recommendations.

The module deploys the **AutoVPA** controller based on Goldilocks tailored for Deckhouse Platform (DP). The controller automatically creates and maintains VPA objects for workloads in selected namespaces and provides recommendations on resource configuration.

Main features:



- Automatic creation of VPA objects for Deployments, StatefulSets, DaemonSets, and Jobs in managed namespaces.
- Flexible namespace selection: manage all namespaces, only namespaces with a specific label, or namespaces matching a label selector.
- Combined namespace selection mode using a label selector together with the special label `autovpa.deckhouse.io/enabled`.
- Automatic creation of VPA objects in recommendation-only mode without changing the workload manifests.
- Per-workload and per-namespace VPA tuning via `autovpa.deckhouse.io/*` annotations and labels.
- Minimal resource footprint: the controller runs as a single replica and requires low CPU and memory resources.

For more details about the module configuration and usage examples, refer to the module documentation.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). > **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
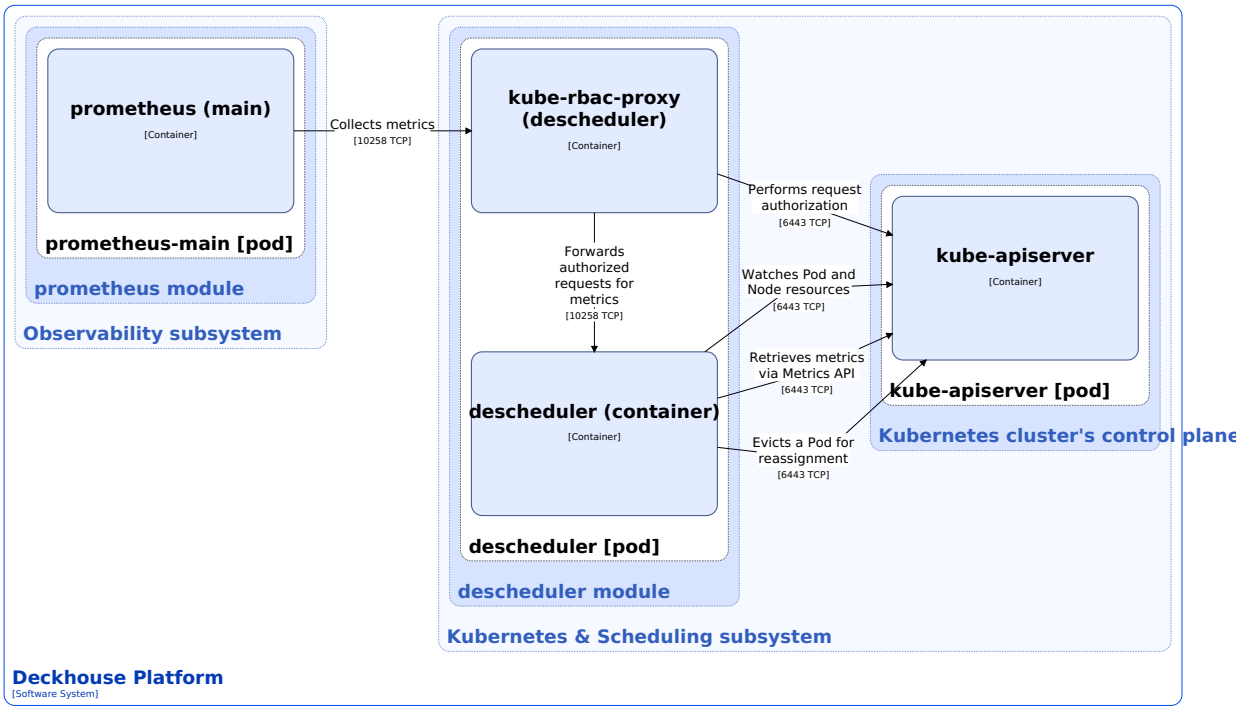
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Descheduler module

The `descheduler` module ensures operation of Descheduler in Deckhouse Platform (DP).

The module analyzes the cluster state periodically and evicts pods that match conditions defined in active strategies. Evicted pods are then scheduled again according to the current cluster state. This helps redistribute workloads in line with the selected strategy.



If the Metrics API service is registered in the cluster, the module uses it to obtain information about the current resource consumption.

Strategy parameters are configured using the Descheduler custom resource. A module hook processes these resources and recreates configuration for Descheduler.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). The Level 2 C4 architecture of the `pod-reloader` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The `pod-reloader` module consists of a single `pod-reloader` component that includes the following containers:

- **manager**: Main container.
- **kube-rbac-proxy**: Sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to pod-reloader metrics. It is an open-source project.

Module interactions

The module interacts with the `kube-apiserver` component:

- Watches ConfigMap and Secret resources.
- Triggers reload or rollout of pods.
- Authorizes requests for metrics.

The `prometheus-main` component interacts with the module by collecting module metrics.

Additional resources

- Module `pod-reloader` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Cluster & Infrastructure subsystem

This section describes the architecture of the Cluster & Infrastructure subsystem of the Deckhouse Platform (DP).

The Cluster & Infrastructure subsystem is responsible for the infrastructure layer of Kubernetes cluster management. Cluster node management is implemented using the `node-manager` module, while interaction with IaaS providers is handled by the corresponding `cloud-provider-` family modules.

This section describes:

- The mechanisms for managing all node types used in DP, as well as hybrid node groups and clusters.
- Bashible service, which is a key component of the Cluster & Infrastructure subsystem. Bashible is used by the `node-manager` module to manage node configuration.

The Cluster & Infrastructure subsystem also includes the following modules:

- `chrony`: Provides time synchronization across all cluster nodes.
- `registry-packages-proxy`: Provides an internal proxy server for container registry packages.
- `terraform-manager`: Provides tools for managing Terraform state within a Kubernetes cluster.

- Modules for cloud providers supported by DP:
  - `cloud-provider-aws`
  - `cloud-provider-azure`
  - `cloud-provider-dvp`
  - `cloud-provider-dynamix`
  - `cloud-provider-gcp`
  - `cloud-provider-huaweicloud`
  - `cloud-provider-openstack`
  - `cloud-provider-vcd`
  - `cloud-provider-vsphere`
  - `cloud-provider-yandex`
  - `cloud-provider-zvirt`
- The `infra-provider-baremetal` module, which creates CloudEphemeral nodes on physical servers.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Node management

Node types and addition mechanics

In Deckhouse Platform (DP), nodes are divided into the following types:

- **CloudEphemeral**: Nodes are automatically provisioned, created, and deleted in the configured cloud provider or on physical servers using the `infra-provider-baremetal` module.
- **CloudPermanent**: Persistent nodes created and updated by the `node-manager` module. The nodes differ in that their configuration comes not from the NodeGroup custom resource, but from a special resource <PROVIDER>ClusterConfiguration (for example, AWSClusterConfiguration for AWS). Also, an important difference is that to apply a node configuration, you need to run `dhctl converge` (by running the DP installer). An example of a CloudPermanent node in a cloud cluster is a cluster master node.
- **CloudStatic**: Created manually or by any external tools, located in the same cloud that is integrated with one of the cloud provider modules:
  - CloudStatic nodes have several features related to integration with the cloud provider. These nodes are managed by the `cloud-controller-manager` component, resulting in:
    - Zone and region metadata being automatically added to the Node object.
    - When the virtual machine is deleted in the cloud, the corresponding Node object is also removed from the cluster.
    - CSI driver can be used to attach cloud volumes.
- **Static**: Static node hosted on a bare-metal server or a virtual machine. In the case of a cloud environment, the `cloud-controller-manager` component does not manage such a node — even if one of the cloud providers is enabled. To learn more about working with static nodes, refer to the `node-manager` documentation.

> For Deckhouse Virtualization Platform (DVP), the DVPClusterConfiguration resource is not used. The CloudPermanent node parameters are set in the NodeGroup, DVPInstanceClass, and `cloud-provider-dvp` ModuleConfig resources.

Nodes are added to the cluster by creating a NodeGroup object, which describes the type, parameters, and configuration of the node group. For CloudEphemeral groups, DP interprets this object and automatically creates the corresponding nodes, registering them in the Kubernetes cluster. For other types (e.g., CloudPermanent or Static), node creation and registration must be done manually or via external tools.

Hybrid groups are also supported, where a single NodeGroup can include both Static nodes deployed in the cloud and static (bare-metal or virtual machine) nodes. For example, the main load may be handled by bare-metal servers, while cloud instances are used as scalable additions during peak loads.

Automatic deployment, configuration, and update of Kubernetes nodes

Automatic deployment (in *static/hybrid* — partial), configuration, and software updates work in all clusters regardless of being cloud or bare metal.

Kubernetes node deployment

DP automatically deploys cluster nodes by performing the following **idempotent** operations:

- OS setup and optimization for working with `containerd` and Kubernetes:
  - Required packages are installed from distribution repositories.
  - Kernel parameters, logging settings, log rotation, and other system parameters are configured.
- Installation of required versions of `containerd` and kubelet, and registration of the node in the Kubernetes cluster.
- Kubernetes-api-proxy setup and updating the upstream list for balancing requests from the node to the Kubernetes API.

Maintaining node state

Two types of updates can be applied to maintain the node’s up-to-date state:

- **Regular**: Always applied automatically and do not cause downtime or reboot.
- **Disruptive**: Such as kernel or `containerd` updates, significant kubelet version changes, etc. These can be configured in manual or automatic mode via the `disruptions` section. In automatic mode, a node drain is performed before the update.

Only one node per group is updated at a time, and only if all nodes in the group are available.

DP includes built-in monitoring metrics to track update progress, notify of issues, or prompt for manual approval if needed.

Working with nodes in supported clouds

Each supported cloud provider allows automatic node provisioning. You need to specify required parameters for each node or group.

Depending on the provider, parameters may include:

- Node type or CPU/memory capacity
- Disk size
- Security settings
- Connected networks, etc.

VM creation, startup, and cluster joining are performed automatically.

Cloud node scaling

Two node scaling modes are available:

- **Automatic scaling.**

  When resources are insufficient and pods are in `Pending` state, nodes are added to the group. If there is no load on one or several nodes, they are removed from the cluster. With automatic scaling, a group priority is considered (groups with higher priority are scaled first).

  To enable auto-scaling, specify different non-zero values for `minPerZone` and `maxPerZone` number of nodes per group.

- **Fixed node count.**

  DP will maintain the specified number of nodes (for example, by provisioning new nodes to replace failed ones).

  To disable auto-scaling and maintain a fixed count, use the same value for `minPerZone` and `maxPerZone`.

Working with Static nodes

When working with static nodes, node-manager functions are limited as follows:

- **No node provisioning.** Resource allocation (bare-metal servers, VMs, etc.) is manual. Further configuration (joining the cluster, monitoring, etc.) can be fully or partially automated.
- **No auto-scaling.** Maintaining node count in a group is available using Cluster API Provider Static (via the `staticInstances.count` parameter). DP tries to keep the specified node count in the group, removing excessive nodes and configuring the new ones (from StaticInstance resources in *Pending* state).

Node configuration, draining, adding to the cluster and removal can be performed in one of the following ways:

- **Manually** using prepared scripts.

  To configure a server (VM) and add a node to the cluster, download and run a bootstrap script. It's generated for each static NodeGroup and stored in the secret `d8-cloud-instance-manager/manual-bootstrap-for-<NODEGROUP-NAME>`.

  To remove a node from the cluster and wipe the server (VM), use the `/var/lib/bashible/cleanup_static_node.sh` script (already present on each static node).

- **Automatically** using Cluster API Provider Static.

  CAPS connects to the server (VM) using StaticInstance and SSHCredentials resources, configures and adds the node to the cluster.

  If needed (e.g., if a corresponding StaticInstance resource is removed or the node count is decreased), CAPS connects to the cluster node, drains it, and removes from the cluster.

- **Manually, with transition to automatic management** via CAPS.

  > **i** Available since DP 1.63.

  To transfer an existing cluster node under CAPS control, prepare StaticInstance and SSHCredentials as for automatic management described above, and annotate the StaticInstance resource with `static.node.deckhouse.io/skip-bootstrap-phase: ""`.

Node grouping and group management

Grouping and managing nodes as a group means that all group nodes will share metadata from the `NodeGroup` custom resource.

Monitoring features for node groups include:

- Grouped node parameter charts
- Grouped node availability alerts
- Alerts for N unavailable nodes or N% group nodes, etc.

What is the Instance resource

The Instance resource in Kubernetes represents a definition of an ephemeral virtual machine object, without a specific implementation. It's an abstraction used to manage machines created by tools such as `MachineControllerManager` or Cluster API Provider Static.

The object has no specification. Its status includes:

1. Reference to InstanceClass if available.
2. Reference to the Kubernetes Node object.
3. Current machine status.
4. Info on how to check machine creation logs (available during machine creation).

Creating or deleting a machine will create or delete the corresponding Instance resource. You cannot manually create an Instance resource, but you can delete it. This will remove the machine from the cluster (implementation-dependent).

When node reboot is required

Some node configuration changes may require a reboot.

For example, a node reboot is needed after modifying `sysctl` parameters like `kernel.yama.ptrace_scope`.

NodeGroup parameter effects on node updates and restarts

NodeGroup parameter	Disruption update	Node reprovisioning	Kubelet restart
chaos	-	-	-
cloudInstances.classReference	-	+	-
cloudInstances.maxSurgePerZone	-	-	-
cri.containerd.maxConcurrentDownloads	-	-	+
cri.type	- (NotManaged) / + (other)	-	-
disruptions	-	-	-
kubelet.maxPods	-	-	+
kubelet.rootDir	-	-	+
kubernetesVersion	-	-	+
nodeTemplate	-	-	-
static	-	-	+
update.maxConcurrent	-	-	-

For full details, see the NodeGroup custom resource documentation.

When the InstanceClass parameters change, the platform replaces the group machines with new ones. How many instances are replaced at the same time is defined by the `cloudInstances.maxSurgePerZone` and `cloudInstances.maxUnavailablePerZone` parameters. When `instancePrefix` changes in the DP configuration, the platform creates new MachineDeployment objects and removes the old ones.

When an update requires a node disruption, a pod eviction process is initiated. If a pod cannot be evicted, the eviction attempt is retried every 20 seconds for up to 5 minutes global timeout. After that, pods that have not been evicted are forcefully removed.

Bashible

Bashible scripts and the bashible service

Node management functions are implemented using specially prepared bash scripts called **bashible**. The service that runs on cluster nodes and executes these scripts is also called bashible. A collection of scripts is referred to as a bundle.

4 bundles are used:

- Bashible installation scripts
- Bootstrap scripts for the first node
- Node configuration scripts for a specific cloud provider (for example, AWS)
- Common scripts

The scripts are implemented as *gotemplate* templates, which allows flexible node configuration depending on the node group. The scripts must be written in such a manner so that they can be safely re-executed in case of failure or repeated runs. An individual script is referred to as a step.

Main node configuration stages:

- Configuring the NodeUser to ensure access to the node.
- Installing CA certificates.
- Creating the `/opt/deckhouse/bin` directory, adding it to `PATH`, and placing required binaries there.
- Downloading required packages from `registrypackages`.
- Installing and configuring the containerd CRI.
- Downloading and configuring **kubernetes-api-proxy**. This component provides access to the Kubernetes API and is implemented as an NGINX instance with upstream servers pointing to master nodes. This ensures high availability of the API in case one master node is unavailable, as well as load balancing.
- Installing, configuring, and starting kubelet.
- Starting the bashible service, which runs `bashible.sh` every minute.
- Rebooting the node if required.

Bashible-api-server

Due to the large number of bashible script variations for different supported operating systems, storing all versions in etcd is not feasible because of key size limitations and the additional load on etcd. For this reason, the **bashible-api-server** component was developed to generate bashible scripts from templates stored in Custom Resources.

Bashible-api-server is a Kubernetes Extension API Server deployed on master nodes.

When kube-apiserver receives a request for resources containing bashible bundles, it forwards the request to bashible-api-server and returns the generated result. The interactions between bashible and bashible-api-server are shown in the architecture diagrams of the `node-manager` module (for example, in the CloudEphemeral nodes diagram).

Bashible-api-server returns the following resources:

- The **second-phase bootstrap script** downloaded during the first phase.
- **Bashibles**: The `bashible.sh` script.
- **Nodegroupbundles**: Rendered bundle containing the set of scripts for bootstrapping and configuring a node.

These resources can be retrieved either via the Kubernetes API or using `kubectl` by specifying the node group name:

- `kubectl get bootstrap.bashible.deckhouse.io master -o yaml`
- `kubectl get bashibles.bashible.deckhouse.io master -o yaml`
- `kubectl get nodegroupbundles.bashible.deckhouse.io master -o yaml`

Bashible-api-server calculates a checksum of all scripts associated with a node group. This is required to implement the update mechanism and ensure correct node group status updates. The checksums are stored in the `d8-cloud-instance-manager/configuration-checksums` secret. A checksum change triggers the re-execution of bashible scripts on nodes when the configuration is modified. In addition, the checksum of the bashible service is reset every 4 hours to force periodic re-execution of bashible.

Node-manager module

Cluster nodes are managed by the `node-manager` module.

For a detailed description of the module’s functions, configuration options, and usage examples, refer to the corresponding documentation section.

Module architecture

The module architecture varies depending on the node type and differs in terms of its component composition. The following pages describe the module architecture for different node types:

- Managing CloudEphemeral nodes
- Managing CloudPermanent nodes
- Managing CloudStatic nodes
- Managing Static nodes
- Managing hybrid node groups and clusters

Additional resources

- Module `node-manager` documentation

CloudEphemeral node management

This page describes the architecture of the `node-manager` module for CloudEphemeral nodes.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `node-manager` module and its interactions with other Deckhouse Platform (DP) components are shown in the following diagram:

Module components

> **i** Bashible is a key component of the Cluster & Infrastructure subsystem that enables the operation of the `node-manager` module. However, it is not part of the module itself, as it runs at the OS level as a system service. For Bashible details, refer to the corresponding documentation section.

The module managing CloudEphemeral nodes consists of the following components:

1. **Bashible-api-server**: A Kubernetes Extension API Server deployed on master nodes. It generates bashible scripts from templates stored in custom resources. When kube-apiserver receives a request for resources containing bashible bundles, it forwards the request to bashible-api-server and returns the generated result. For more details about bashible and bashible-api-server, refer to the corresponding documentation section.
2. **Node-controller** (Deployment): A controller that manages NodeGroup custom resources lifecycle. Node-controller performs the following operations:
   - Manages NodeGroup custom resources lifecycle.
   - Implements NodeGroup custom resources validating webhooks using the Validating Admission Controllers mechanism.
   - Implements NodeGroup and Instance custom resources conversion webhooks.
   - Cleans up Node resource labels and taints that remain after the bashible first run to initialize the node.
   - Ensures draining a node.
   - Applies labels, taints and annotations from the `spec.nodeTemplate` section of a NodeGroup custom resource to all Node resources belonging to it.
   - Calculates and updates a NodeGroup custom resource `status` subresource based on aggregated information obtained from the corresponding Node resources and infrastructure custom resources.
   - Sets the `spec.providerId = "static://"` attribute for Static type Node resources if it is missing.
   - Manages the node update lifecycle: approving updates, handling node disruptions, draining a node and cleanup after a successful update.

   The component includes:
   - **node-controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.
3. **Node-group-exporter** (Deployment): A component that exports NodeGroup resource metrics in Prometheus format, containing information about the number of nodes in each node group: the total number, the number of nodes in the `Ready` status, the number of nodes in error, the minimum and maximum number of nodes in the group, etc.

   The component includes:
   - **node-group-exporter**: Main container.
   - **kube-rbac-proxy** Sidecar container providing an RBAC-based authorization proxy for secure access to exporter metrics.
4. **Capi-controller-manager** (Deployment): Core controllers from the Kubernetes Cluster API project. Cluster API extends Kubernetes to manage clusters as custom resources within another Kubernetes cluster.

   The component includes:
   - **control-plane-manager**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.
5. **Cluster-autoscaler** (Deployment): An additional Kubernetes component that automatically adjusts the number of nodes in the cluster based on workload. For more details, refer to the node management documentation section.

   The component includes:
   - **cluster-autoscaler**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cluster-autoscaler metrics.
6. **Fencing-agent** (DaemonSet) and **fencing-controller**: Components that implement the fencing mechanism. The operation principles of both components are described in detail in the `spec.fencing.mode` parameter description of the NodeGroup resource. For details on how the fencing mechanism handles different node types, refer to FAQ in the `node-manager` module documentation.
7. **Standby-holder** (Deployment): A pod used to reserve nodes. When the `spec.cloudinstances.standby` parameter is enabled in the NodeGroup custom resource, standby nodes are created in all configured zones.

A standby node is a cluster node with pre-reserved resources available for immediate scaling. This allows cluster-autoscaler to schedule workloads without waiting for node initialization, which may take several minutes.

The standby-holder pod does not perform useful work. It simply reserves resources to prevent cluster-autoscaler from deleting temporarily unused nodes.

The pod has the lowest PriorityClass and is evicted when real workloads are scheduled. For details on pod priority and preemption, refer to the Kubernetes documentation.

The component includes a single container **reserve-resources**.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Retrieves the `kube-system/d8-node-manager-cloud-provider` Secret for cloud connectivity.
   - Works with Cluster API custom resources.
   - Manages Node and NodeGroup resources.
   - Monitors node load.
   - Performs node autoscaling.
   - Authorizes metric requests.
2. Node filesystem:
   - `/dev/watchdog`: Sends signals to reset the Watchdog timer.

> **i** The module interacts with the `cloud-provider` module via kube-apiserver using the `kube-system/d8-node-manager-cloud-provider` Secret to obtain cloud connection settings and create CloudEphemeral nodes. The `cloud-provider` module also provides provider-specific Cluster API custom resource templates to `node-manager`.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Executes validating and conversion webhooks of node-controller.
   - Executes mutating and validating webhooks of capi-controller-manager.
   - Forwards requests for bashible resources to bashible-api-server.
2. **Prometheus-main**:
   - Collects metrics from `node-manager` module components.

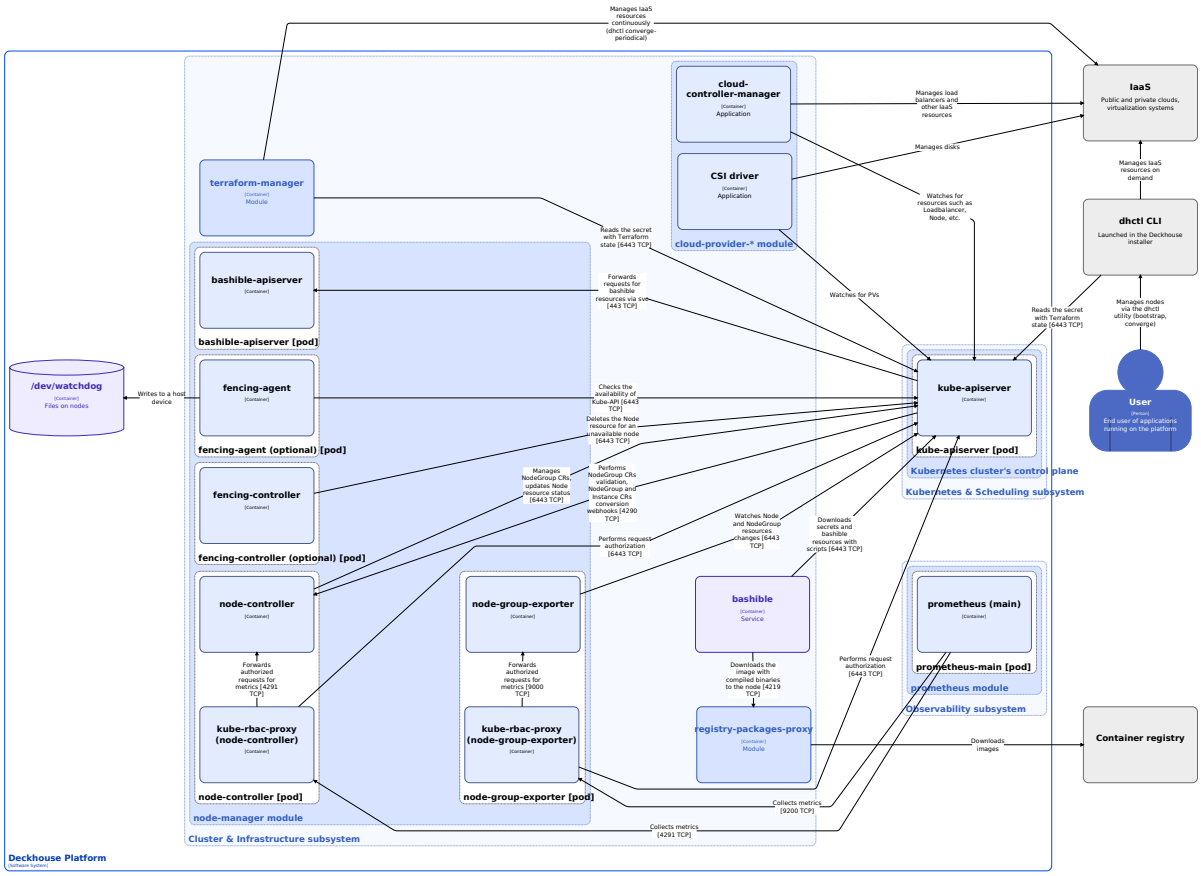
Architecture features specific to CloudEphemeral nodes

1. Nodes are ephemeral and automatically created and deleted by the module.
2. A configured cloud provider module (`cloud-provider-*`) is required for interaction with cloud infrastructure. It also includes csi-driver and cloud-controller-manager. Nodes on physical servers are created using the `infra-provider-baremetal` module, which does not include csi-driver or cloud-controller-manager.
3. **Capi-controller-manager** manages the lifecycle of the cluster and its nodes through higher-level custom resources, without directly provisioning infrastructure. It generates infrastructure-specific custom resources, leaving provisioning to the `cloud-provider` module.
4. **Cluster-autoscaler** enables node autoscaling.
5. Node reservation is supported.

Additional resources

- Module `infra-provider-baremetal` documentation
- Module `node-manager` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.



CloudPermanent node management

This page describes the architecture of the `node-manager` module for CloudPermanent nodes.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `node-manager` module and its interactions with other Deckhouse Platform (DP) components are shown in the following diagram:

Module components

> **i** Bashible is a key component of the Cluster & Infrastructure subsystem that enables the operation of the `node-manager` module. However, it is not part of the module itself, as it runs at the OS level as a system service. For Bashible details, refer to the corresponding documentation section.

The module managing CloudPermanent nodes consists of the following components:

1. **Bashible-api-server**: A Kubernetes Extension API Server deployed on master nodes. It generates bashible scripts from templates stored in custom resources. When kube-apiserver receives a request for resources containing bashible bundles, it forwards the request to bashible-api-server and returns the generated result. For more details about bashible and bashible-api-server, refer to the corresponding documentation section.
2. **Node-controller** (Deployment): A controller that manages NodeGroup custom resources lifecycle. Node-controller performs the following operations:
   - Manages NodeGroup custom resources lifecycle.
   - Implements NodeGroup custom resources validating webhooks using the Validating Admission Controllers mechanism.
   - Implements NodeGroup and Instance custom resources conversion webhooks.
   - Cleans up Node resource labels and taints that remain after the bashible first run to initialize the node.

- Ensures draining a node.
- Applies labels, taints and annotations from the `spec.nodeTemplate` section of a NodeGroup custom resource to all Node resources belonging to it.
- Calculates and updates a NodeGroup custom resource `status` subresource based on aggregated information obtained from the corresponding Node resources and infrastructure custom resources.
- Sets the `spec.providerId = "static://"` attribute for Static type Node resources if it is missing.
- Manages the node update lifecycle: approving updates, handling node disruptions, draining a node and cleanup after a successful update.

The component includes:

- **node-controller**: Main container.
- **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.

3. **Node-group-exporter** (Deployment): A component that exports NodeGroup resource metrics in Prometheus format, containing information about the number of nodes in each node group: the total number, the number of nodes in the `Ready` status, the number of nodes in error, the minimum and maximum number of nodes in the group, etc.

   The component includes:

   - **node-group-exporter**: Main container.
   - **kube-rbac-proxy** Sidecar container providing an RBAC-based authorization proxy for secure access to exporter metrics.

4. **Fencing-agent** (DaemonSet) and **fencing-controller**: Components that implement the fencing mechanism. The operation principles of both components are described in detail in the `spec.fencing.mode` parameter description of the NodeGroup resource. For details on how the fencing mechanism handles different node types, refer to FAQ in the `node-manager` module documentation.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Manages Node and NodeGroup resources.
   - Authorizes metric requests.
2. Node filesystem:
   - `/dev/watchdog`: Sends signals to reset the Watchdog timer.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Executes validating and conversion webhooks of node-controller.
   - Forwards requests for bashible resources to bashible-api-server.
2. **Prometheus-main**:
   - Collects metrics from `node-manager` module components.

Architecture features specific to CloudPermanent nodes

1. Nodes are persistent and are created, managed, and deleted by the user. Node management is performed not directly in the infrastructure but via the **dhctl** utility executed as part of the DP installer.
2. `Terraform-manager` is a module used for automated management of cloud infrastructure resources. It checks the Terraform state and applies non-destructive changes to infrastructure resources. The module architecture is described on the corresponding documentation page.
3. **Csi-driver** is used to provision disks in the cloud infrastructure.
4. **Cloud-controller-manager** is used to provision load balancers and other infrastructure resources according to its specification.
5. **Infrastructure-provider** is not required. All node management operations are performed by the user via the **dhctl** utility and the `terraform-manager` module.
6. Automatic node scaling is not supported.

Additional resources

CloudStatic node management

This page describes the architecture of the `node-manager` module for CloudStatic nodes.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `node-manager` module and its interactions with other Deckhouse Platform (DP) components are shown in the following diagram:

Module components

> Bashible is a key component of the Cluster & Infrastructure subsystem that enables the operation of the `node-manager` module. However, it is not part of the module itself, as it runs at the OS level as a system service. For Bashible details, refer to the corresponding documentation section.

The module managing CloudStatic nodes consists of the following components:

1. **Bashible-api-server**: A Kubernetes Extension API Server deployed on master nodes. It generates

bashible scripts from templates stored in custom resources. When kube-apiserver receives a request for resources containing bashible bundles, it forwards the request to bashible-api-server and returns the generated result. For more details about bashible and bashible-api-server, refer to the corresponding documentation section.

2. **Node-controller** (Deployment): A controller that manages NodeGroup custom resources lifecycle. Node-controller performs the following operations:

   - Manages NodeGroup custom resources lifecycle.
   - Implements NodeGroup custom resources validating webhooks using the Validating Admission Controllers mechanism.
   - Implements NodeGroup and Instance custom resources conversion webhooks.
   - Cleans up Node resource labels and taints that remain after the bashible first run to initialize the node.
   - Ensures draining a node.
   - Applies labels, taints and annotations from the `spec.nodeTemplate` section of a NodeGroup custom resource to all Node resources belonging to it.
   - Calculates and updates a NodeGroup custom resource `status` subresource based on aggregated information obtained from the corresponding Node resources and infrastructure custom resources.
   - Sets the `spec.providerId = "static://"` attribute for Static type Node resources if it is missing.
   - Manages the node update lifecycle: approving updates, handling node disruptions, draining a node and cleanup after a successful update.

   The component includes:

   - **node-controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.

3. **Node-group-exporter** (Deployment): A component that exports NodeGroup resource metrics in Prometheus format, containing information about the number of nodes in each node group: the total number, the number of nodes in the `Ready` status, the number of nodes in error, the minimum and maximum number of nodes in the group, etc.

   The component includes:

   - **node-group-exporter**: Main container.
   - **kube-rbac-proxy** Sidecar container providing an RBAC-based authorization proxy for secure access to exporter metrics.

4. **Capi-controller-manager** (Deployment): Core controllers from the Kubernetes Cluster API project. Cluster API extends Kubernetes to manage clusters as custom resources within another Kubernetes cluster.

   The component includes:

   - **control-plane-manager**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.

5. **Caps-controller-manager** (Deployment): CAPI Provider Static (CAPS), an implementation of a provider for declarative management of static nodes (bare-metal servers or virtual machines) in the Kubernetes Cluster API project. It operates as an extension to capi-controller-manager.

   CAPS provides an additional abstraction layer over the existing DP mechanism for automatic configuration and cleanup of static nodes using scripts generated for each node group. The component is not tied to a specific cloud provider. For more details, refer to the `node-manager` documentation.

6. **Fencing-agent** (DaemonSet) and **fencing-controller**: Components that implement the fencing mechanism. The operation principles of both components are described in detail in the `spec.fencing.mode` parameter description of the NodeGroup resource. For details on how the fencing mechanism handles different node types, refer to FAQ in the `node-manager` module documentation.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Works with Cluster API custom resources.
   - Manages Node and NodeGroup resources.
   - Authorizes metric requests.

2. Node filesystem:

   - `/dev/watchdog`: Sends signals to reset the Watchdog timer.

3. Infrastructure:
    - Manages static nodes (partially, without provisioning).

The following external components interact with the module:

1. **Kube-apiserver**:
    - Executes validating and conversion webhooks of node-controller.
    - Executes mutating and validating webhooks of capi-controller-manager.
    - Forwards requests for bashible resources to bashible-api-server.
2. **Prometheus-main**:
    - Collects metrics from `node-manager` module components.

Architecture features specific to CloudStatic nodes

1. Users create and configure nodes in the following ways:
    - Manually, using bashible scripts preconfigured in DP.
    - Manually, with the following node handover to CAPS for automated management.
    - Automatically, using CAPS.
2. **Capi-controller-manager** manages the lifecycle of the cluster and its nodes through higher-level custom resources, without directly provisioning infrastructure. It generates infrastructure-specific custom resources, leaving provisioning to the infrastructure provider (CAPS).
3. **Caps-controller-manager**: Component managing static nodes (partially, without provisioning).
4. **Csi-driver** is used to provision disks in the cloud infrastructure.
5. **Cloud-controller-manager** is used to provision load balancers and other infrastructure resources according to its specification.
6. **Infrastructure-provider** of a specific cloud is not required, as CAPS acts on its behalf.
7. Automatic node scaling is not supported.

Additional resources

Static node management

This page describes the architecture of the `node-manager` module for Static nodes.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `node-manager` module and its interactions with other Deckhouse Platform (DP) components are shown in the following diagram:

Module components

> **i** Bashible is a key component of the Cluster & Infrastructure subsystem that enables the operation of the `node-manager` module. However, it is not part of the module itself, as it runs at the OS level as a system service. For Bashible details, refer to the corresponding documentation section.

The module managing Static nodes consists of the following components:

1. **Bashible-api-server**: A Kubernetes Extension API Server deployed on master nodes. It generates bashible scripts from templates stored in custom resources. When kube-apiserver receives a request for resources containing bashible bundles, it forwards the request to bashible-api-server and returns the generated result. For more details about bashible and bashible-api-server, refer to the corresponding documentation section.

2. **Node-controller** (Deployment): A controller that manages NodeGroup custom resources lifecycle. Node-controller performs the following operations:

   - Manages NodeGroup custom resources lifecycle.
   - Implements NodeGroup custom resources validating webhooks using the Validating Admission Controllers mechanism.
   - Implements NodeGroup and Instance custom resources conversion webhooks.
   - Cleans up Node resource labels and taints that remain after the bashible first run to initialize the node.
   - Ensures draining a node.
   - Applies labels, taints and annotations from the `spec.nodeTemplate` section of a NodeGroup custom resource to all Node resources belonging to it.
   - Calculates and updates a NodeGroup custom resource `status` subresource based on aggregated information obtained from the corresponding Node resources and infrastructure custom resources.
   - Sets the `spec.providerId = "static://"` attribute for Static type Node resources if it is missing.
   - Manages the node update lifecycle: approving updates, handling node disruptions, draining a node and cleanup after a successful update.

   The component includes:

   - **node-controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.

3. **Node-group-exporter** (Deployment): A component that exports NodeGroup resource metrics in

Prometheus format, containing information about the number of nodes in each node group: the total number, the number of nodes in the `Ready` status, the number of nodes in error, the minimum and maximum number of nodes in the group, etc.

The component includes:

- **node-group-exporter**: Main container.
- **kube-rbac-proxy** Sidecar container providing an RBAC-based authorization proxy for secure access to exporter metrics.

4. **Capi-controller-manager** (Deployment): Core controllers from the Kubernetes Cluster API project. Cluster API extends Kubernetes to manage clusters as custom resources within another Kubernetes cluster.

   The component includes:

   - **control-plane-manager**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.

5. **Caps-controller-manager** (Deployment): CAPI Provider Static (CAPS), an implementation of a provider for declarative management of static nodes (bare-metal servers or virtual machines) in the Kubernetes Cluster API project. It operates as an extension to capi-controller-manager.

   CAPS provides an additional abstraction layer over the existing DP mechanism for automatic configuration and cleanup of static nodes using scripts generated for each node group. The component is not tied to a specific cloud provider. For more details, refer to the `node-manager` documentation.

6. **Fencing-agent** (DaemonSet) and **fencing-controller**: Components that implement the fencing mechanism. The operation principles of both components are described in detail in the `spec.fencing.mode` parameter description of the NodeGroup resource. For details on how the fencing mechanism handles different node types, refer to FAQ in the `node-manager` module documentation.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Works with Cluster API custom resources.
   - Manages Node and NodeGroup resources.
   - Authorizes metric requests.
2. Node filesystem:
   - `/dev/watchdog`: Sends signals to reset the Watchdog timer.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Executes validating and conversion webhooks of node-controller.
   - Executes mutating and validating webhooks of capi-controller-manager.
   - Forwards requests for bashible resources to bashible-api-server.
2. **Prometheus-main**:
   - Collects metrics from `node-manager` module components.

Architecture features specific to Static nodes

1. Users create and configure nodes in the following ways:
   - Manually, using bashible scripts preconfigured in DP.
   - Manually, with the following node handover to CAPS for automated management.
   - Automatically, using CAPS.
2. **Capi-controller-manager** manages the lifecycle of the cluster and its nodes through higher-level custom resources, without directly provisioning infrastructure. It generates infrastructure-specific custom resources, leaving provisioning to the infrastructure provider, which is deployed by the specific cloud provider module (CAPS for static nodes).
3. **Caps-controller-manager**: Component managing static nodes (partially, without provisioning).
4. Static nodes can be used not only on bare metal, but in cloud as well. In that case, such a node is not managed by cloud-controller-manager, even if one of the cloud providers is enabled. Csi-driver is not installed on such nodes.
5. Automatic node scaling is not supported.

Additional resources

- Module `node-manager` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Hybrid node group and cluster management

It is important to distinguish between hybrid node groups and hybrid clusters:

- **Hybrid node groups** may include both Static nodes deployed in the cloud and servers deployed in the customer's on-premises data center (bare metal or virtual machines).

  For example, the primary workload may run on bare-metal servers, while cloud instances are used as a scalable addition during peak loads. Since nodes of the same type (Static) are used both in the customer's data center and in the cloud, the architecture of the `node-manager` module in this case corresponds to the Static node variant. The only mandatory requirement is the presence of L3 connectivity between the on-premises data center and the cloud. For example, Yandex Cloud provides a Cloud Interconnect mechanism.

- **Hybrid clusters** are DP clusters that simultaneously include:

  - NodeGroup with Static nodes deployed in the customer's on-premises data center (bare metal or virtual machines).
  - NodeGroup with CloudEphemeral nodes deployed in the cloud.

  In this case, the components required to manage both node types are deployed. The architecture of the `node-manager` module corresponds to the Static node variant. In addition, components required for CloudEphemeral nodes are deployed:

  - **cloud-provider**: Provides interaction with the cloud infrastructure. A configured provider for the corresponding cloud is required. It also includes csi-driver and cloud-controller-manager.
  - **cluster-autoscaler**: Provides automatic scaling of cluster nodes.

  As with hybrid node groups, hybrid clusters require L3 connectivity between the on-premises data center and the cloud.

Additional resources

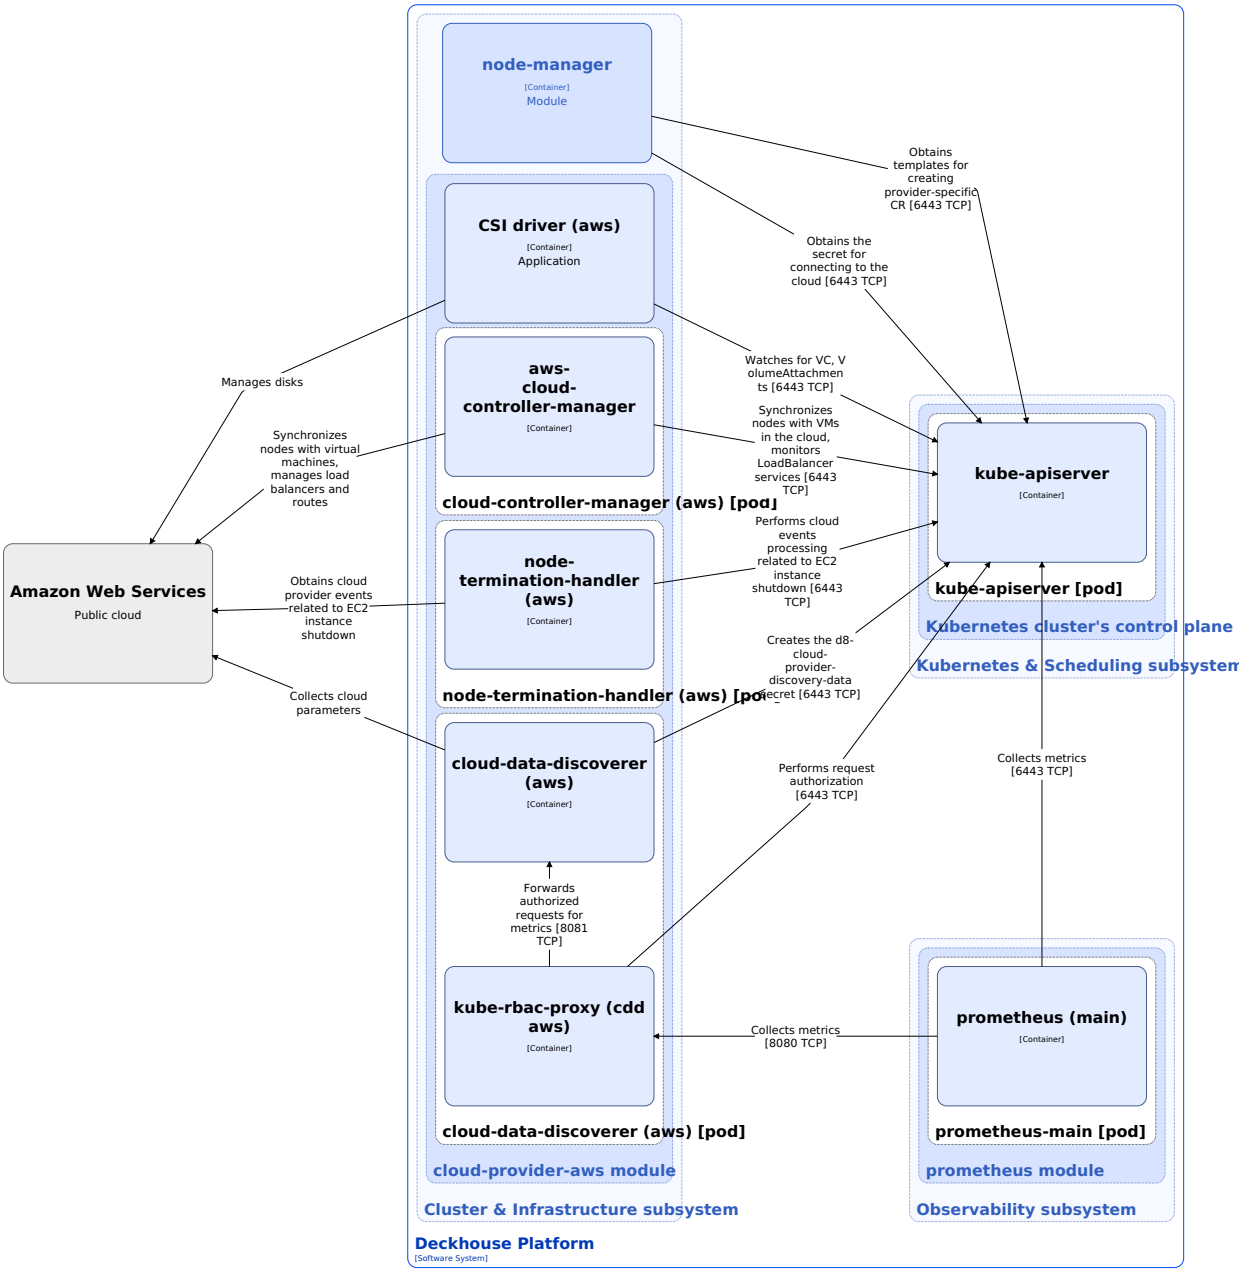
Cloud-provider-aws module

The `cloud-provider-aws` module is responsible for interacting with the Amazon Web Services cloud resources. It allows the `node-manager` module to use AWS resources for provisioning nodes for the specified node group.



For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-aws` module and its interactions with other components

of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-controller-manager**: It is an implementation of cloud controller manager for AWS. It provides interaction with the AWS cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.
   - Creates network routes for the `PodNetwork` network in the cloud.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **aws-cloud-controller-manager**.

2. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-aws` module.

   It consists of the following containers:

- **cloud-data-discoverer**: Main container.
- **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

3. **CSI driver (aws)**: It is an implementation of the CSI driver for AWS. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation section.

4. **Node-termination-handler**: AWS Node Termination Handler. It is responsible for gracefully handling the termination of EC2 instances in the Kubernetes control plane.

   Node-termination-handler processes the following AWS events:

   - EC2 maintenance events
   - EC2 Spot interruptions
   - ASG Scale-In
   - ASG AZ Rebalance
   - EC2 Instance Termination

   It consists of a single container:

   - **node-termination-handler**.

   After receiving an event when it is necessary to drain and then to delete a node, for example, in case of a regular interruption of a spot instance, node-termination-handler sets the `aws-node-termination-handler/spot-itn` taint for the corresponding node. A node drain itself, and then node removal are performed by the `node-manager` module using the module hooks mechanics.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.

2. **Amazon Web Services**:

   - Collects cloud parameters.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages network routes for `PodNetwork` network.
   - Collects cloud events of EC2 instance termination.
   - Manages disks.

The following external components interact with the module:

- **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-aws` module provides `node-manager` with following artifacts:

   - Provider-specific custom resource templates to be used by `cloud-provider-aws` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific custom resources created based on the templates mentioned above.

2. The `cloud-provider-aws` module provides Terraform/OpenTofu components for AWS cloud used when building the `dhctl` executable file for the `terraform-manager` module, such as:

   - Terraform/OpenTofu provider.
   - Terraform modules.

   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:

     - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty
     - `master-node`
     - `static-node`.

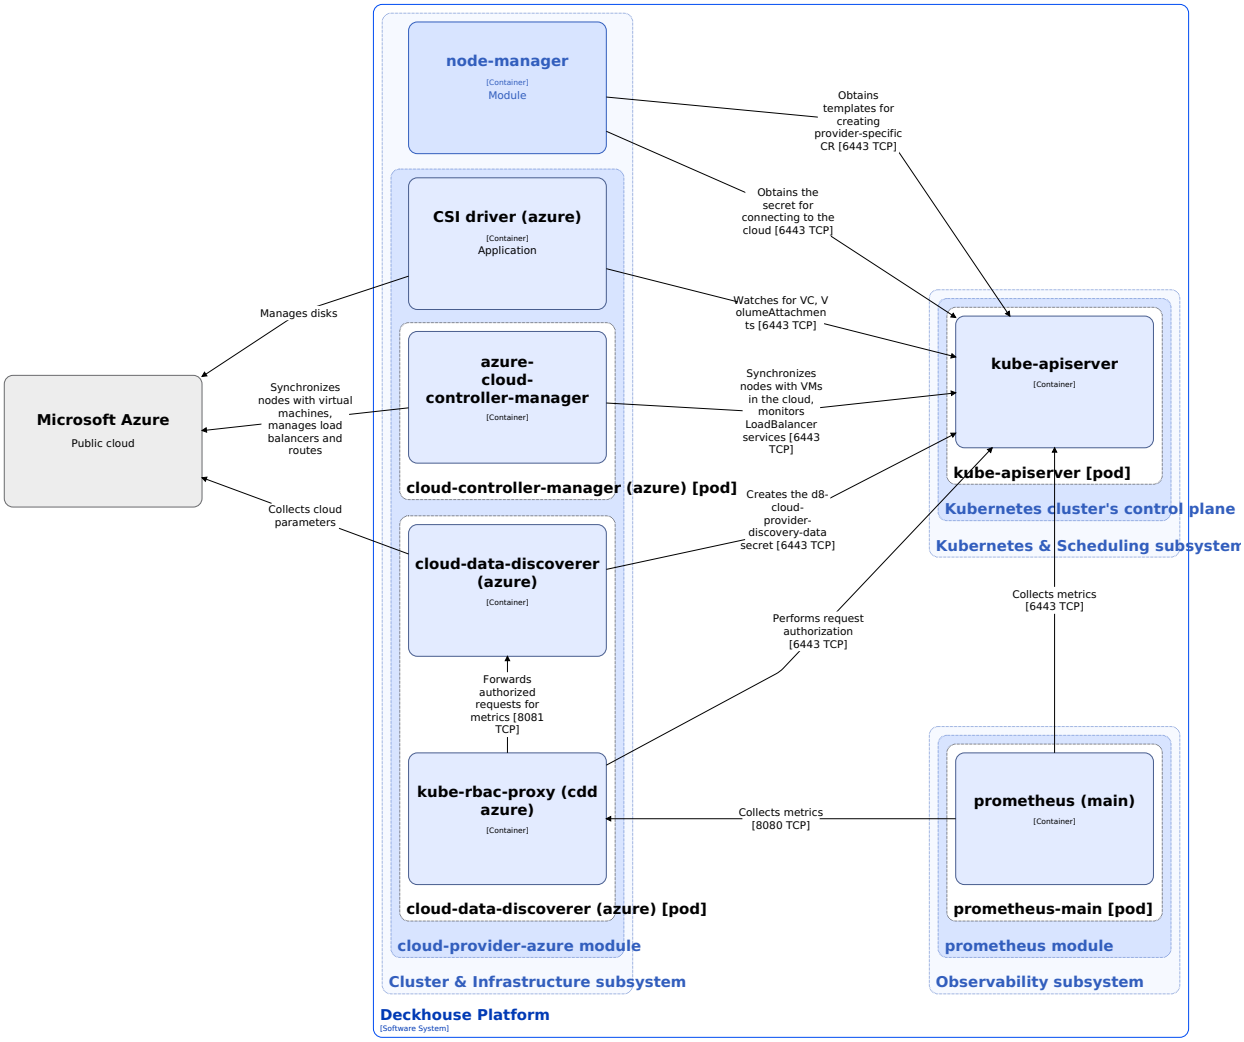
Cloud-provider-azure module



The `cloud-provider-azure` module is responsible for interacting with the Microsoft Azure cloud resources. It allows the `node-manager` module to use Microsoft Azure resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-azure` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-controller-manager**: It is an implementation of cloud controller manager for Microsoft Azure. It provides interaction with the Azure cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.
   - Creates network routes for the `PodNetwork` network in the cloud.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **azure-cloud-controller-manager**.

2. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-azure` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

3. **CSI driver (azure)**: It is an implementation of the CSI driver for Microsoft Azure. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation section.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **Microsoft Azure**:
   - Collects cloud parameters.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages network routes for `PodNetwork` network.
   - Manages disks.

The following external components interact with the module:

- **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-azure` module provides `node-manager` with following artifacts:
   - Provider-specific custom resource templates to be used by `cloud-provider-azure` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific custom resources created based on the templates mentioned above.
2. The `cloud-provider-azure` module provides Terraform/OpenTofu components for Microsoft Azure cloud used when building the `dhctl` executable file for the `terraform-manager` module, such as:
   - Terraform/OpenTofu provider.
   - Terraform modules.
   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
     - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty
     - `master-node`
     - `static-node`.

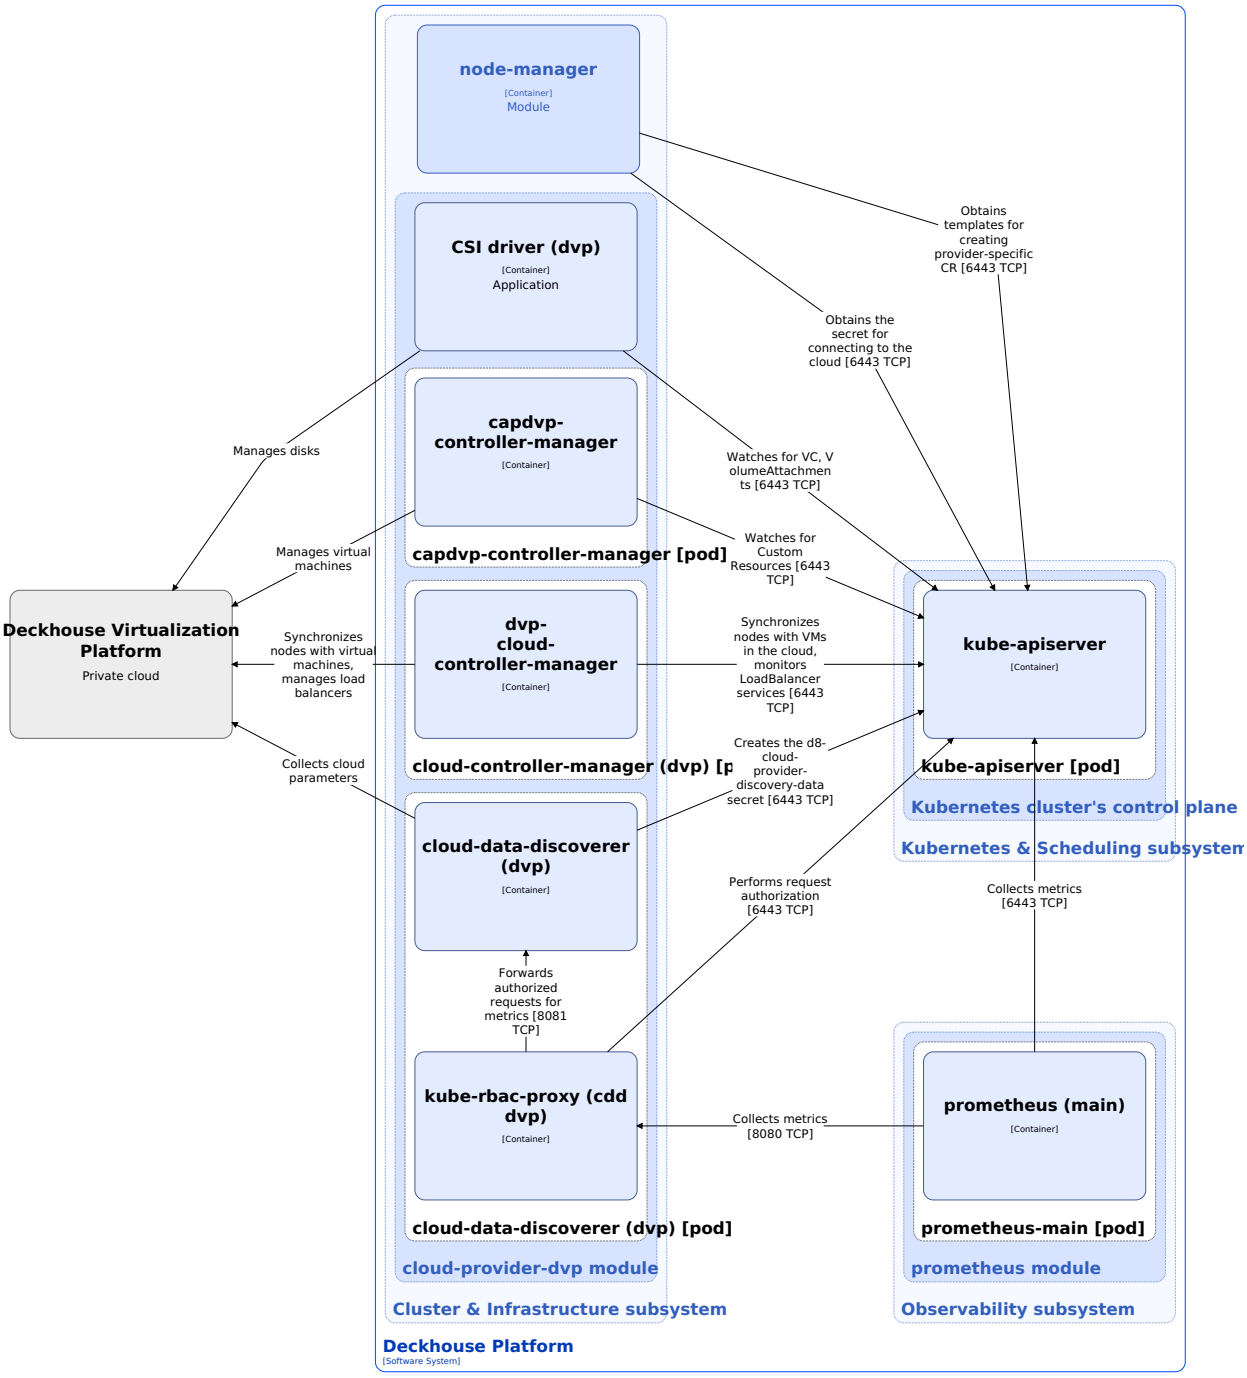
Cloud-provider-dvp module



The `cloud-provider-dvp` module is responsible for interacting with the Deckhouse Virtualization Platform (DVP) cloud resources. It allows the `node-manager` module to use DVP resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-dvp` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Capdvp-controller-manager**: Kubernetes Cluster API Provider for DVP. Cluster API is an extension for Kubernetes that allows you to manage Kubernetes clusters as custom resources inside another Kubernetes cluster. Cluster API Provider allows clusters running the Cluster API to order virtual machines in the cloud provider's infrastructure, DVP in this case. Capdvp-controller-manager works with the following custom resources:

- DeckhouseCluster: Description of a DVP-based cluster.
- DeckhouseMachineTemplate: Template describing the characteristics of the machines created in the cloud.
- DeckhouseMachine: Description of the characteristics of a machine created based on DeckhouseMachineTemplate.

It consists of a single container:

- **capdvp-controller-manager**.

2. **Cloud-controller-manager**: It is an implementation of Cloud controller manager for DVP. It provides interaction with the DVP cloud and performs the following functions:

   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **dvp-cloud-controller-manager**.

3. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-dvp` module. For example, for DVP, these are parameters such as a list of availability zones, StorageClass resources, etc.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

4. **CSI driver (DVP)**: It is an implementation of the CSI driver for DVP. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation page.

   CSI driver (DVP) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Reconciles DeckhouseCluster, DeckhouseMachineTemplate, and DeckhouseMachine custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **DVP cloud**:
   - Collects cloud parameters.
   - Manages virtual machines.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.

The following external components interact with the module:

1. **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-dvp` module provides `node-manager` with following artifacts:
   - Provider-specific Cluster API custom resource templates to be used by `cloud-provider-dvp` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are

registered in the provider-specific Cluster API custom resources created based on the templates mentioned above.

2. The `cloud-provider-dvp` module provides Terraform/OpenTofu components for DVP cloud used when building the dhctl executable file for the `terraform-manager` module, such as:
    - Terraform/OpenTofu provider.
    - Terraform modules.
    - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
        - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty.
        - `master-node`
        - `static-node`

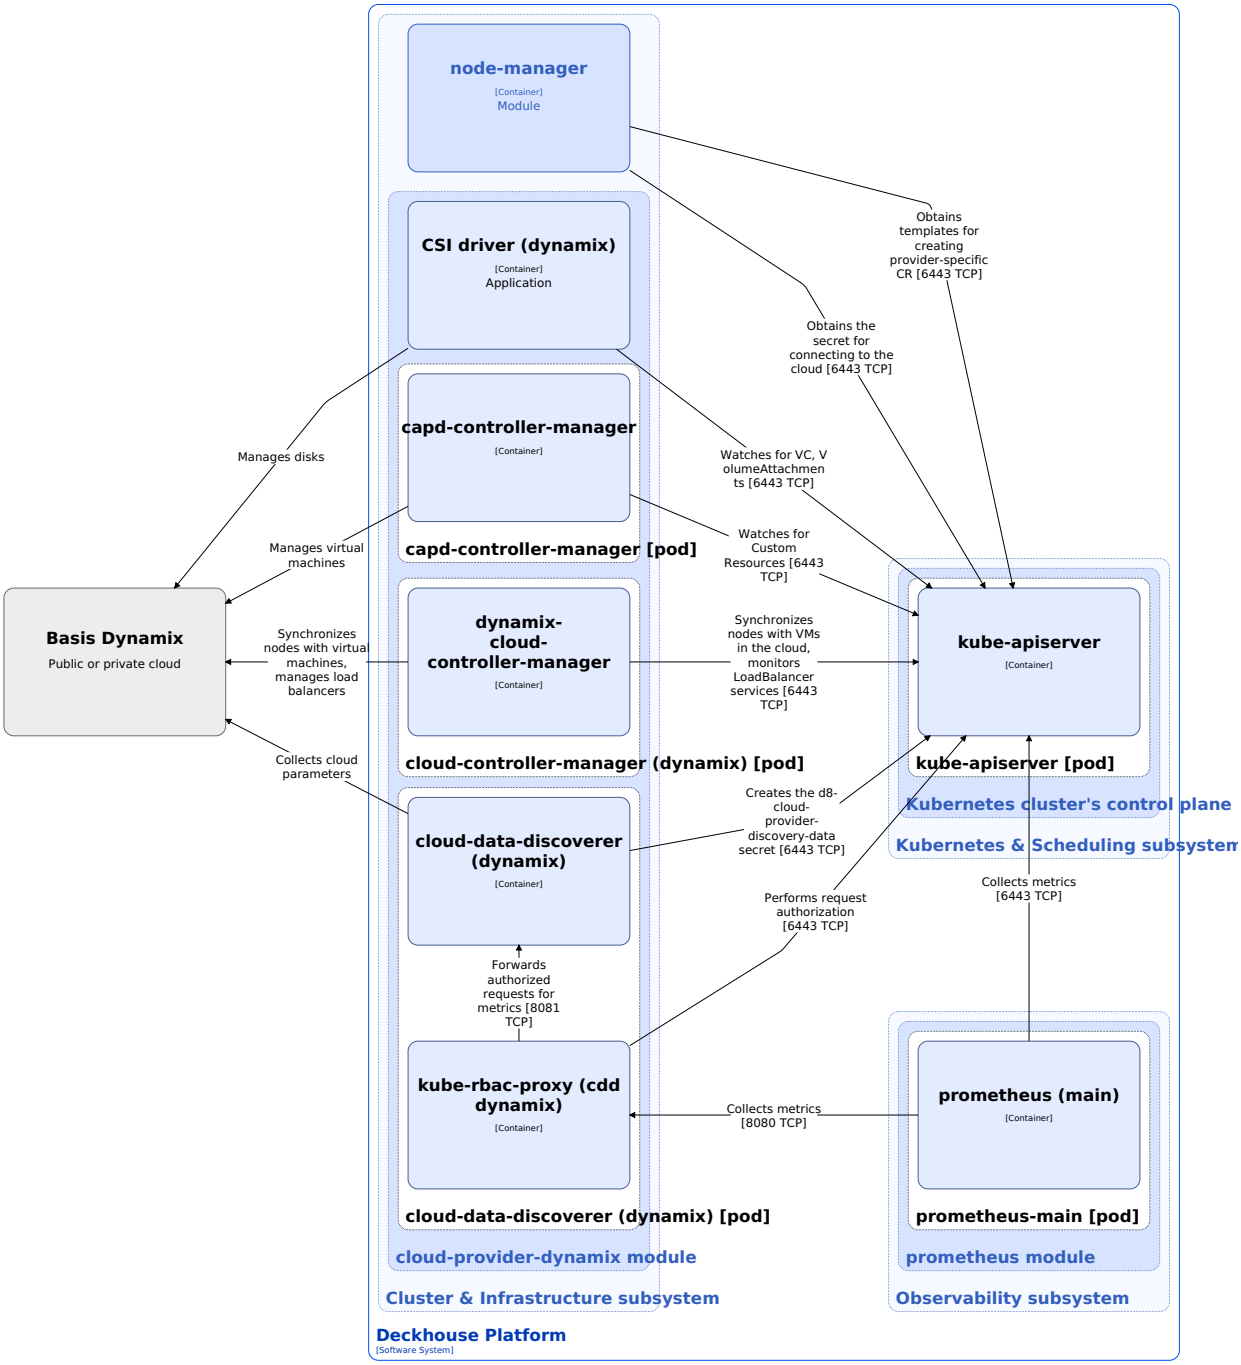
Cloud-provider-dynamix module



The `cloud-provider-dynamix` module is responsible for interacting with the Basis Dynamix cloud resources. It allows the `node-manager` module to use Basis Dynamix resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-dynamix` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Capd-controller-manager**: Kubernetes Cluster API Provider for Basis Dynamix. Cluster API is an extension for Kubernetes that allows you to manage Kubernetes clusters as custom resources inside another Kubernetes cluster. Cluster API Provider allows clusters running the Cluster API to order virtual machines in the cloud provider’s infrastructure, Basis Dynamix in this case. Capd-controller-manager works with the following custom resources:

   - DynamixCluster: Description of a Basis Dynamix-based cluster.
   - DynamixMachineTemplate: Template describing the characteristics of the machines created in the cloud.
   - DynamixMachine: Description of the characteristics of a machine created based on DynamixMachineTemplate.

   It consists of a single container:

   - **capd-controller-manager**.

2. **Cloud-controller-manager**: It is an implementation of Cloud controller manager for Basis Dynamix. It provides interaction with the Basis Dynamix cloud and performs the following functions:

   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud

provider. To do this:

- It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
- It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.

- When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

For more details about cloud-controller-manager, refer to the Kubernetes documentation.

It consists of a single container:

- **dynamix-cloud-controller-manager**.

3. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-dynamix` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

4. **CSI driver (dynamix)**: It is an implementation of the CSI driver for Basis Dynamix. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation page.

   CSI driver (dynamix) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Reconciles DynamixCluster, DynamixMachineTemplate, and DynamixMachine custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **Basis Dynamix cloud**:
   - Collects cloud parameters.
   - Manages virtual machines.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.

The following external components interact with the module:

1. **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-dynamix` module provides `node-manager` with following artifacts:
   - Provider-specific Cluster API custom resource templates to be used by `cloud-provider-dynamix` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific Cluster API custom resources created based on the templates mentioned above.
2. The `cloud-provider-dynamix` module provides Terraform/OpenTofu components for Basis Dynamix cloud used when building the dhctl executable file for the `terraform-manager` module, such as:
   - Terraform/OpenTofu provider.
   - Terraform modules.
   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
     - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty.
     - `master-node`

    - `static-node`

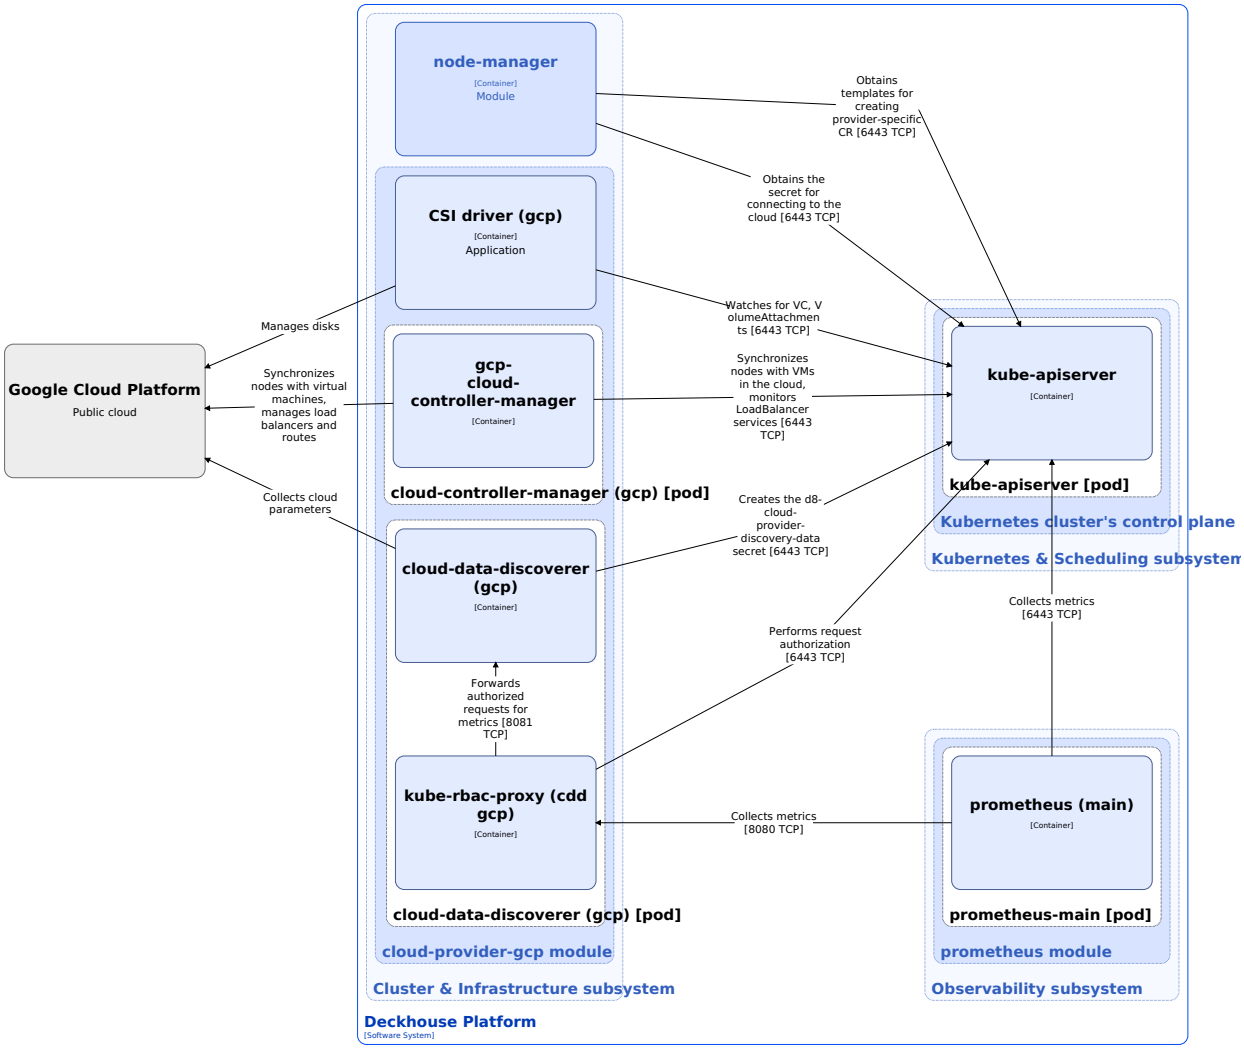
Cloud-provider-gcp module



The `cloud-provider-gcp` module is responsible for interacting with the Google Cloud Platform cloud resources. It allows the `node-manager` module to use GCP resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-gcp` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-controller-manager**: It is an implementation of cloud controller manager for GCP. It provides interaction with the GCP cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.
   - Creates network routes for the `PodNetwork` network in the cloud.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **gcp-cloud-controller-manager**.

2. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-gcp` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

3. **CSI driver (gcp)**: It is an implementation of the CSI driver for GCP. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation section.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **Google Cloud Platform**:
   - Collects cloud parameters.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages network routes for `PodNetwork` network.
   - Manages disks.

The following external components interact with the module:

- **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-gcp` module provides `node-manager` with following artifacts:
   - Provider-specific custom resource templates to be used by `cloud-provider-gcp` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific custom resources created based on the templates mentioned above.
2. The `cloud-provider-gcp` module provides Terraform/OpenTofu components for GCP cloud used when building the `dhctl` executable file for the `terraform-manager` module, such as:
   - Terraform/OpenTofu provider.
   - Terraform modules.
   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
     - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty
     - `master-node`
     - `static-node`.

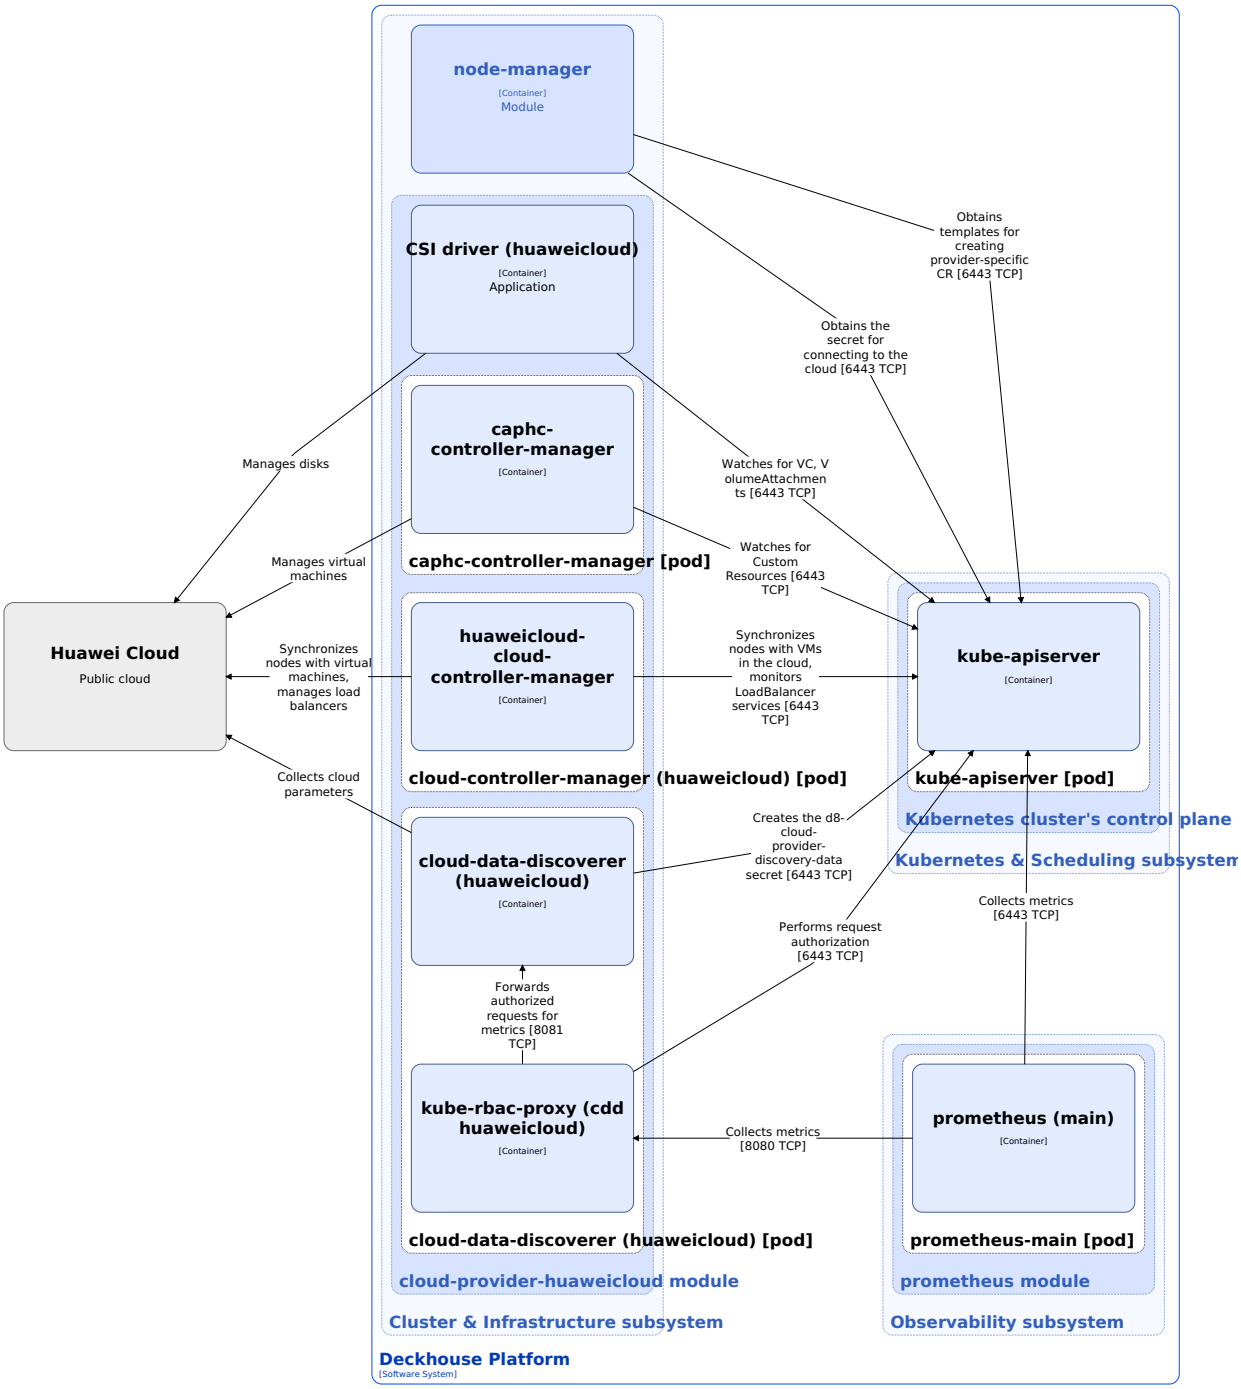
Cloud-provider-huaweicloud module



The `cloud-provider-huaweicloud` module is responsible for interacting with the Huawei Cloud resources. It allows the `node-manager` module to use Huawei Cloud resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-huaweicloud` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Caphc-controller-manager**: Kubernetes Cluster API Provider for Huawei Cloud. Cluster API is an extension for Kubernetes that allows you to manage Kubernetes clusters as custom resources inside another Kubernetes cluster. Cluster API Provider allows clusters running the Cluster API to order virtual machines in the cloud provider's infrastructure, Huawei Cloud in this case. Caphc-controller-manager works with the following custom resources:

- HuaweiCloudCluster: Description of a Huawei Cloud-based cluster.
- HuaweiCloudMachineTemplate: Template describing the characteristics of the machines created in the cloud.
- HuaweiCloudMachine: Description of the characteristics of a machine created based on HuaweiCloudMachineTemplate.

It consists of a single container:

- **caphc-controller-manager**.

2. **Cloud-controller-manager**: It is an implementation of Cloud controller manager for Huawei Cloud. It provides interaction with the Huawei Cloud and performs the following functions:

   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **huaweicloud-cloud-controller-manager**.

3. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-huaweicloud` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

4. **CSI driver (huaweicloud)**: It is an implementation of the CSI driver for Huawei Cloud. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation page.

   CSI driver (huaweicloud) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Reconciles HuaweiCloudCluster, HuaweiCloudMachineTemplate, and HuaweiCloudMachine custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **Huawei Cloud**:
   - Collects cloud parameters.
   - Manages virtual machines.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.

The following external components interact with the module:

1. **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-huaweicloud` module provides `node-manager` with following artifacts:
   - Provider-specific Cluster API custom resource templates to be used by `cloud-provider-huaweicloud` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific Cluster API custom resources created based on the templates

mentioned above.

2. The `cloud-provider-huaweicloud` module provides Terraform/OpenTofu components for Huawei Cloud used when building the dhctl executable file for the `terraform-manager` module, such as:
    - Terraform/OpenTofu provider.
    - Terraform modules.
    - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
        - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty.

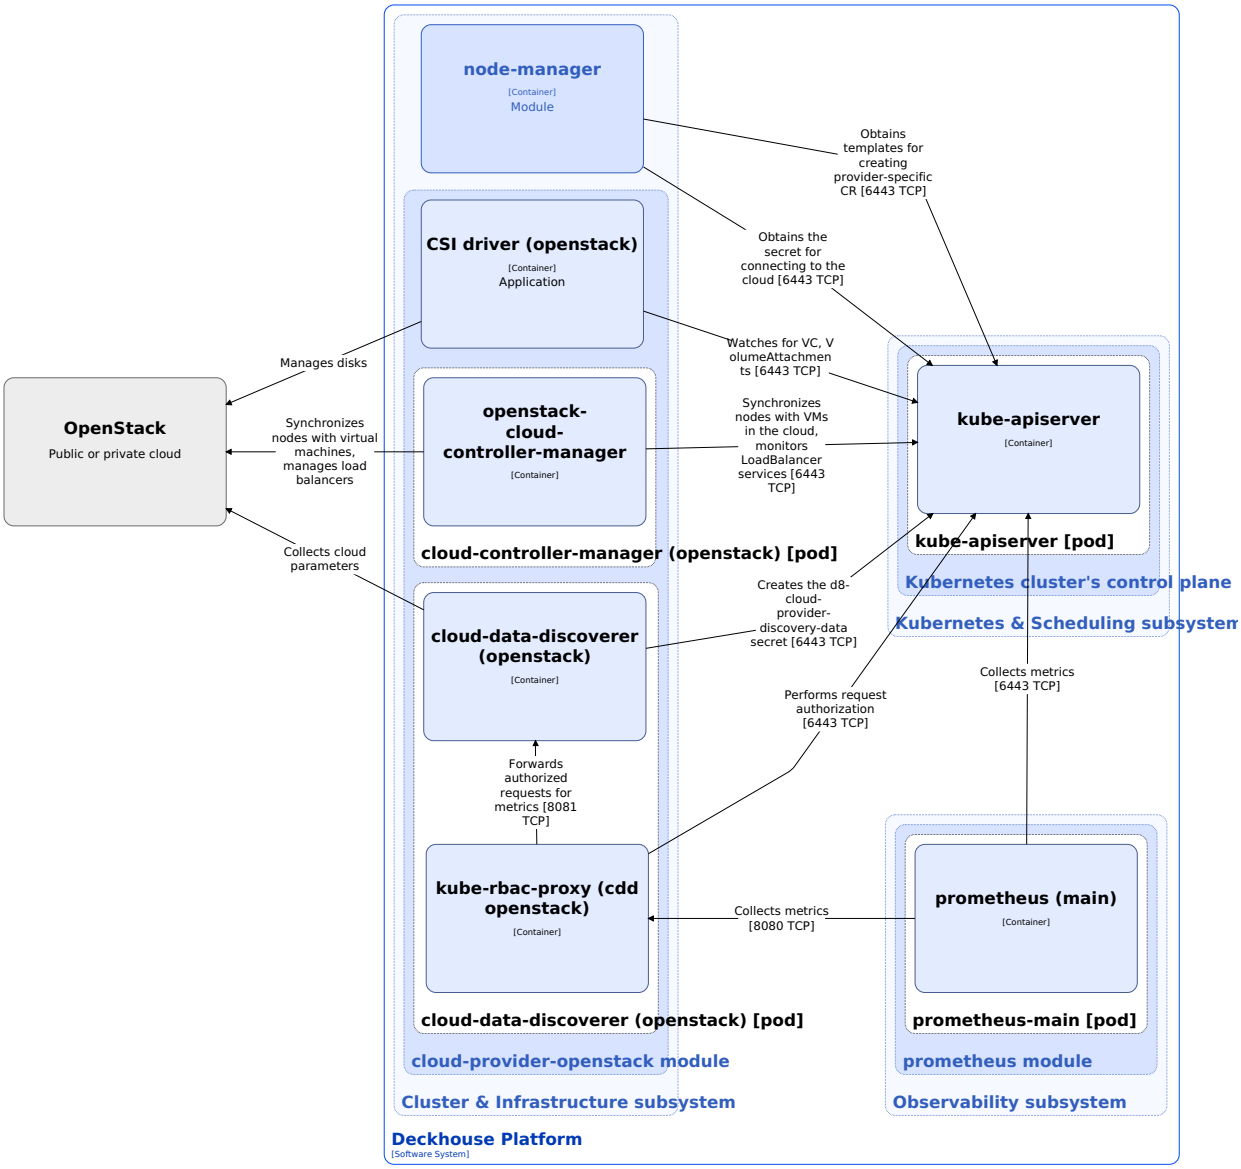
Cloud-provider-openstack module



The `cloud-provider-openstack` module is responsible for interacting with the OpenStack cloud resources. It allows the `node-manager` module to use OpenStack resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-openstack` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-controller-manager**: Kubernetes external cloud provider for OpenStack, an implementation of Cloud controller manager for OpenStack. It provides interaction with the OpenStack cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.
   - Creates network routes for the `PodNetwork` network in the cloud.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **openstack-cloud-controller-manager**.

2. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-openstack` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

3. **CSI driver (openstack)**: It is an implementation of the CSI driver for OpenStack. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation page.

   CSI driver (openstack) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **OpenStack**:
   - Collects cloud parameters.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages network routes for `PodNetwork` network.
   - Manages disks.

The following external components interact with the module:

1. **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-openstack` module provides `node-manager` with following artifacts:
   - Provider-specific custom resource templates to be used by `cloud-provider-openstack` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific custom resources created based on the templates mentioned above.
2. The `cloud-provider-openstack` module provides Terraform/OpenTofu components for OpenStack cloud used when building the dhctl executable file for the `terraform-manager` module, such as:
   - Terraform/OpenTofu provider.
   - Terraform modules.
   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:

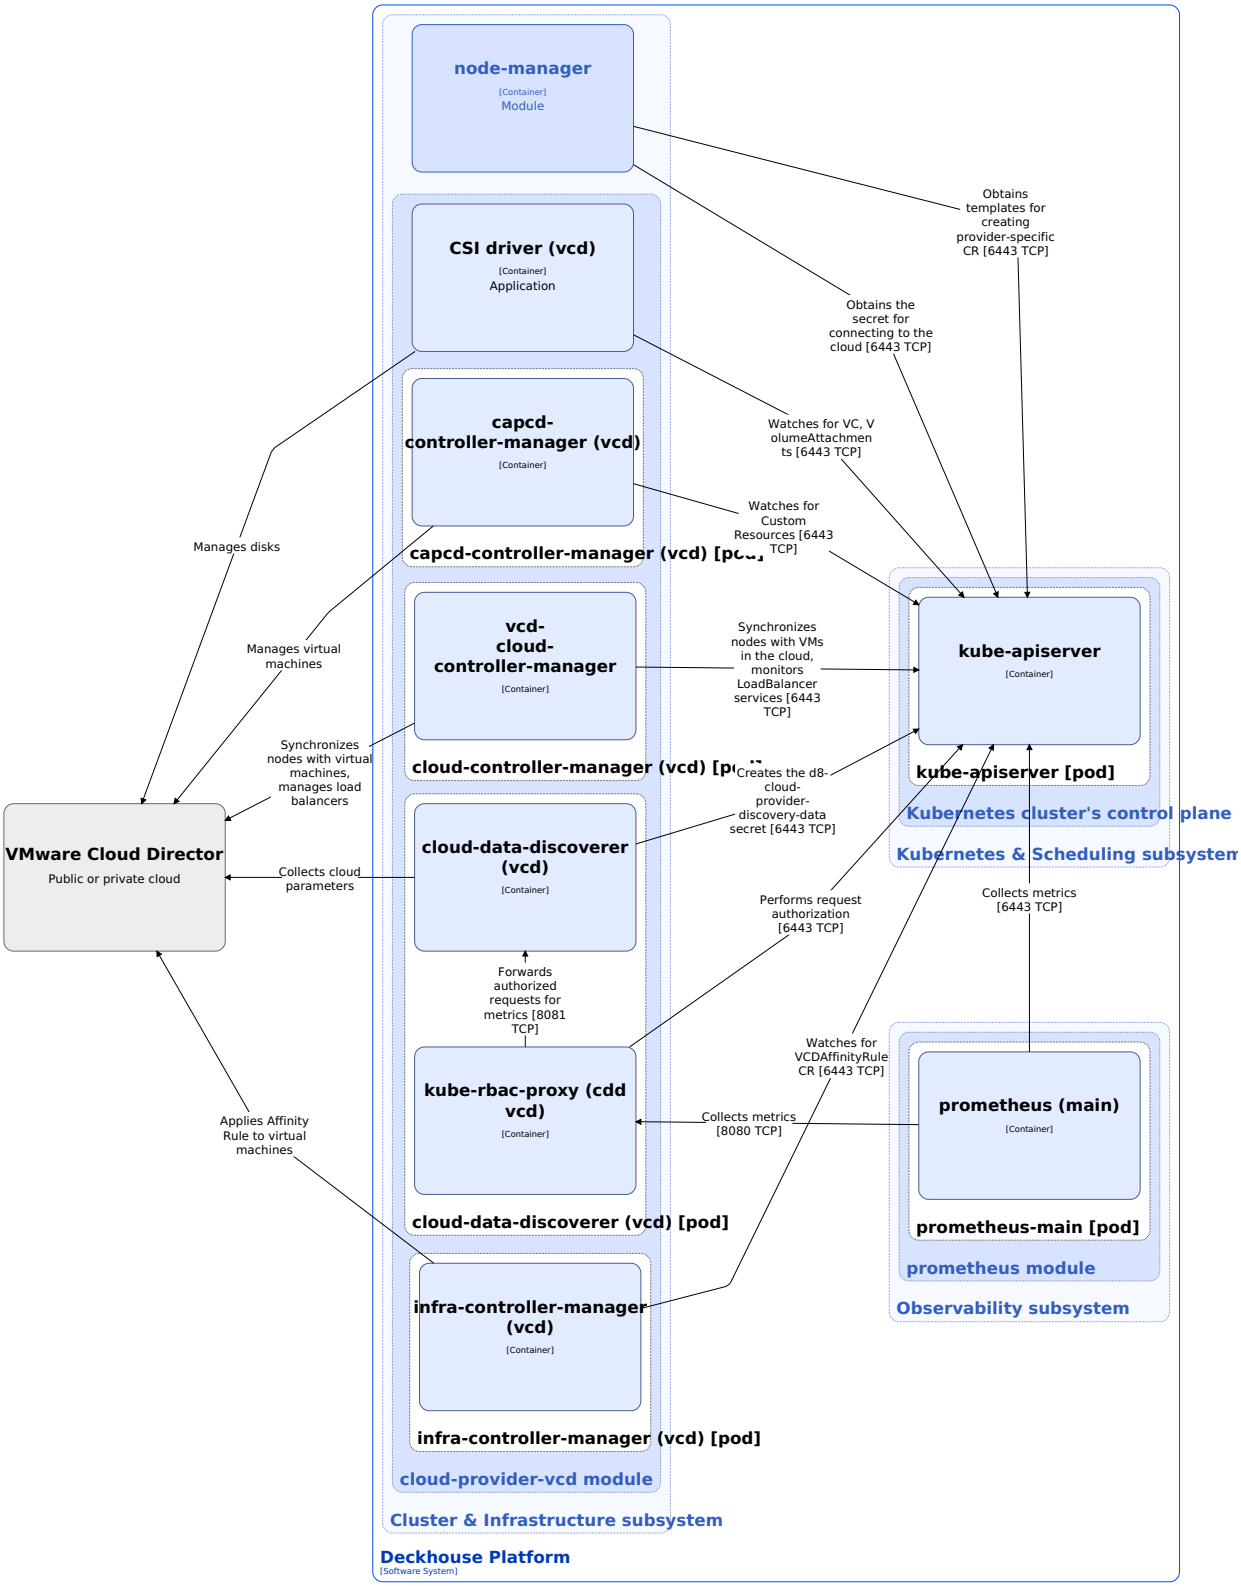
Cloud-provider-vcd module



The `cloud-provider-vcd` module is responsible for interacting with the VMware Cloud Director cloud resources. It allows the `node-manager` module to use VMware Cloud Director resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-vcd` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Capcd-controller-manager**: Kubernetes Cluster API Provider Cloud Director. Cluster API is an extension for Kubernetes that allows you to manage Kubernetes clusters as custom resources inside another Kubernetes cluster. Cluster API Provider allows clusters running the Cluster API to order virtual machines in the cloud provider's infrastructure, VMware Cloud Director in this case. Capcd-controller-manager works with the following custom resources:
   - VCDClusterTemplate: Template describing the characteristics of the cluster created in the cloud.
   - VCDCluster: Description of the characteristics of a cluster created based on VCDClusterTemplate.
   - VCDMachineTemplate: Template describing the characteristics of the machines created in the cloud.
   - VCDMachine: Description of the characteristics of a machine created based on

VCDMachineTemplate.

It consists of a single container:

- **capcd-controller-manager**.

2. **Cloud-controller-manager**: Kubernetes External Cloud Provider for VMware Cloud Director. It is an implementation of cloud controller manager for VMware Cloud Director. It provides interaction with the VMware Cloud Director cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **vcd-cloud-controller-manager**.

3. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-vcd` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

4. **Infra-controller-manager**: It is responsible for managing the schedulling of node location relative to each other at the hypervisor level, which can help improve fault tolerance, and control the distribution of workloads. Infra-controller-manager works with a custom resource VCDAffinityRule. It specifies the affinity rule applied only to virtual machines of node groups referencing this instance class within the cluster.

   It consists of a single container:

   - **infra-controller-manager**.

5. **CSI driver (VCD)**: It is an implementation of the CSI driver for VMware Cloud Director. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation section. `Cloud-provider-vcd` module uses CSI driver for VMware Cloud Director Named Independent Disks.

   CSI driver (VCD) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Reconciles VCDClusterTemplate, VCDCluster, VCDMachineTemplate, VCDMachine, and VCDAffinityRule custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **VMware Cloud Director**:
   - Collects cloud parameters.
   - Manages virtual machines.
   - Applies Affinity Rules to virtual machines.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.

The following external components interact with the module:

- **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-vcd` module provides `node-manager` with following artifacts:
    - Provider-specific Cluster API custom resource templates to be used by `cloud-provider-vcd` to create VMs in the cloud.
    - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific Cluster API custom resources created based on the templates mentioned above.
2. The `cloud-provider-vcd` module provides Terraform/OpenTofu components for VMware Cloud Director cloud used when building the `dhctl` executable file for the `terraform-manager` module, such as:
    - Terraform/OpenTofu provider.
    - Terraform modules.
    - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
        - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty
        - `master-node`
        - `static-node`.

> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-vsphere` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-controller-manager**: Kubernetes vSphere Cloud Provider. It is an implementation of cloud controller manager for VMware vSphere. It provides interaction with the VMware vSphere cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

   For more details about cloud-controller-manager, refer to the Kubernetes documentation.

   It consists of a single container:

   - **vsphere-cloud-controller-manager**.

2. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-vsphere` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

3. **CSI driver (vsphere)**: It is an implementation of the CSI driver for VMware vSphere. To study the `cloud-provider-vsphere` CSI driver architecture, refer to the corresponding documentation section.

   CSI driver (vsphere) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **VMware vSphere**:
   - Collects cloud parameters.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.

The following external components interact with the module:

- **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-vsphere` module provides `node-manager` with following artifacts:
   - Provider-specific custom resource templates to be used by `cloud-provider-vsphere` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific custom resources created based on the templates mentioned above.
2. The `cloud-provider-vsphere` module provides Terraform/OpenTofu components for VMware vSphere cloud used when building the `dhctl` executable file for the `terraform-manager` module, such as:
   - Terraform/OpenTofu provider.
   - Terraform modules.
   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:
     - `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty
     - `master-node`
     - `static-node`.

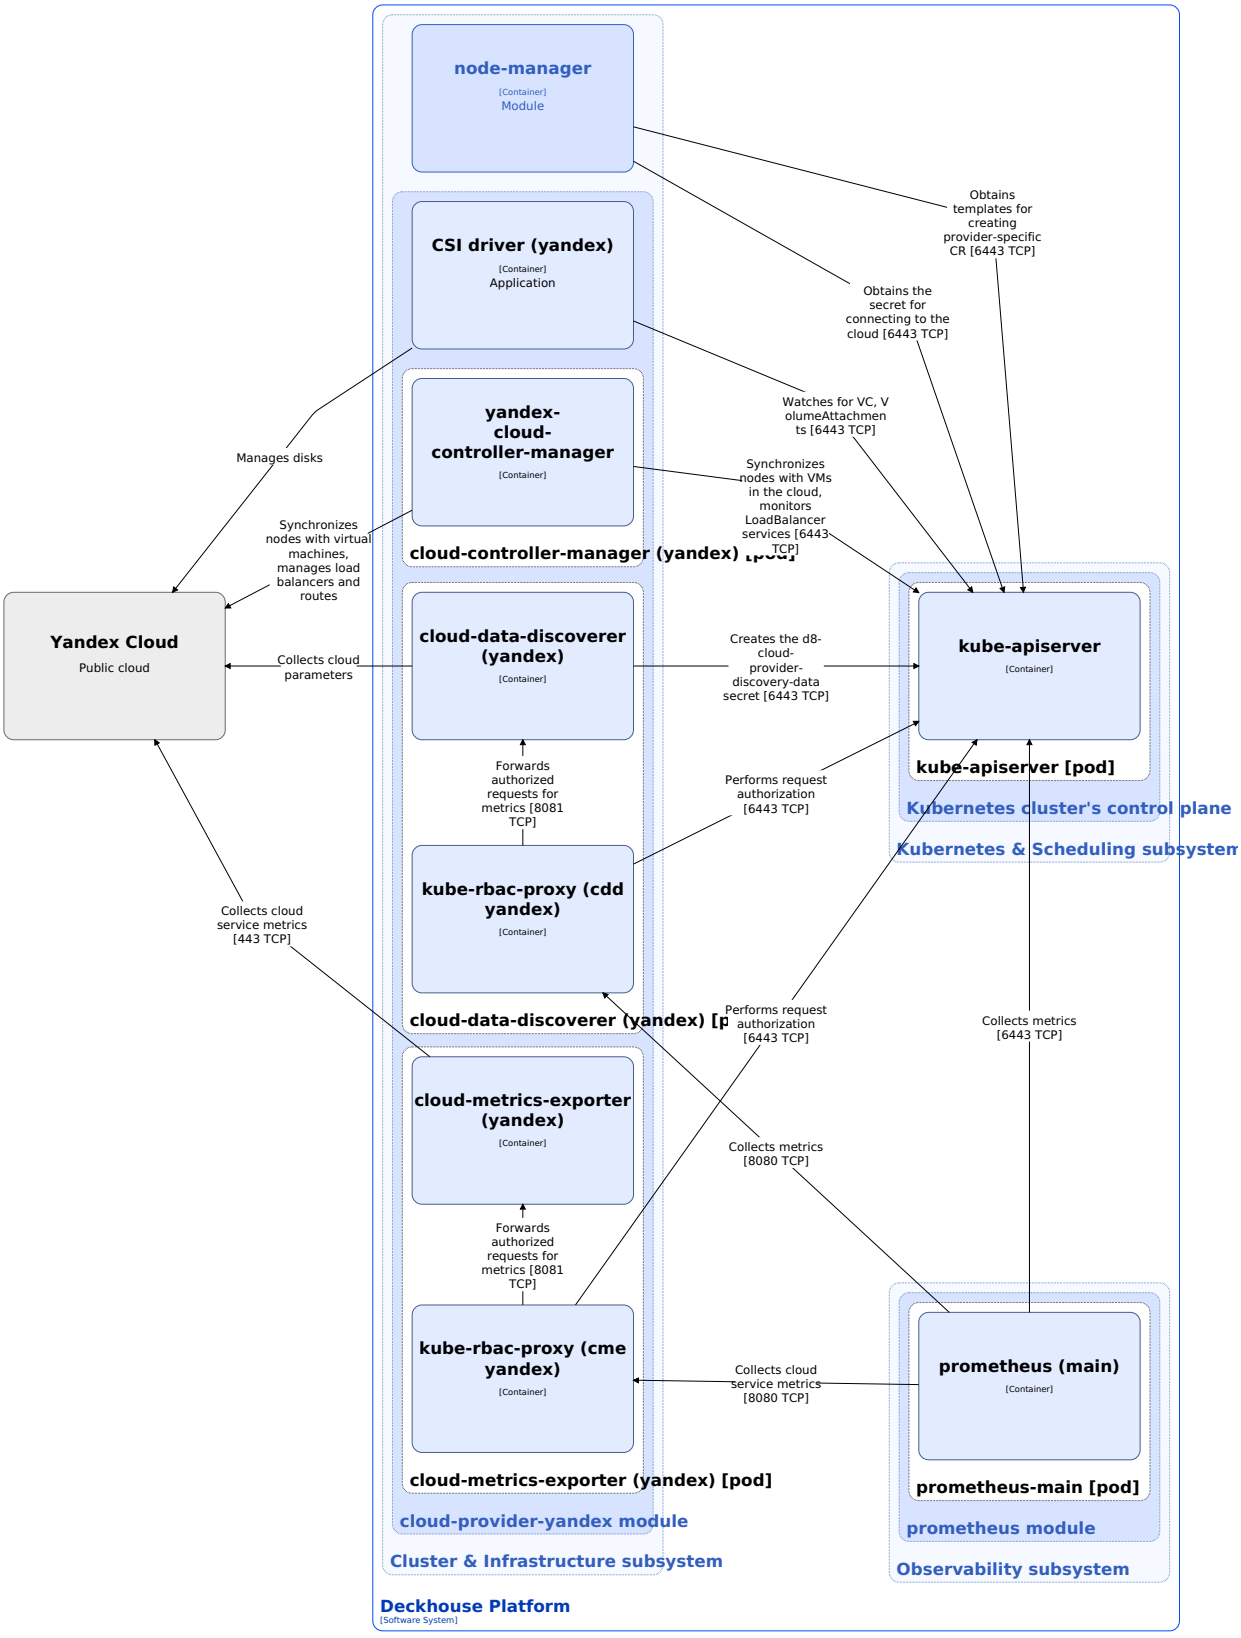
Cloud-provider-yandex module



The `cloud-provider-yandex` module is responsible for interacting with the Yandex Cloud cloud resources. It allows the `node-manager` module to use Yandex Cloud resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-yandex` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-controller-manager**: It is an implementation of Cloud controller manager for Yandex Cloud. It provides interaction with the Yandex Cloud and performs the following functions:
   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud provider. To do this:
     - It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
     - It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.
   - When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

- Creates network routes for the `PodNetwork` network in the cloud.

For more details about cloud-controller-manager, refer to the Kubernetes documentation.

It consists of a single container:

- **yandex-cloud-controller-manager**.

2. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-yandex` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

3. **Cloud-metrics-exporter**: It is responsible for collecting metrics from the cloud provider's API and providing them in Prometheus format.

   It consists of the following containers:

   - **cloud-metrics-exporter**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-metrics-exporter metrics.

4. **CSI driver (yandex)**: It is an implementation of the CSI driver for Yandex Cloud. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation page.

   CSI driver (yandex) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.

2. **Yandex Cloud**:

   - Collects cloud parameters.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.
   - Manages network routes for `PodNetwork` network.
   - Collects cloud service metrics.

The following external components interact with the module:

1. **Prometheus-main**:

   - Collects cloud-data-discoverer metrics.
   - Collects cloud provider's metrics using cloud-metrics-exporter.

Indirect interactions:

1. The `cloud-provider-yandex` module provides `node-manager` with following artifacts:

   - Provider-specific custom resource templates to be used by `cloud-provider-yandex` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific custom resources created based on the templates mentioned above.

2. The `cloud-provider-yandex` module provides Terraform/OpenTofu components for Yandex Cloud used when building the dhctl executable file for the `terraform-manager` module, such as:

   - Terraform/OpenTofu provider.
   - Terraform modules.

   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. For

example, for one scheme, nodes may have public IP addresses, but they will not for the other. Each layout should have three modules:

- `base-infrastructure`: Basic infrastructure (for example, creation of networks), can also be empty.
- `master-node`
- `static-node`

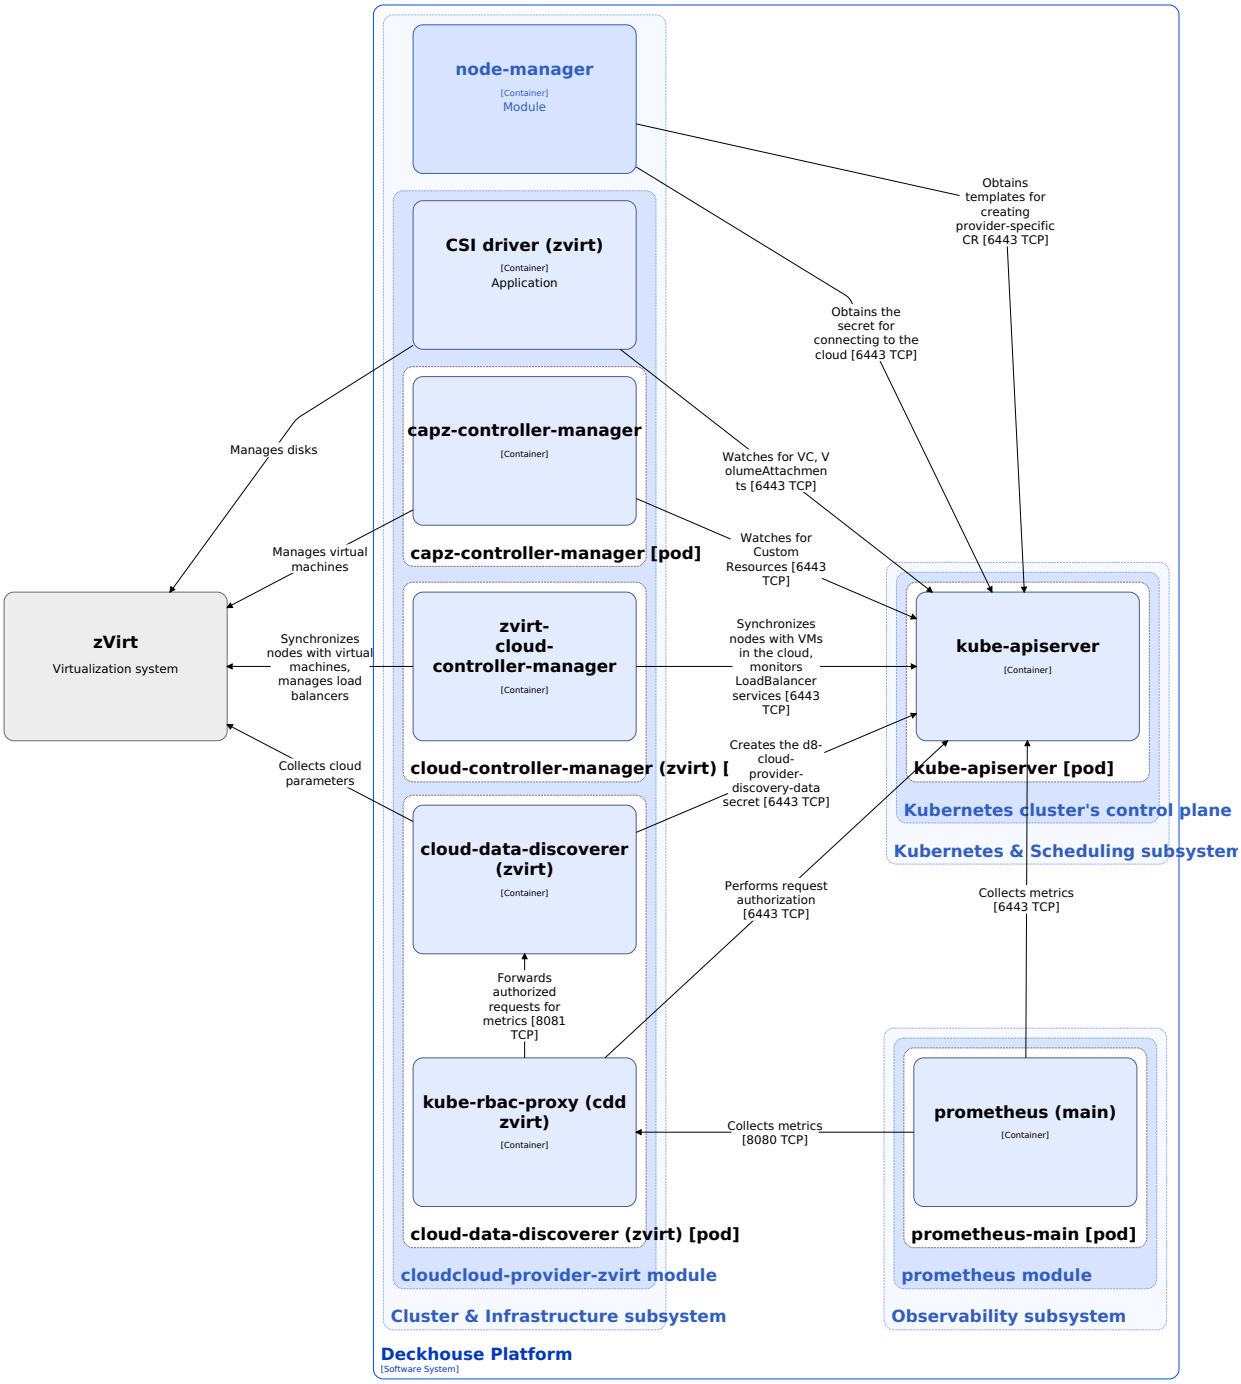
Cloud-provider-zvirt module



The `cloud-provider-zvirt` module is responsible for interacting with the zVirt cloud resources. It allows the `node-manager` module to use zVirt resources for provisioning nodes for the specified node group.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cloud-provider-zvirt` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Capz-controller-manager**: Kubernetes Cluster API Provider for zVirt. Cluster API is an extension for Kubernetes that allows you to manage Kubernetes clusters as custom resources inside another Kubernetes cluster. Cluster API Provider allows clusters running the Cluster API to order virtual machines in the cloud provider’s infrastructure, zVirt in this case. Capz-controller-manager works with the following custom resources:

   - ZvirtCluster: Description of a zVirt-based cluster.
   - ZvirtMachineTemplate: Template describing the characteristics of the machines created in the cloud.
   - ZvirtMachine: Description of the characteristics of a machine created based on ZvirtMachineTemplate.

   It consists of a single container:

   - **capz-controller-manager**.

2. **Cloud-controller-manager**: It is an implementation of Cloud controller manager for zVirt. It provides interaction with the zVirt cloud and performs the following functions:

   - Implements a 1:1 relationship between a Node resource in Kubernetes and a VM in a cloud

provider. To do this:

- It fills the `spec.providerId` and `NodeInfo` fields of the Node resource.
- It checks for a VM in the cloud and deletes the Node resource in the cluster if it is missing.

- When creating a LoadBalancer Service resource in Kubernetes, it creates a load balancer in the cloud that routes traffic from outside into the cluster nodes.

For more details about cloud-controller-manager, refer to the Kubernetes documentation.

It consists of a single container:

- **zvirt-cloud-controller-manager**.

3. **Cloud-data-discoverer**: It is responsible for collecting data from the cloud provider's API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used by other components of the `cloud-provider-zvirt` module.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

4. **CSI driver (zvirt)**: It is an implementation of the CSI driver for zVirt. To study the `cloud-provider-*` CSI driver typical architecture, refer to the corresponding documentation page.

   CSI driver (zvirt) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Reconciles ZvirtCluster, ZvirtMachineTemplate, and ZvirtMachine custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Synchronizes Kubernetes nodes with cloud VMs.
   - Watches for LoadBalancer services.
   - Authorizes the requests for metrics.
2. **zVirt**:
   - Collects cloud parameters.
   - Manages virtual machines.
   - Gets `ProviderId` and other information about the VMs that are cluster nodes.
   - Manages load balancers.
   - Manages disks.

The following external components interact with the module:

1. **Prometheus-main**: Collects cloud-data-discoverer metrics.

Indirect interactions:

1. The `cloud-provider-zvirt` module provides `node-manager` with following artifacts:
   - Provider-specific Cluster API custom resource templates to be used by `cloud-provider-zvirt` to create VMs in the cloud.
   - The `kube-system/d8-node-manager-cloud-provider` Secret, which contains all the necessary settings to connect to the cloud and to create CloudEphemeral nodes. These settings are registered in the provider-specific Cluster API custom resources created based on the templates mentioned above.
2. The `cloud-provider-zvirt` module provides Terraform/OpenTofu components for zVirt cloud used when building the dhctl executable file for the `terraform-manager` module, such as:
   - Terraform/OpenTofu provider.
   - Terraform modules.
   - Layouts: Set of cloud placement schemes, which define how the basic infrastructure is created, how and with which additional characteristics should nodes be created for this placement. Chrony module

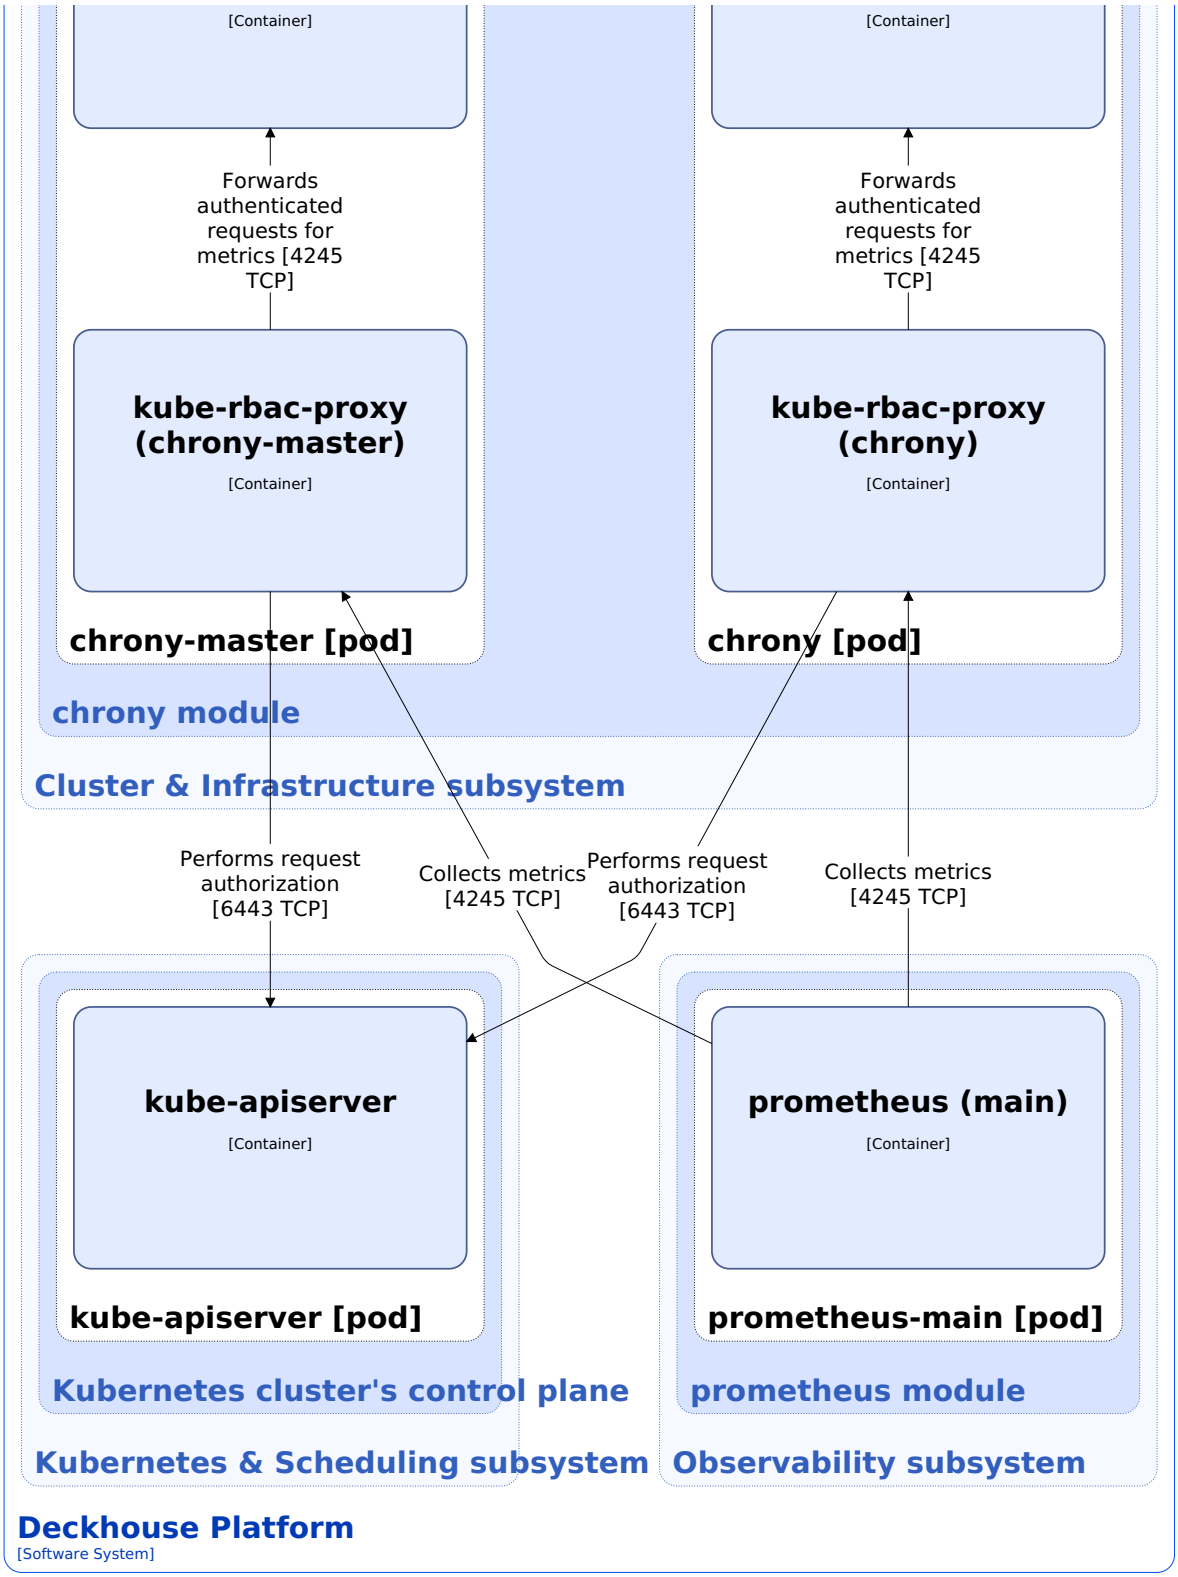
The `chrony` module provides time synchronization on all nodes in the Deckhouse Platform (DP) cluster using chrony NTP server/client implementation.



For more details, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `chrony` module its interactions with other DP components are shown in the following diagram:

Module components

The module consists of the following components:

1. **Chrony-master**: Time synchronization service on cluster master nodes with external NTP servers.

   It consists of the following containers:

   - **chrony**: Main container.
   - **chrony-exporter**: A sidecar container that collects metrics from the chrony container and exposes them in Prometheus format.
   - **kube-rbac-proxy**: A sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to metrics from the chrony-exporter container.

2. **Chrony**: Time synchronization service on all cluster nodes except master nodes, synchronized with the

chrony-master component.

It consists of the following containers:

- **chrony**: Main container.
- **chrony-exporter**: A sidecar container that collects metrics from the chrony container and exposes them in Prometheus format.
- **kube-rbac-proxy**: A sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to metrics from the chrony-exporter container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**: Authorizes requests to retrieve metrics.
2. **External NTP servers**: Performs time synchronization.

The following external components interact with the module:

- **Prometheus-main**: Collects metrics from chrony and chrony-master.

Gpu module

The `gpu` module manages Graphics Processing Units (GPU) in Deckhouse Platform (DP).

The module operates in two mutually exclusive modes. The mode is defined by the `dra.enabled` parameter:

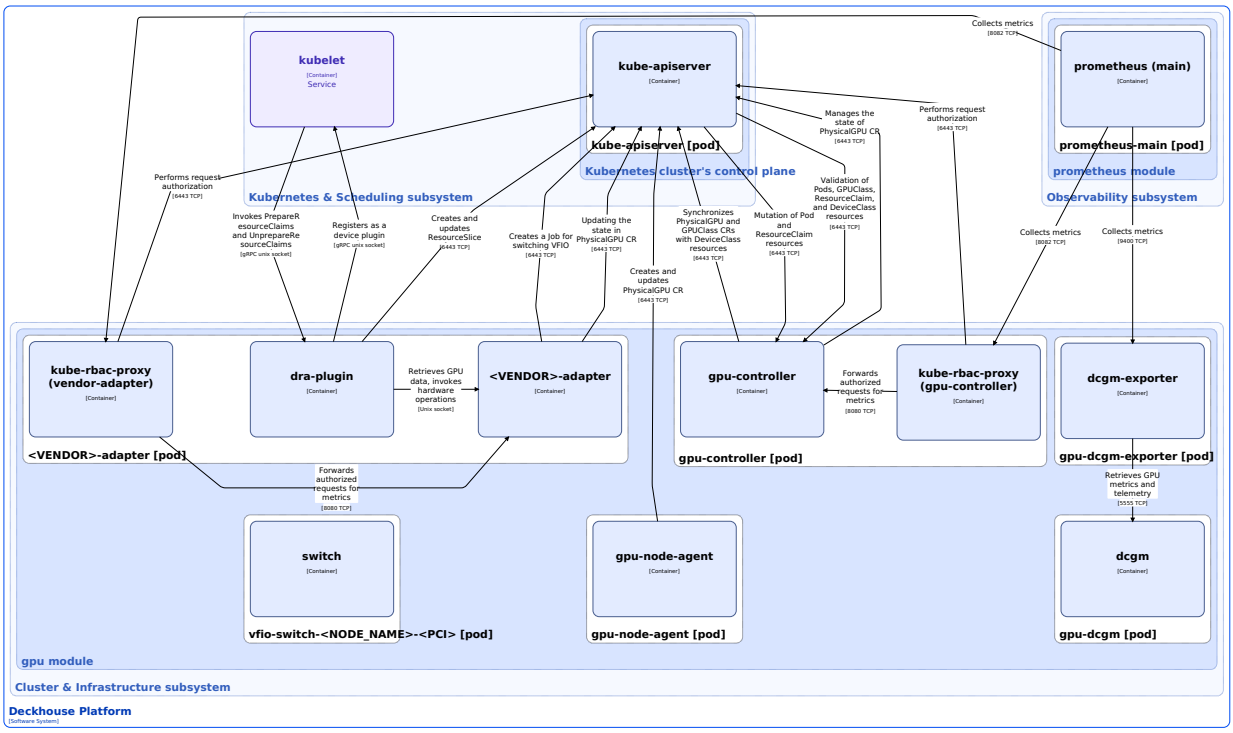
- Dynamic Resource Allocation (DRA): The module uses a Kubernetes mechanism for requesting and sharing devices that provides dynamic and declarative allocation of GPU compute resources.
- Device Plugin mode (default): The module uses the classic Kubernetes model for working with node compute resources and publishes `nvidia.com/gpu` or `nvidia.com/mig-*` resources, which kube-scheduler uses to schedule pods that consume these resources.

For more details, refer to the corresponding documentation section.

The module architecture depends on the operating mode.

DRA mode

In DRA mode, the module is built around a vendor-independent core and adapters for the NVIDIA and MetaX vendors.



The module works with the following resources:

- DeviceClass: A DRA resource that stores descriptions of device classes that can be used for dynamic resource assignment.
- GPUClass: A custom resource that stores requirements for a GPU group (memory size, hardware capabilities) and the usage and compatibility policy.
- PhysicalGPU: A custom resource that stores a description of a physical GPU, including device characteristics.
- ResourceClaim: A DRA resource that contains a request to allocate a resource for a pod and describes the required characteristics and usage parameters.
- ResourceSlice: A DRA resource that represents an allocated share or part of a resource assigned within a ResourceClaim.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `gpu` module in DRA mode and its interactions with other DP components are shown in the following diagram:

Module components

The module consists of the following components:

1. **gpu-controller** (Deployment): A controller that processes GPU resource requests and runs admission webhooks for DRA objects through the Validating/Mutating Admission Controllers mechanism. The controller runs on master nodes.

   The gpu-controller performs the following actions:

   - Creates and updates DeviceClass DRA resources based on PhysicalGPU and GPUClass custom resources.
   - Validates and mutates Pod create and update requests, creating ResourceClaim resources when necessary.
   - Watches ResourceClaim resource changes and, based on this data, maintains the state and occupancy of PhysicalGPU resources.
   - Validates Pod, GPUClass, ResourceClaim, and DeviceClass resources.
   - Manages the PhysicalGPU state.

   It consists of the following containers:

   - **gpu-controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the main container. This component is an Open Source project.

2. **gpu-node-agent** (DaemonSet): A component that consists of a single **gpu-node-agent** container and performs the following actions:

   - Scans the host `/sys` filesystem and the PCI ID database.
   - Matches devices against the `gpu-supported-vendors` ConfigMap.
   - Creates PhysicalGPU custom resources for each discovered GPU.
   - Sets the `gpu.deckhouse.io/vendor=<VENDOR>` labels on the Node resource.

   The component runs on all cluster nodes except the control plane.

3. **<VENDOR>-adapter** (DaemonSet): A component that works with hardware to prepare, allocate, and

release GPU resources. Currently, two hardware vendors are supported: NVIDIA and MetaX.

The component performs the following actions:

- Registers in kubelet as a DRA kubelet plugin.
- Prepares and releases allocated resources for pods through the `PrepareResourceClaims` and `UnprepareResourceClaims` operations.
- Publishes the list of available devices through ResourceSlice resources.
- Retrieves hardware capabilities.
- Partitions GPU resources and makes them available to pods.
- Enriches the status in PhysicalGPU resources.

It consists of the following containers:

- **dra-plugin**: Sidecar container that implements the DRA kubelet plugin and interacts with the vendor adapter.
- **<VENDOR>-adapter**: Vendor-specific sidecar container that interacts with the hardware on the node.
- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the dra-plugin container.

The component runs on all cluster nodes that have the `gpu.deckhouse.io/vendor=<VENDOR>` label.

4. **gpu-dcgm** (DaemonSet): A component that consists of a single **dcgm** container and runs Data Center GPU Manager (DCGM). DCGM collects GPU health and utilization data (Error Correction Code (ECC), power). It works only with NVIDIA cards.
5. **gpu-dcgm-exporter** (DaemonSet): A component that consists of a single **dcgm-exporter** container, retrieves GPU metrics from the gpu-dcgm component, and exposes them in Prometheus format.
6. **vfio-switch-<NODE_NAME>-<PCI>** (Job): A component that consists of a single **switch** container. It switches the driver in use between `nvidia` and `vfio-pci`. The component is created by nvidia-adapter to control the switching process.

Module interactions

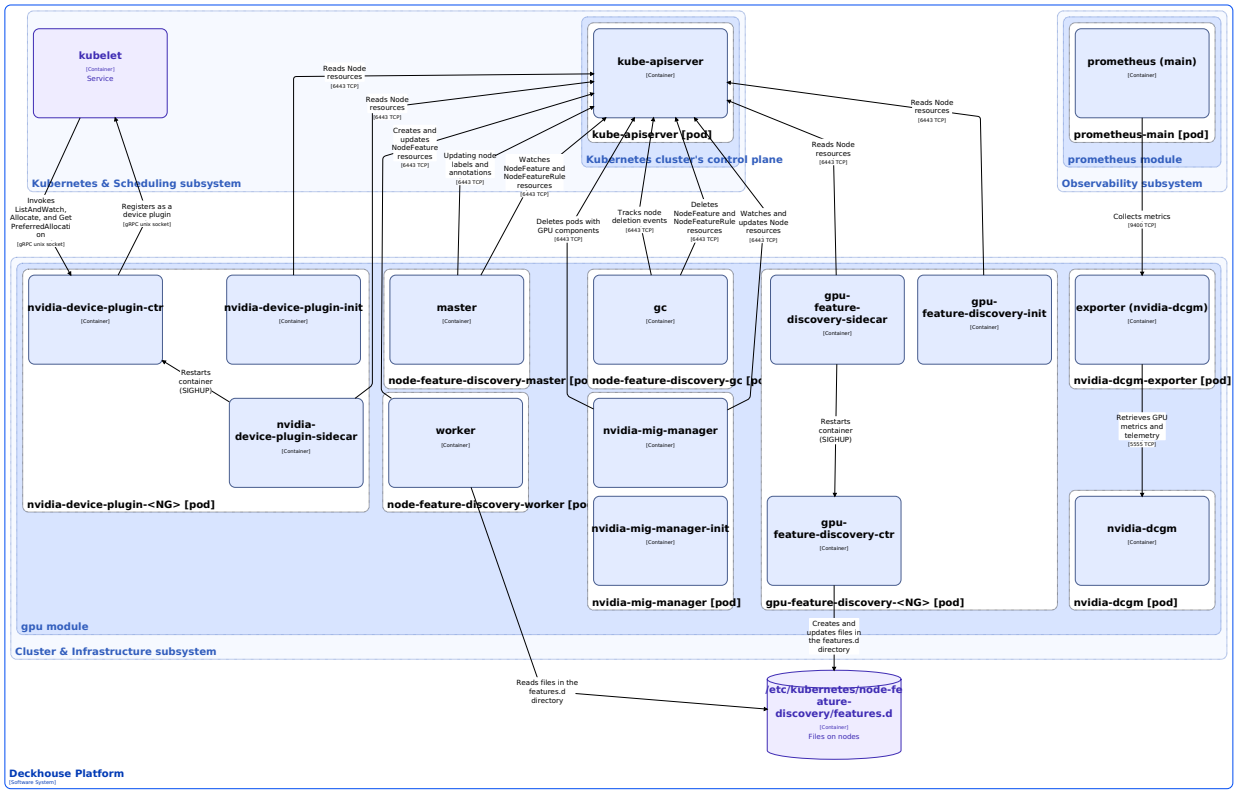
The module interacts with the following components:

1. **Kube-apiserver**:
   - Authorizes requests to retrieve metrics.
   - Works with PhysicalGPU and GPUClass custom resources.
   - Updates Node resources.
   - Validates Pod, GPUClass, ResourceClaim, and DeviceClass resources.
   - Works with DeviceClass, ResourceClaim, and ResourceSlice resources.
   - Creates and monitors `vfio-switch-<NODE_NAME>-<PCI>` Jobs.
2. **Kubelet**: Registers the module as a DRA kubelet plugin.

The following external components interact with the module:

1. **Kubelet**: Calls the `PrepareResourceClaims` and `UnprepareResourceClaims` gRPC methods.
2. **Kube-apiserver**: Validates Pod, GPUClass, ResourceClaim, and DeviceClass resources.
3. **Prometheus-main**: Collects metrics from the gpu-dcgm and <VENDOR>-adapter components.

Device Plugin mode



In Device Plugin mode, the module consists of components that work only with NVIDIA adapters.

The module interacts with the following resources:

- NodeFeature: Stores actual information about the hardware capabilities of a specific node.
- NodeFeatureRule: Stores a set of rules used by the module to configure labels, annotations, and taints for a cluster node.

Module architecture

The Level 2 C4 architecture of the `gpu` module in Device Plugin mode and its interactions with other DP components are shown in the following diagram:

Module components

The module consists of the following components:

1. **node-feature-discovery-master** (Deployment): A component that consists of a single **master** container, which collects information about node hardware capabilities from NodeFeature resources, and publishes them as `feature.node.kubernetes.io/*` and `nvidia.com/*` labels on the corresponding nodes. The master obtains the rules for assigning labels, taints, and annotations from NodeFeatureRule resources.

2. **node-feature-discovery-worker** (DaemonSet): A component that consists of a single **worker** container, which runs on each GPU node, discovers connected PCI and USB devices on the node, and publishes them as NodeFeature resources. The component also publishes information received from the gpu-feature-discovery-<NG> component as NodeFeature resources.

3. **node-feature-discovery-gc** (Deployment): A component that consists of a single **gc** container, which deletes obsolete NodeFeature resources when a node is deleted.

4. **gpu-feature-discovery-<NG>** (DaemonSet): A component that queries the GPU driver via the NVIDIA Management Library (NVML) and writes information about GPU hardware capabilities to the `/etc/kubernetes/node-feature-discovery/features.d/gfd` file. Node-feature-discovery-worker publishes this information as NodeFeature resources, from which node-feature-discovery-master updates the corresponding `nvidia.com/*` labels for cluster nodes.

   The component is created by the Deckhouse controller of the `deckhouse` module for every NodeGroup (NG) whose configuration specifies the `.spec.gpu` parameter.

   It consists of the following containers:

   - **gpu-feature-discovery-init**: Init container that prepares the configuration for the main gpu-feature-discovery-ctr container.
   - **gpu-feature-discovery-ctr**: Main container.
   - **gpu-feature-discovery-sidecar**: Sidecar container that watches configuration changes and restarts the main container to apply them.

5. **nvidia-device-plugin-<NG>** (DaemonSet): A component that registers with kubelet through the Kubernetes Device Plugin API and publishes GPU resources for kube-scheduler.

   To work with resources, kubelet calls the `ListAndWatch`, `Allocate`, and `GetPreferredAllocation` gRPC methods on nvidia-device-plugin-ctr. After that, the component updates the number of available resources on the node and returns this information through kubelet.

   It consists of the following containers:

   - **nvidia-device-plugin-init**: Init container that prepares the configuration for the main nvidia-device-plugin-ctr container.

- **nvidia-device-plugin-ctr**: Main container.
- **nvidia-device-plugin-sidecar**: Sidecar container that watches configuration changes and restarts the main container to apply them.

6. **nvidia-mig-manager** (DaemonSet): An optional component that manages changes to the Multi-Instance GPU (MIG) profile on nodes with GPUs A100 and H100.

   The component performs the following actions:

   - Retrieves the desired MIG profile (the `nvidia.com/mig.config` label) and the current state.
   - Puts the node into maintenance mode when necessary (applies a taint, cordon, and drain).
   - Stops pods that use GPUs on the node.
   - Applies the MIG profile.
   - Initiates a node reboot when necessary.
   - Returns the node to service.

   It consists of the following containers:

   - **nvidia-mig-manager-init**: Init container that prepares executables and libraries.
   - **nvidia-mig-manager**: Main container.

7. **nvidia-dcgm** (DaemonSet): A component that consists of a single **nvidia-dcgm** container, which runs Data Center GPU Manager (DCGM). DCGM collects GPU health and utilization data (Error Correction Code (ECC), power).

8. **nvidia-dcgm-exporter** (DaemonSet): A component that consists of a single **exporter** container, which retrieves GPU metrics from the nvidia-dcgm component, and exposes them in Prometheus format.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Authorizes requests to retrieve metrics.
   - Works with NodeFeature and NodeFeatureRule resources.
   - Watches and updates Node resources.
   - Terminates pods that use GPU resources when the MIG profile changes.
2. **Kubelet**: Registers the module through the Device Plugin API.

The following external components interact with the module:

1. **Kubelet**: Calls the `ListAndWatch`, `Allocate`, and `GetPreferredAllocation` gRPC methods.
2. **Prometheus-main**: Collects metrics from nvidia-dcgm.

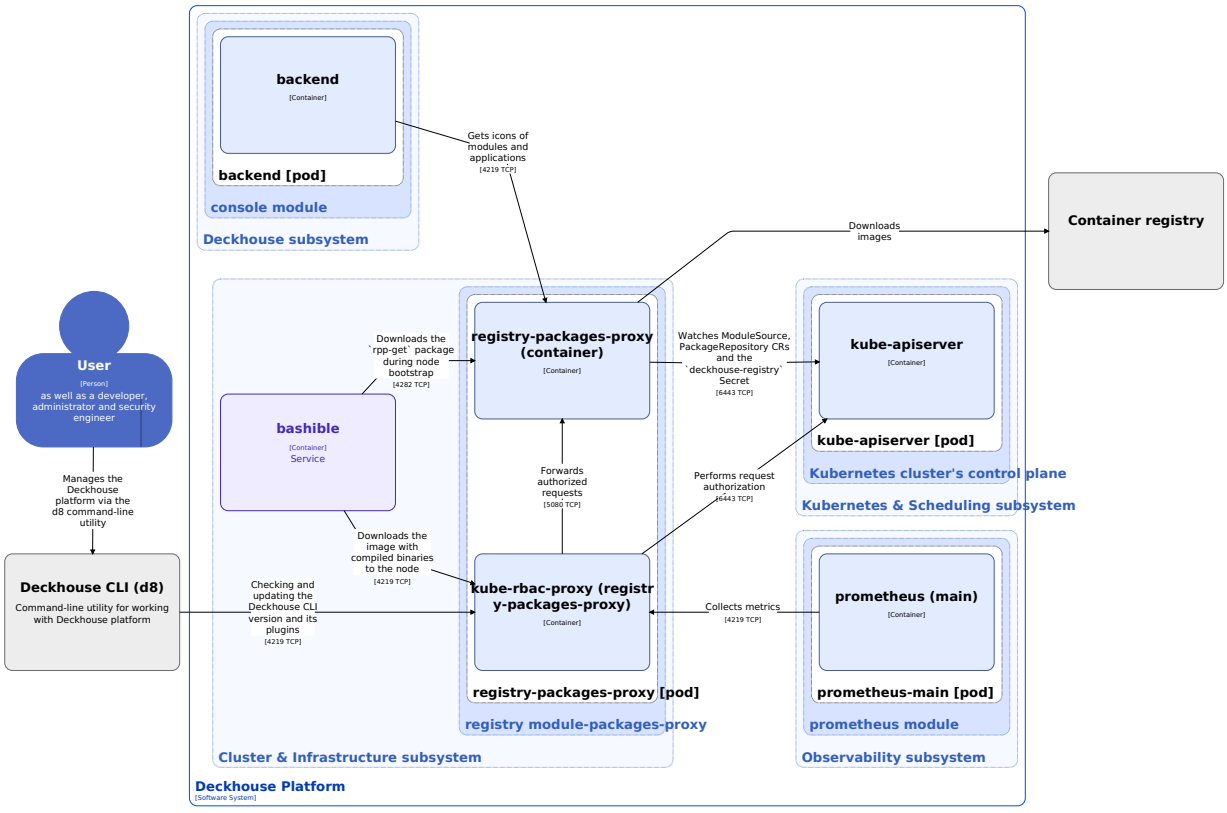
Registry-packages-proxy module

The `registry-packages-proxy` module provides an in-cluster HTTP proxy service for accessing packages from container registries in the Deckhouse Platform (DP). It acts as an intermediary between cluster components and external or internal registries, offering caching capabilities to optimize bandwidth usage and improve package retrieval performance.

This module is a critical infrastructure component that runs on master nodes and is used during cluster bootstrap, as well as during cluster operation, to fetch packages from container registries.

The module deploys a highly-available proxy service that:

- Runs on master nodes with `hostNetwork` enabled to ensure availability during bootstrap when CNI is not yet available.
- Exposes a separate HTTP endpoint on port `4282` for downloading `rpp-get` (a utility for interacting with



the module's main endpoint) during node bootstrap. Requests to this port do not go through TLS or kube-rbac-proxy, unlike the main proxy on port `4219`.
- Listens on port `4219` (HTTPS) on each master node's IP address.
- Provides a `GET /package` endpoint for retrieving registry packages by digest.
- Implements local caching of retrieved packages (up to 1 GB) to reduce network traffic and improve performance.
- Watches the `deckhouse-registry` Secret in the `d8-system` namespace to obtain credentials for the main registry.
- Watches ModuleSource and PackageRepository custom resources to obtain registry credentials.
- Uses RBAC-based authorization to secure access to the proxy and metrics endpoints.
- Exposes a public HTTPS API (via Ingress) for Deckhouse CLI binaries and plugins.
- Exposes an in-cluster HTTPS API for package icons (no public Ingress).

For more information about the module, see the module overview section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `registry-packages-proxy` module and its interactions with other DP components are shown in the following diagram:

Module components

The `registry-packages-proxy` module consists of a single **registry-packages-proxy** component that includes the following containers:

- **registry-packages-proxy**: Main container.
- **kube-rbac-proxy**: Sidecar container with a Kubernetes RBAC-based authorization proxy that provides secure access to the endpoints of the registry-packages-proxy main container. This component is an Open Source project.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Reading and watching ModuleSource and PackageRepository custom resources.
   - Watching the `deckhouse-registry` Secret.
   - Authorizing requests to access the endpoints of the main container.
2. **Container registry**: Downloads container images from container registries.

The following external components interact with the module:

1. **Bashible**: Downloads the image with assembled binaries to nodes during cluster bootstrap.
2. **Prometheus-main**: Collects metrics from the registry-packages-proxy container.
3. **Console**: Retrieves package icons.
4. **Deckhouse CLI**: Retrieves versions of the `d8` utility and its plugins.

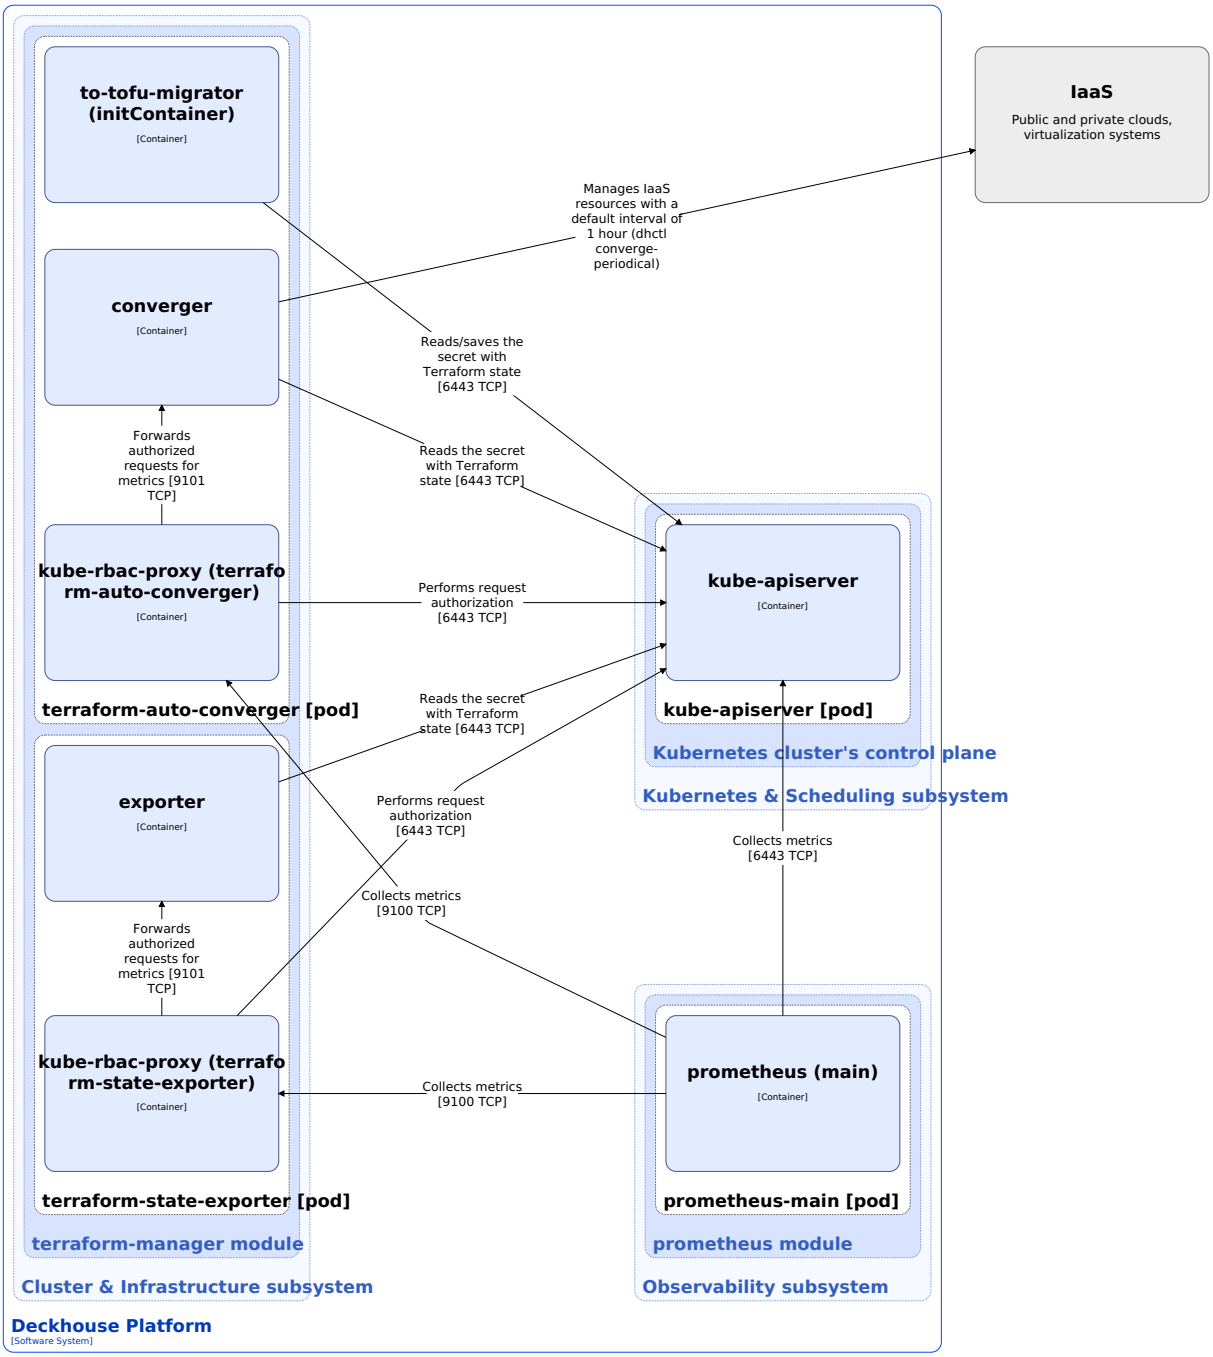
Terraform-manager module



The `terraform-manager` module provides tools for managing the Terraform state in a DP cluster.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `terraform-manager` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Terraform-auto-converger**: Periodically (once per hour by default) checks the Terraform state and applies non-destructive changes to infrastructure resources.

   The component operates only on the base infrastructure of the cluster. Cluster nodes are not automatically reconciled to the desired state. The check interval is configured using the `autoConvergerPeriod` parameter.

   It consists of the following containers:

   - **to-tofu-migrator**: Init container used to migrate the Terraform state to OpenTofu. It runs the `dhctl` utility with the `converge-migration` command.
   - **converger**: Main container running the `dhctl` utility with the `converge-periodical` command.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the metrics of the converger container. This component is an open-source project.

2. **Terraform-state-exporter**: Checks the Terraform state and exports related metrics.

   It consists of the following containers:

   - **exporter**: Main container running the `dhctl` utility with the `terraform converge-exporter` command.

- **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the metrics of the exporter container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Reading and writing the Secret containing the Terraform state.
   - Authorization of metric requests.
2. **Cloud infrastructure** (or virtualization platform): Manages base infrastructure resources and reconciles them to the desired state.

The following external components interact with the module:

- **prometheus-main**: Collects metrics from terraform-auto-converger and terraform-state-exporter.

Additional resources

- Module `terraform-manager` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

IAM subsystem

This subsection describes the architecture of the IAM subsystem (Identity and Access Management) of Deckhouse Platform (DP).

The IAM subsystem provides the following features in DP:

- User authentication
- Role-based access control (RBAC)
- Multitenancy
- Automatic assignment of annotations and labels to namespaces

The IAM subsystem includes the following modules that implement the features described above:

- `user-authn`: User authentication.
- `user-authz`: Role-based access control (RBAC).
- `multitenancy-manager`: Multitenancy.
- `namespace-configurator`: Automatic assignment of annotations and labels to namespaces.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Authentication

Connecting to Kubernetes API using a generated kubeconfig

1. **Initialization**. kube-apiserver reads the configuration of the OIDC provider (in this case — Dex): the `issuer` and the JWKS endpoint for token validation. In Kubernetes 1.30 and later, it reads it through the Dex Service inside the cluster.
2. **Kubeconfig generation**. The Deckhouse Platform (DP) web UI generates a kubeconfig file that includes an `ID token` and a `refresh token`. This file is used by `kubectl` or other Kubernetes clients.
3. **Authentication when accessing the API**. Upon receiving a request with an `ID token`, the `kube-apiserver` verifies the token's signature using keys from the JWKS endpoint. It then compares the `iss` (issuer) and `aud` (audience) claims in the token against the server configuration.

Protection against credential brute-forcing in Dex

Dex limits failed sign-in attempts per client IP address on the password endpoints. Configure the limit with the `rateLimit` parameter. It is turned off by default.

Dex also locks an account after failed sign-in attempts. Configure the lockout with the `passwordPolicy.lockout` parameter. It applies to local users, and to LDAP and Crowd users if their types are listed in `applyToConnectors`.

Authentication via DexAuthenticator

1. **Login process via Dex**. In most cases, Dex redirects the user to the login page of an external identity provider (e.g., GitHub, Okta, Keycloak), then expects the user to return to the `/callback` URL after successful authentication.
   However, for providers like LDAP or Atlassian Crowd, this flow is not supported. Instead, the user enters their login and password in the Dex login form, and Dex performs authentication by calling the provider's API directly.
2. **Token and session storage**. DexAuthenticator sets a cookie containing the full `refresh token`, rather than issuing a short-lived ticket as with the `ID token`.
   This is because Redis, used by DexAuthenticator, does not persist data to disk.
   If the `ID token` is missing from Redis, the user can obtain a new one using the `refresh token` stored in the cookie.
3. **Passing the token to the application**. DexAuthenticator sets the `Authorization` HTTP header with the `ID token` from Redis.
   This may be optional for some applications, such as Upmeter, where other authorization mechanisms are used.
   However, for applications like the Kubernetes Dashboard, this behavior is critical, as the Dashboard forwards the `ID token` to access the Kubernetes API on behalf of the user.

DP-specific Dex extensions

DP ships Dex with additional capabilities:

- Groups for static users (the Group object).
- Two-factor authentication (2FA) for local users and for the users of LDAP and Atlassian Crowd providers (the `twoFactor` parameter).
- A password policy for static users: complexity, password history, rotation and lockout after failed sign-in attempts (the `passwordPolicy` parameter).
- A forced password change at the next sign-in after an administrator resets the password.
- Lockout after failed sign-in attempts for LDAP and Atlassian Crowd users (the `passwordPolicy.lockout.applyToConnectors` parameter).
- Per-IP rate limiting of failed sign-in attempts (the `rateLimit` parameter).
- Locking and unlocking users with the UserOperation object, also without a password policy.
- Lists of allowed users and groups in DexClient and DexAuthenticator that Dex checks at sign-in and at every refresh-token request.
- Limits on the identities a provider may assert (the `spec.allowedIdentities` parameter of DexProvider).
- Kerberos (SPNEGO) sign-in through the LDAP provider without the password form, with tickets from the `Authorization: Negotiate` header validated by the service keytab.
- Refresh tokens for the SAML provider.
- A custom CA certificate for the GitLab provider (the `gitlab.rootCAData` parameter).

High availability mode

In high availability mode (`highAvailability`), Dex and the other `user-authn` components run in several replicas, so sign-in keeps working if one pod fails. DexAuthenticator follows the same setting unless its own `spec.highAvailability` is set.

Additional resources

- Module `user-authn` parameters
- Module `user-authn` custom resources

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Multitenancy

The `multitenancy-manager` module allows you to create isolated projects within the Deckhouse Platform (DP). Projects provide resource quotas, network isolation, and security features that go beyond standard namespaces.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Internal logic

Project creation

The following custom resources are used to create a project:

- ProjectTemplate: Describes the project template. It defines the list of resources to be created in the project and the parameter schema that can be passed during project creation.
- Project: Describes a specific project.

When a Project is created from a specified ProjectTemplate, the following occurs:

1. The provided parameters are validated against the OpenAPI specification (defined in the `parametersSchema.openAPIV3Schema` parameter of the ProjectTemplate resource).
2. A namespace is created with the name of the Project.
3. The project objects are created from the template. In a `deckhouse.io/v1alpha2` template, settings such as the pod security profile, network isolation, log collection and node placement are described by structured fields, and the controller creates the corresponding objects in every namespace of the project. Other objects are described in `manifests` and are applied with the rights of the `d8:project:admin` role in the project namespaces, not with the rights of the controller. A template with a Helm text in `resourcesTemplate` is rendered through Helm. This form is deprecated, no template can get a new `resourcesTemplate`, and a template is created through `deckhouse.io/v1alpha2` only.
4. The standard fields of the project are applied independently of the template: `.spec.quota` is reconciled into a ResourceQuota, and `.spec.administrators` into an auto-managed ProjectRoleBinding.

> ⚠ If you modify a project template, all previously created projects will be updated according to the new template.

Project isolation

A namespace alone does not isolate a project. The project adds the following:

- Access to the whole project through `.spec.administrators`, ProjectRoleBinding and ClusterProjectRoleBinding. A plain RoleBinding in one namespace is allowed for delegatable roles.
- A resource limit through `.spec.quota`, applied as the `d8-project-quota` ResourceQuota in the main namespace.
- Network isolation through the `networkPolicy.mode: Isolated` field of the template.
- The pod security profile through the `podSecurityStandard` field of the template.

Managing access to cluster-wide resources

Objects in project namespaces can reference cluster-wide resources. For example, a PersistentVolumeClaim can use a StorageClass, a Certificate can use a ClusterIssuer, and a RoleBinding can use a ClusterRole. The module allows cluster administrators to define which cluster-wide resources can be used from project namespaces and which values are used by default.

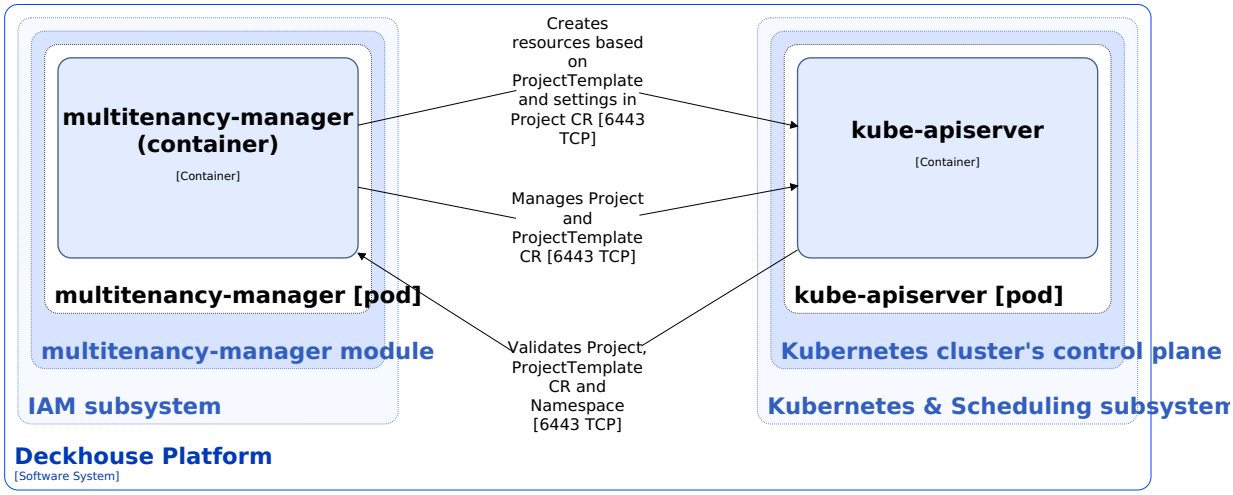
This mechanism works independently of RBAC. RBAC determines *who can create and modify* objects, while the cluster-wide resource access mechanism determines *which resources* those objects can use.

The mechanism uses four custom resources:

- GrantableClusterResourceDefinition registers a type of cluster-wide resource whose access can be managed. These resources are provided by DP or module developers.
- GrantableClusterResourceReference defines where a registered cluster-wide resource is used, for example, which resource field contains a reference to it. These resources are provided by modules.
- ClusterResourceGrantPolicy defines access rules. In the `v1alpha2` version, a cluster administrator selects the projects to which the policy applies by the labels of Project objects (`projectSelector`) and narrows the choice by the labels of project namespaces (`namespaceSelector`). The policy also defines the allowed and denied resources, as well as the resource used by default.
- In every namespace of every project, the controller keeps an AvailableClusterResource for each GrantableClusterResourceDefinition. It lists the cluster-wide resources available to the project under the policies that apply and is read-only.

Until the administrator creates a ClusterResourceGrantPolicy, resource availability is determined by their registration: resources are available to all projects if `defaultAvailability: All` (the default value) is set in GrantableClusterResourceDefinition and the resource does not match the `excluded` or `reserved` filters.

Access checks are performed only for objects in project namespaces. If an access policy changes, cluster-wide resources already used by existing objects remain available to those objects.



The webhooks reject requests while the module controller is unavailable. Until it is back, objects of the registered kinds (for example, PersistentVolumeClaim, Service or RoleBinding) cannot be created or changed in project namespaces, except by the platform components and members of the `system:masters` group. To keep the controller available, enable `highAvailability`.

For a detailed description of the access management mechanism, refer to the `multitenancy-manager` module documentation.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The architecture of the `multitenancy-manager` module at Level 2 of the C4 model and its interactions with other DP components are shown in the following diagram.

Module components

The module consists of the following components:

- **Multitenancy-manager**: The component consists of a single **multitenancy-manager** container and provides the following functions:
  - Managing the Project and ProjectTemplate custom resources.
  - Validating the Project and ProjectTemplate custom resources.
  - Creating the resources specified in the ProjectTemplate custom resource based on the parameters set in Project.
  - Managing the grants mechanism for cluster-wide resources — the `GrantableClusterResourceDefinition`, `GrantableClusterResourceReference`, `ClusterResourceGrantPolicy`, and `AvailableClusterResource` custom resources. It renders the per-project AvailableClusterResource catalogs and runs the validating and mutating admission webhooks (`/is-granted`, `/defaults`, `/protect`) that enforce which cluster resources a project may reference and substitute per-project defaults on CREATE.

> **i** **Warning.** Multitenancy-manager has `cluster-admin` permissions. Objects described in the `manifests` field of ProjectTemplate are applied not with these permissions but with the rights of the `d8:project:admin` role in the project namespaces.

Module interactions

The module interacts with the following components:

- **Kube-apiserver**:
  - Managing the Project and ProjectTemplate custom resources.
  - Validating the Project and ProjectTemplate custom resources.
  - Creating the resources specified in the ProjectTemplate custom resource based on the parameters set in Project.
  - Managing the GrantableClusterResourceDefinition, GrantableClusterResourceReference, ClusterResourceGrantPolicy, and AvailableClusterResource custom resources.
  - Validating the AvailableClusterResource custom resources.
  - Creating validation admission webhooks based on conditions in GrantableClusterResourceDefinition and GrantableClusterResourceReference custom resources.

Additional resources

- Module `multitenancy-manager` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>

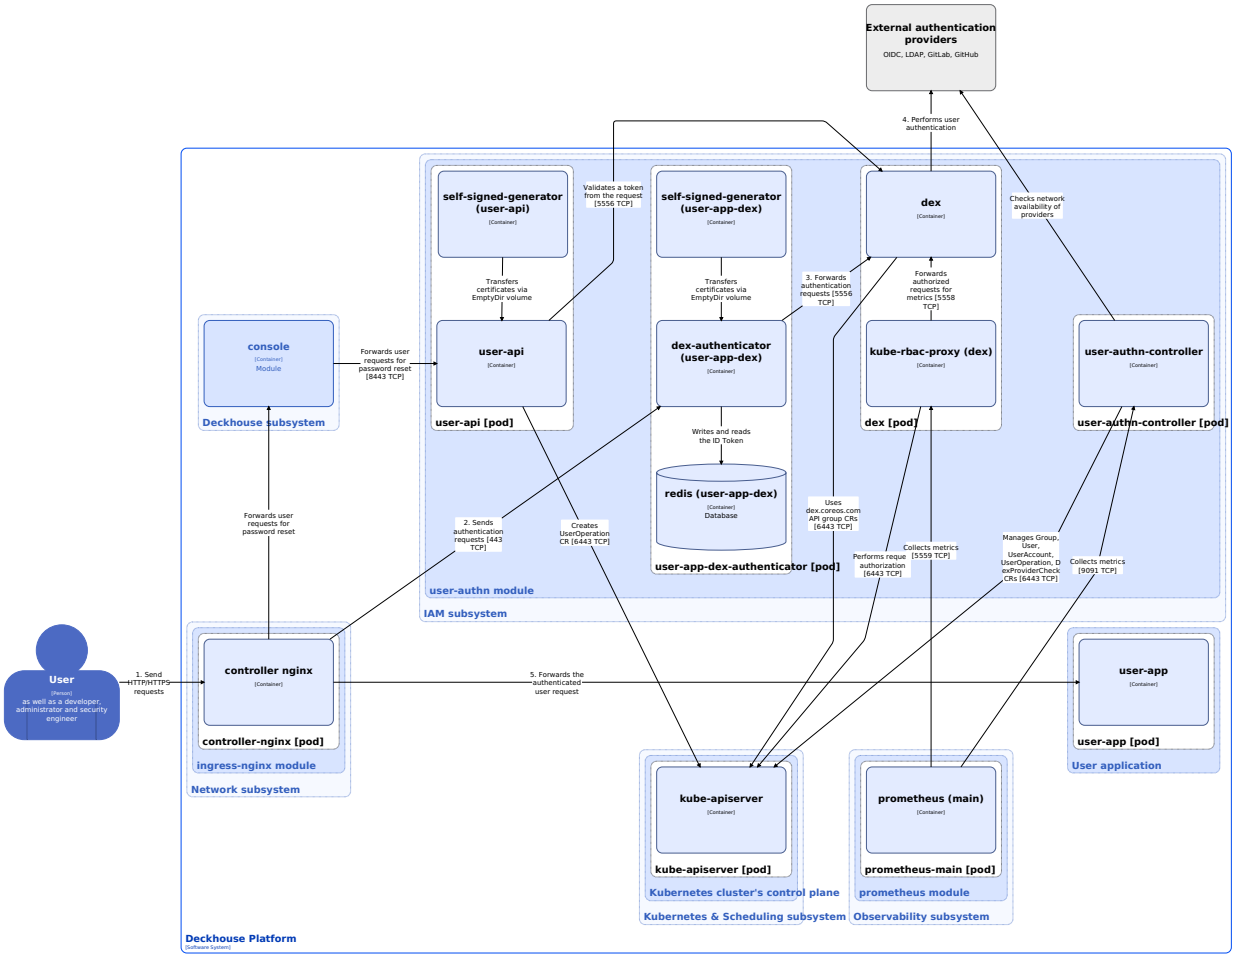
User-authn module

The `user-authn` module implements a unified authentication system integrated with Kubernetes and the web interfaces used by modules of Deckhouse Platform (DP), such as the `console` module.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

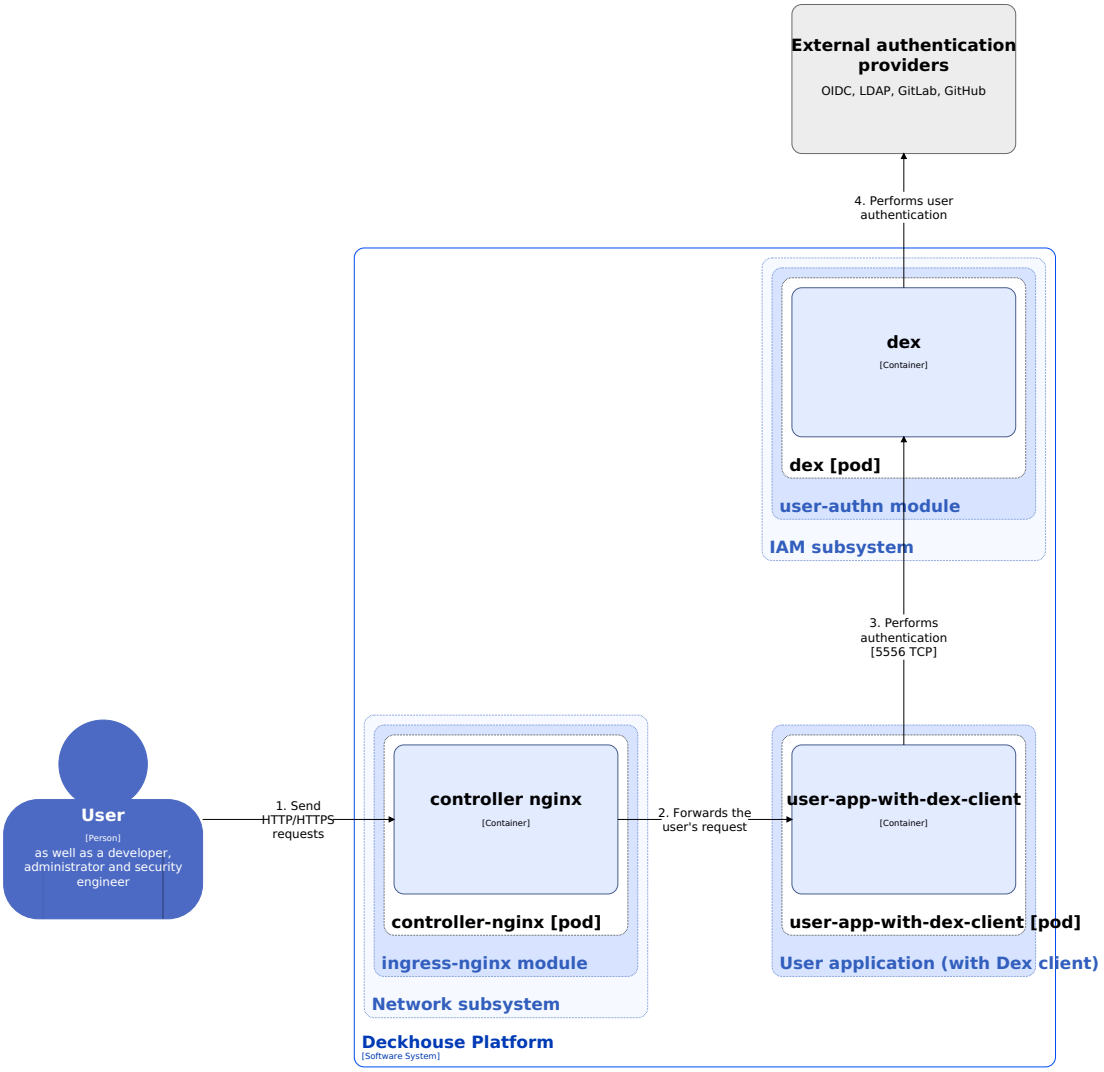
Module architecture



> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

In DP, two authentication schemes are used for platform services and user applications:

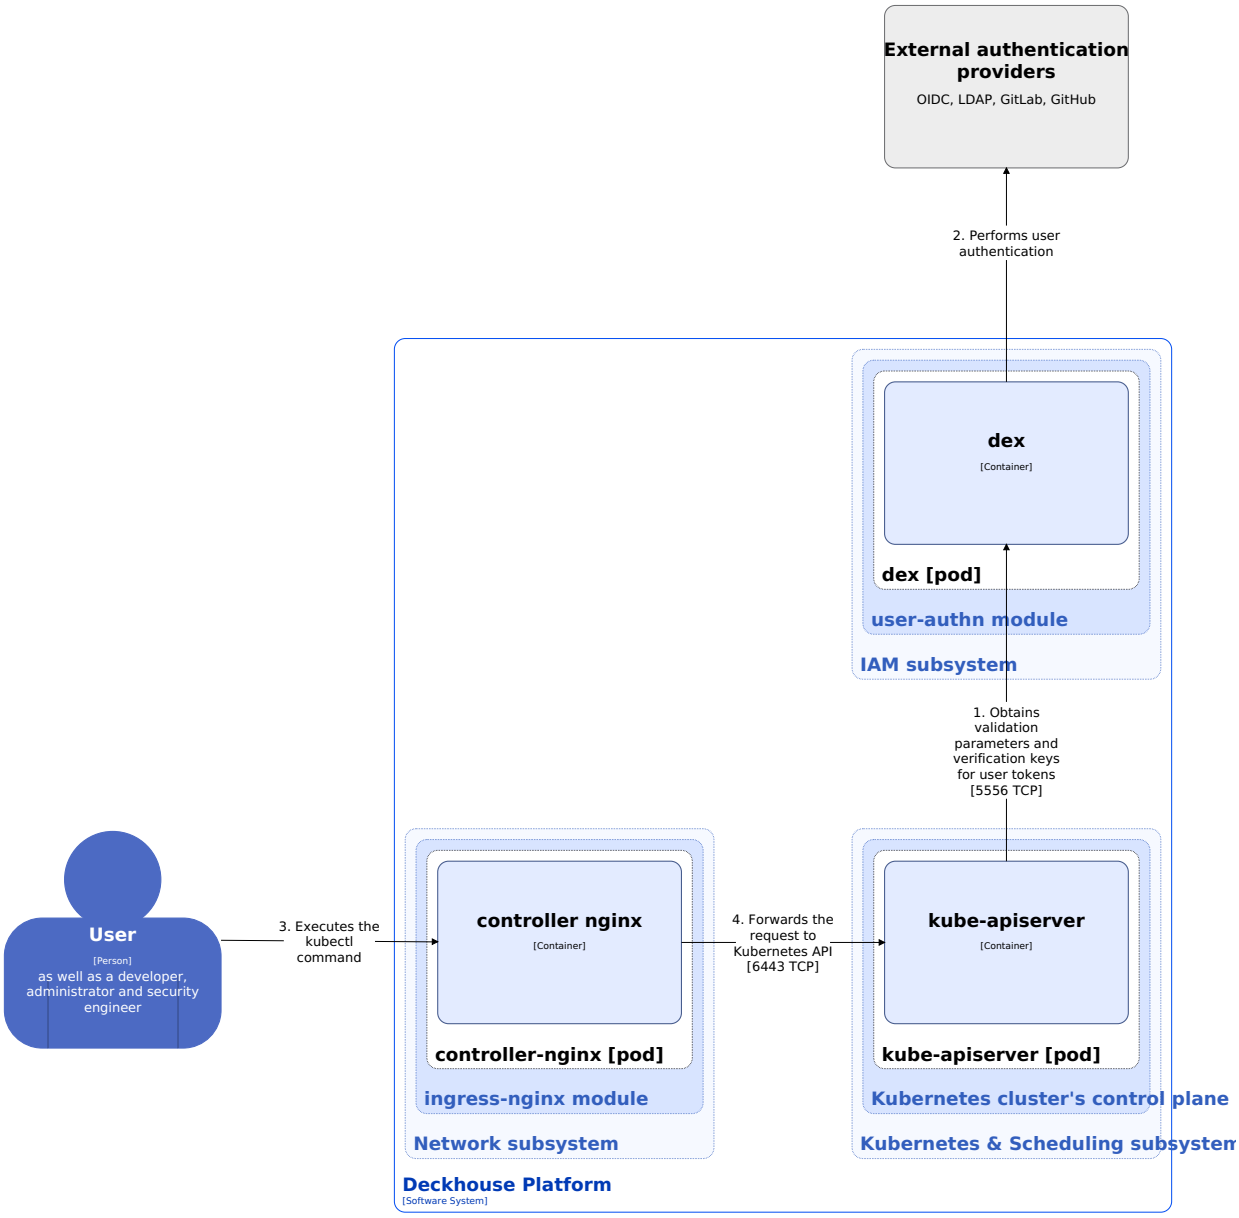
- Using dex-authenticator
- Using the Dex client



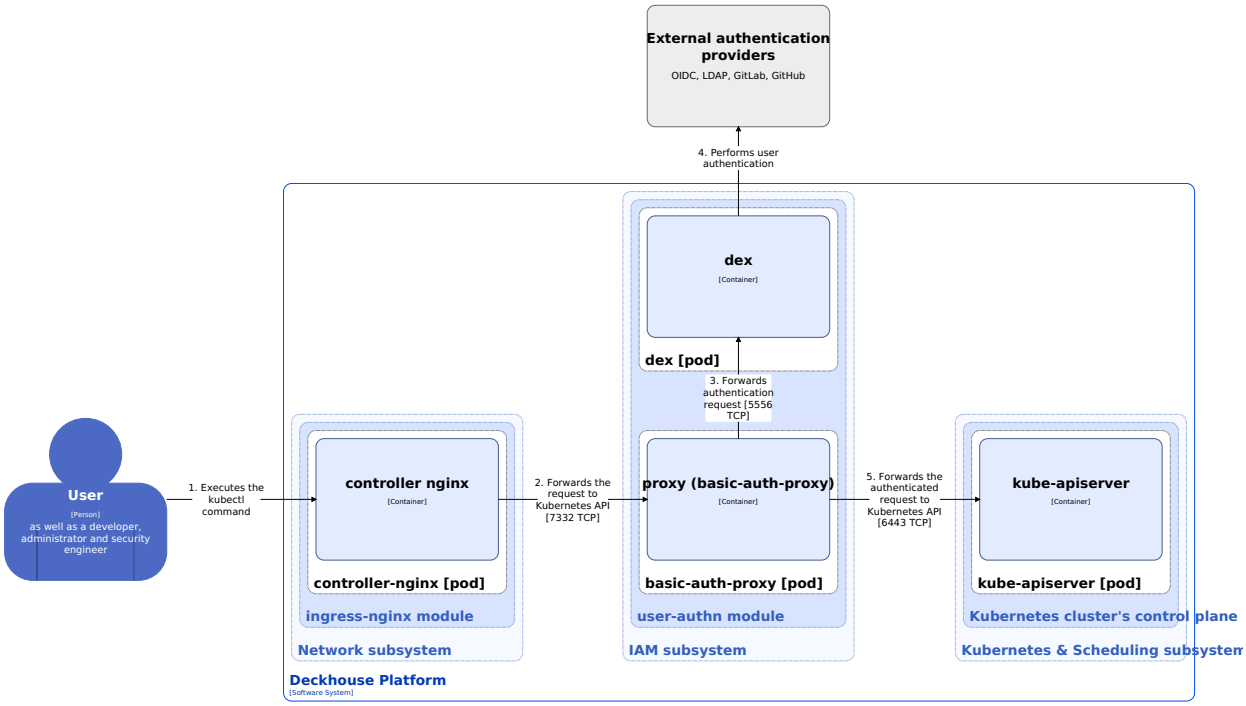
The architecture of the `user-authn` module at Level 2 of the C4 model and its interactions with other DP components are shown in the following diagrams.

Using dex-authenticator:

> **i** For simplicity, the following diagrams show only the components and their interactions that distinguish these diagrams from the variant using dex-authenticator.



Using the Dex client:



When connecting to the Kubernetes API using `d8`, `kubectl` or other Kubernetes clients with a generated kubeconfig, a separate authentication schemes are used:

- Token authentication. It is described in detail in the corresponding documentation section.
- Basic authentication. An example of configuring basic authentication using an LDAP provider is described in the module documentation section.

Using a generated kubeconfig and a token authentication:

Using a generated kubeconfig and a basic authentication:

Module components

The module consists of the following components:

1. **Dex**: Federated OpenID Connect provider that supports static users and integration with external authentication providers such as SAML, GitLab, or GitHub. The module uses a modified version of Dex to support:

   - Groups for static user accounts.
   - Two-factor authentication (2FA).
   - Password policies.
   - Forced password change.
   - Kerberos (SPNEGO) support for the LDAP connector. When enabled, Dex accepts `Authorization: Negotiate` tickets, validates them with a service keytab, and completes the login without rendering the password form, etc.

   For actual list of Dex modifications, refer to the module repository.

   It consists of the following containers:

   - **dex**: Main container implementing Dex functions.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to provider metrics. It is an open source project.

2. **Dex-authenticator**: Middleware service used to authenticate requests to applications through the DP cluster authentication service.

   When the Ingress controller is configured accordingly (using the NGINX `auth_request` module), requests are first forwarded to dex-authenticator for authentication.

   It consists of the following containers:

   - **dex-authenticator**: Main container of the service.
   - **redis**: Sidecar container with a Redis database used for temporary storage of ID tokens and fast access to them (since the database resides in memory).
   - **self-signed-generator**: Init container that generates a self-signed certificate when the pod starts.

3. **User-authn-controller**: A controller that consists of a single **user-authn-controller** container and performing following operations:

   - Manages module custom resources:
     - Group: A resource that describes user group.
     - User: A resource that describes static user.
     - UserAccount: A resource that describes view of Dex Password, OfflineSessions, and UserIdentity objects for the Deckhouse web UI.
     - UserOperation: A resource that describes an operation to be applied to a user (password reset, forced password change, 2FA reset, lock/unlock, logout).
     - DexProviderCheck: A resource that describes a connectivity check for the specific DexProvider. The check verifies that the provider exists, is enabled, Dex is reachable, and the provider endpoint is reachable. It does not perform a full user authentication flow.
   - Deletes expired Users (users whose `status.expireAt` field is in the past).
   - Checks periodically an availability of configured external authentication providers (using DexProviderCheck custom resources).
   - Finds out conflicting TLS-certificates in external LDAP provider configuration settings and exports the corresponding metric.
   - Revokes the sessions of a user on a lock, a password or 2FA reset, a logout and a user deletion: raises the generation of the user’s Dex account, writes a Dex Revocation object, and deletes the user’s Dex AuthSession and RefreshToken objects.
   - Serves the revocations to dex-authenticator over HTTPS (the `revocation-feed` Service), so that dex-authenticator ends the revoked sessions within seconds.
   - Keeps the `kubernetes` Dex client (OAuth2Client) and its `trustedPeers`: the DexAuthenticators and DexClients allowed access to Kubernetes, and the static clients of the module configuration.

   User-authn-controller uses `dex.coreos.com` API group custom resources (Password, OfflineSessions, UserIdentity, and RefreshToken used by Dex as a storage) as a backend to manage module custom resources.

4. **Dexclient-controller**: A controller that consists of a single **dexclient-controller** container (the image of user-authn-controller) and keeps the credentials of every DexClient: the `dex-client-<name>` Secret in the namespace of the DexClient and its Dex clients (OAuth2Client). It is the only component of the module that can write Secrets in other namespaces, and it serves nothing on the network but health and metrics.

5. **User-api**: A component that implements self-service operations for the user who is signed in to the DKP web interface: signing out on all devices and changing the password of a local account. It accepts only the ID tokens of the DKP web interface and does not require platform administrator rights. For

each operation, the component creates a UserOperation custom resource of the `Logout` or `RequirePasswordChange` type, which is processed by the user-authn-controller component. A ValidatingAdmissionPolicy allows user-api to create only these operations.

It consists of the following containers:

- **user-api**: Main container of the service.

6. **Basic-auth-proxy**: An optional component consisting of a single **proxy** container, which is launched when basic authentication is enabled in the settings of one of an external providers. When connecting to the Kubernetes API, the basic-auth-proxy component performs basic user authentication (through Dex for an LDAP provider, directly with the provider for a Crowd or OIDC provider), caches credentials validation results, and proxies authenticated requests to the Kubernetes API.

Module interactions

The module interacts with the following components:

1. **External authentication providers**.
2. **Kube-apiserver**:
   - Manages module custom resources.
   - Authorizes requests for metrics.

The following external components interact with the module:

1. **Ingress controller**: Forwards authentication requests to dex-authenticator for DP platform services and user applications.
2. **User applications**: Can authenticate directly with dex (without dex-authenticator) if an OAuth2 client is configured in Dex for the application. For more details about configuring a Dex client, refer to the `user-authn` module documentation.
3. **Kube-apiserver**: Queries dex when processing Kubernetes API requests made using a kubeconfig file:
   - kube-apiserver reads the OIDC provider configuration (Dex in this case) to obtain the `issuer` and the parameters required to validate tokens via the JWKS endpoint. In Kubernetes 1.30 and later, it reads it through the Dex Service inside the cluster.
   - When receiving a request with an ID token, kube-apiserver verifies its signature using the keys obtained from the JWKS endpoint, then it compares token claims against the server configuration.

   More details about connecting to the Kubernetes API using a generated kubeconfig can be found in the corresponding documentation page.
4. **Prometheus-main**: Collects metrics from the dex provider.
5. **Deckhouse web UI**: Forwards user requests for password reset.

User-authz module

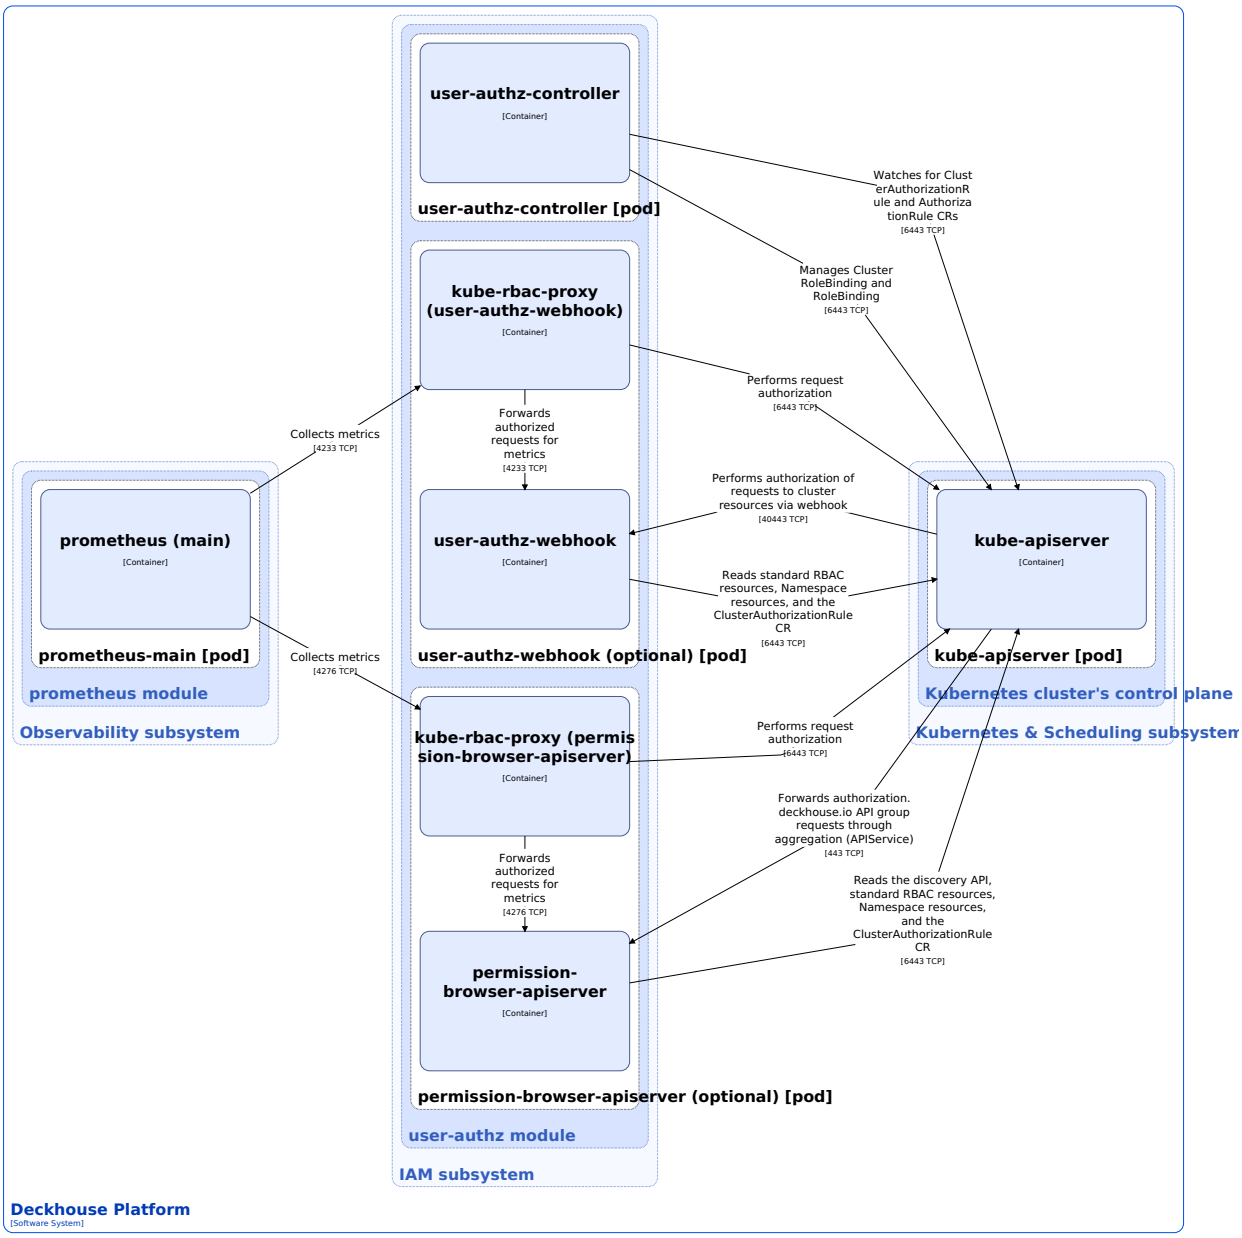
The `user-authz` module implements role-based access control (RBAC) in Deckhouse Platform (DP). The module creates cluster roles for managing user and group access to cluster resources, and, in the Ultimate, CSE Core, and CSE Pro editions of DP, also supports namespace-scoped authorization (multitenancy).

For more details about the role-based access control model, refer to the corresponding section of the module documentation.

The module works with the following custom resources of the `deckhouse.io` API group:

- ClusterAuthorizationRule: Defines access rules at the cluster level.
- AuthorizationRule: Defines access rules within a single namespace.

In the Ultimate, CSE Core, and CSE Pro editions of DP, the module additionally works with the following custom resources of the `authorization.deckhouse.io` API group:



- BulkSubjectAccessReview: A resource for bulk-checking user permissions across multiple objects or actions.
- AccessibleNamespace: A resource for retrieving the list of namespaces accessible to a specific user.
- WhoCan: A resource for finding which users, groups, and service accounts are allowed to perform a given action.
- SubjectAccessReport: A resource for retrieving the full list of permissions granted to a subject.
- RoleAccessReport: A resource for retrieving the full list of resources and actions granted by a role.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> **i** The following assumptions are made to simplify the diagram:
>
> - The diagram shows direct interaction between containers from different pods. In practice, they communicate through corresponding Kubernetes Services (internal load balancers). Service names are omitted when they are clear from context. In other cases, the service name is shown above the arrow.
> - Pods can run with multiple replicas, but all pods are shown as a single replica in the diagram.

The level 2 C4 architecture of the `user-authz` module and its interactions with other DP components are shown in the following diagram:

Module components

The module consists of the following components:

1. **User-authz-controller** (Deployment): This component includes a single **user-authz-controller** container and watches the ClusterAuthorizationRule and AuthorizationRule custom resources, creating, updating, and deleting the corresponding ClusterRoleBinding and RoleBinding resources.

The Ultimate, CSE Core, and CSE Pro editions of DP additionally include the following components:

1. **User-authz-webhook** (DaemonSet): An optional component that implements the Webhook authorization mode for kube-apiserver, placed between the built-in Node and RBAC authorizers in the authorization chain. The component runs on all master nodes with `hostNetwork` enabled.

   The webhook authorization mode for kube-apiserver is configured by the `control-plane-manager` module if the `.controlPlaneConfigurator.enabled` parameter in the module settings is set to `true` (the default). As part of this, the `control-plane-manager` module creates an AuthorizationConfiguration whose `matchConditions` parameter excludes the following subjects from being checked by the webhook:

   - Core control plane system identities, such as `kubernetes-admin`.
   - Node identities, `system:node:*`.
   - Service accounts from the `kube-system` and `d8-*` namespaces.

   Upon receiving a `SubjectAccessReview` request, the webhook checks the namespace access restrictions defined in the ClusterAuthorizationRule custom resource (multitenancy). It does not restrict a subject that has RBAC access regardless of the ClusterAuthorizationRule restrictions. This allows both access models to work together.

   The component can only deny a request explicitly; for every other request it returns no opinion, and the decision falls through to the RBAC authorizer. User-authz-webhook is fail-closed, so if the webhook is unavailable or does not respond in time, kube-apiserver denies every non-excluded request instead of falling back to RBAC.

   The following fail-closed parameters are used for the webhook:

   - `failurePolicy` is set to `Deny`.
   - Timeout: 3 seconds.
   - Decisions are cached separately for authorized and unauthorized requests (`authorizedTTL: 5m` / `unauthorizedTTL: 30s`).

   The Deckhouse controller deploys this component if the `.enableMultiTenancy` parameter in the module settings is set to `true` (default is `false`).

   Includes the following containers:

   - **user-authz-webhook**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to component metrics.

2. **Permission-browser-apiserver** (Deployment): An optional component, a Kubernetes API extension that publishes custom resources of the `authorization.deckhouse.io` API group.

   The BulkSubjectAccessReview, AccessibleNamespace, WhoCan, SubjectAccessReport, and RoleAccessReport custom resources of the `authorization.deckhouse.io` API group are used by the `console` module and provide extended capabilities for determining user, resource, or action permissions.

   The Deckhouse controller deploys this component if the `.enableMultiTenancy` parameter in the module settings is set to `true` (default is `false`).

   To expand wildcard RBAC rules into the cluster's actual API resources and determine whether each one is namespaced or cluster-scoped, it periodically queries the Kubernetes Discovery API endpoint and caches the result.

   Includes the following containers:

   - **permission-browser-apiserver**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to component metrics.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches the ClusterAuthorizationRule and AuthorizationRule custom resources.
   - Manages the ClusterRoleBinding and RoleBinding resources.
   - Reads Namespace and RBAC resources, and queries the discovery API.
   - Authorizes requests for metrics.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Authorizes requests to cluster resources.
   - Forwards requests to the `authorization.deckhouse.io` API group.
2. **Prometheus-main**: Collects metrics from the user-authz-webhook and permission-browser-apiserver components.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Security subsystem

This subsection describes the architecture of the Security subsystem of Deckhouse Platform (DP).

The Security subsystem includes the following modules:

- `admission-policy-engine`: Lets you use security policies in the cluster according to Kubernetes Pod Security Standards. The module uses Gatekeeper to enforce these policies.
- `runtime-audit-engine`: Implements runtime audit (threat detection based on Linux kernel events and Kubernetes API audit events using Falco). The architecture is described in “Runtime audit”.
- `security-events-manager`: Performs declarative collection, processing, normalization, and delivery of security events from logs of applications and Kubernetes infrastructure components. The architecture is described in “Security events”.
- `operator-trivy`: Performs periodic vulnerability scanning of the DP cluster.
- `cert-manager`: Manages TLS certificates in the cluster.
- `secrets-store-integration`: Delivers secrets to Kubernetes applications by integrating secrets, keys, and certificates stored in external secret stores.
- `secret-copier`: Automatically copies secrets to cluster namespaces.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Integrity control

Integrity control is a set of mechanisms for verifying containers to ensure their security and compliance with the specified configuration.

Deckhouse Platform (DP) provides the following mechanisms:

- Integrity control of user workloads at startup: image signature verification during Kubernetes API request validation.
- Integrity control of running containers: runtime audit.
- Integrity protection of DP modules: modules are installed as immutable images.

Container image integrity control at the CRI level

Cryptographic image signature verification when a container image is pulled and a container starts, as well as protection of unpacked image layers from modification using DM-Verity, are implemented at the containerd level and are available **only in DP Certified Core and Certified Pro editions**. These editions use a modified version of containerd. The DM-Verity root hash is calculated for each image layer during the platform build and verified by containerd when the image is unpacked. Integrity control includes verification when image blocks are accessed and periodic re-verification:

- After unpacking, DM-Verity verifies image blocks whenever they are accessed, throughout the entire container runtime.

- In addition, containerd periodically (once per hour by default) rechecks running containers in protected namespaces. It verifies the image manifest signature again and fully checks image layers against the DM-Verity root hash (`veritysetup verify`). Layers are not checked all at once. The queue is processed at a rate of one container per minute, so a complete pass over a node takes longer as the number of containers on the node increases.

Platform image signatures are verified against a built-in set of public certificates in containerd. The signing private key belongs to the platform vendor, and you cannot add your own verification key. For more details about this mechanism, refer to the Certified Core and Certified Pro documentation.

In other DP editions (CE, BE, SE, SE+, EE, Ultimate, Core), image signature verification at the CRI level is not available:

- When using containerd v2, the EROFS snapshotter is used. Each OCI image layer is converted into a separate EROFS file and mounted read-only. This reduces the risk of tampering with data in images already unpacked on a node, but does not eliminate it completely and does not replace image authenticity verification. For details on switching to containerd v2, refer to “Migrating container runtime to containerd v2”.
- The SHA-256 hash verification performed by containerd when pulling an image protects against data corruption in transit, but does not confirm the image authenticity, because it does not make it possible to determine who built the image.

To control the integrity and authenticity of user application images in these editions, use signature verification during Kubernetes API request validation (for details, refer to “Integrity control of user workloads at startup”).

Integrity control of user workloads at startup

The integrity and authenticity of user application images are verified during Kubernetes API request validation, that is, before a Pod is created, rather than at the CRI level. The mechanism is implemented by the `admission-policy-engine` module and relies on signatures created with Cosign.

The sequence of integrity checks at startup:

1. At the build stage, the image is signed with a private key using Cosign. The signature is published in the container image registry as a separate tag and does not modify the image itself.
2. A SecurityPolicy resource with the `policies.verifyImageSignatures` parameter is created in the cluster, listing the public keys and the image address patterns.
3. When a Pod is created or updated, the validating webhook passes the request to Gatekeeper, which in turn queries the Ratify component.
4. Ratify verifies the image signature against the specified public keys.
5. If the signature is missing or does not match the specified keys, Pod creation is denied.

Additionally, you can restrict the list of container image registries that Pods are allowed to be started from using the `policies.allowedRepos` parameter of the OperationPolicy resource.

For more details on the configuration, refer to “Image signature verification”.

Integrity control of running containers

Runtime auditing in DP includes analyzing Linux kernel events and Kubernetes API audit events. This makes it possible to track whether applications in pods are running unchanged, conform to their expected state, and have not been modified.

Auditing uses:

- Built-in rules
- Custom rules that can be added using the Falco condition syntax

Integrity control of running containers can detect threats such as launching command-line shells inside containers or pods, discovering containers running in privileged mode, mounting insecure paths into containers, or attempts to read sensitive data.

For more details on configuring runtime audit, refer to “Runtime audit”.

Integrity protection of DP modules

Starting with version 1.74, DP modules are installed not as a directory with files, but as an image in the EROFS format that is mounted read-only through the DM-Verity kernel mechanism. This protects the contents of an already installed module from being modified on the node. The module files cannot be overwritten in the mounted image, and DM-Verity verifies the image blocks when they are accessed.

This is a separate mechanism unrelated to container image integrity control at the CRI level: here, the DP controller applies DM-Verity to the platform module image rather than containerd applying it to container image layers. Therefore, the edition restriction described in “Container image integrity control at the CRI level” does not apply to this mechanism.

The mechanism is enabled automatically if the `erofs` filesystem is registered in the kernel on the node

running the DP controller (a master node by default), that is, the corresponding kernel module is either loaded or built into the kernel. To check it, run the following command:

```
grep -w erofs /proc/filesystems
```

If the `erofs` filesystem is not available, DP will continue to operate and will install modules the regular way, without protecting their integrity. The switch happens without a dedicated alert, so make sure to check `erofs` availability in advance.

⚠ DP loads the `erofs` kernel module and configures it to load automatically only on nodes that use containerd v2 as the container runtime. If master nodes use containerd v1, the `erofs` module may end up not loaded, and DP modules will be installed without integrity protection, even if the kernel supports `erofs`.

To make sure the mechanism is engaged, either switch master nodes to containerd v2, or have the operating system load the `erofs` module.

Note the following when using this mechanism:

- The mechanism protects modules from being modified after installation, but does not confirm their authenticity: there is no cryptographic signature verification for modules. The container image registry the module is pulled from remains the source of trust.
- The mechanism applies only to DP modules and does not cover user application images.
- The mechanism is available in all DP editions and does not need to be enabled separately.

Additional resources

- Module `admission-policy-engine` custom resources

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Runtime audit architecture

The runtime audit of Deckhouse Platform (DP) is based on the Falco threat detection system. This mechanism analyzes Linux kernel events and Kubernetes API audit events to detect suspicious activity in running containers and across the cluster.

DP deploys Falco agents on each node as part of a DaemonSet. Once started, the agents begin collecting OS system calls and Kubernetes audit data.

i Falco developers recommend running it as a systemd service, which can be challenging in Kubernetes clusters that support autoscaling. DP includes additional security mechanisms such as multitenancy and resource control policies. Combined with the DaemonSet deployment, these mechanisms ensure a high level of protection.

Each cluster node runs a Falco Pod with the following components:

- `falco`: Collects events, enriches them with metadata, and outputs them to stdout.
- `rules-loader`: Retrieves rule data from FalcoAuditRules custom resources and stores them in a shared directory.
- `falcosidekick`: Receives events from `falco` and exports them as metrics to external systems.
- `kube-rbac-proxy`: Protects the `falcosidekick` metrics endpoint from unauthorized access.

For a detailed architecture of the `runtime-audit-engine` module, which implements DP security event audit, refer to the corresponding documentation section.

Audit rules

Runtime audit event analysis is performed using rules that define suspicious behavior patterns. Each rule consists of a condition expression written in accordance with Falco's condition syntax.

Built-in rules

DP provides the following types of built-in rules:

- **Kubernetes audit rules**: Help detect security issues in DP and in the audit mechanism itself. These rules are located in the `falco` container at `/etc/falco/k8s_audit_rules.yaml`.

Custom rules

Custom rules can be defined using the FalcoAuditRules custom resource.

Each Falco agent includes a sidecar container with a `shell-operator` instance. This instance reads rules from Kubernetes resources, converts them into Falco rule format, and stores them in the `/etc/falco/rules.d/` directory inside the Pod. When a new rule is added, Falco automatically reloads the configuration.

Additional resources

- Module `runtime-audit-engine` documentation

Security events architecture

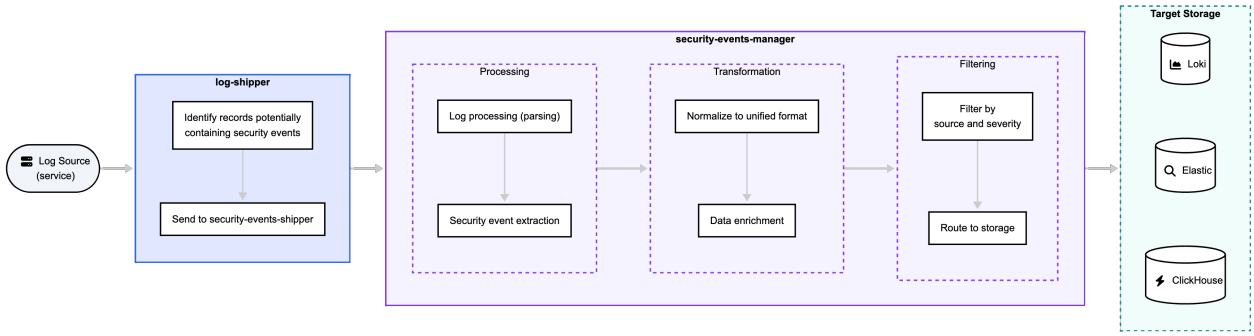
The `security-events-manager` module within Deckhouse Platform (DP) performs declarative collection, processing, normalization, and delivery of security events extracted from logs of applications and Kubernetes infrastructure components.

A security event is a structured record of an action or fact that is significant from an information security perspective. Typical categories of such events include:

- Authentication and authorization
- Access to APIs and configuration
- Changes to cluster objects
- Runtime and network activity anomalies

Regardless of the original log format, the output is a uniform event model with a mandatory minimum set of attributes.

> ⚠ The `security-events-manager` module is in the `Experimental` stage and may change in future releases.



Solution architecture

The architecture is intended to build a unified pipeline for working with security events extracted from the logs of applications and Kubernetes infrastructure components. The module performs three processing stages:

1. **Collection**: Collecting logs from pod sources and node files, initial selection of records that may contain security events.
2. **Processing and enrichment**: Parsing logs, extracting event signals, transforming into a unified model, and enriching with context.
3. **Delivery**: Policy-based filtering and delivery to configured storages.

At the delivery stage, sending to several types of storage and analytics systems is supported (such as Loki, Elasticsearch, Kafka, Splunk, Vector, File).

Processing pipeline

The architecture separates three stages of the pipeline: **collection**, **processing and enrichment**, and **delivery**.

Collection layer (log-shipper)

Collection is performed via the auxiliary `log-shipper` module:

- Container sources use application logs within the namespace.
- Cluster sources use node files and system service logs (for example, `/var/log/kube-audit/audit.log`, `/var/log/auth.log`).

A two-tier scheme is used:

- The `log-shipper` module performs preliminary selection of log records using simple comparison operators (`In`, `NotIn`, `Regex`, `NotRegex`, `Exists`, `DoesNotExist`) and forwards them to the gateway.
- The `security-events-manager` module (gateway) performs field recognition (parsing), further processing, and delivery.

Because log parsing is resource-intensive, it is performed only for records pre-selected as potentially containing security events, not for all incoming logs. Therefore, the initial selection stage does not perform deep field-value filtering that requires full content parsing.

Example of an input log for the selection stage:

```
{
  "time": "2026-05-10T14:21:03Z",
  "kind": "Event",
  "source": "kube-apiserver",
  "level": "Metadata",
  "message": "Unauthorized",
  "reason": "Unauthorized",
  "code": 401,
  "requestURI": "/api/v1/namespaces/default/secrets",
  "user": "system:serviceaccount:default:demo",
  "sourceIPs": [
    "206.123.145.70"
  ]
}
```

Processing and extraction

After being forwarded to the gateway, the log structure is recognized. Standard processing strategies are supported:

- `JSON`: For structured logs.
- `Regex`: For string formats with predictable patterns.
- `Grok`: For complex, non-unified formats.

The processing result is used to derive event signals and build a unified set of fields.

Example output of the processing stage:

```
{
  "parsed": {
    "timestamp": "2026-05-10T14:21:03Z",
    "source_component": "kube-apiserver",
    "http_status": 401,
    "request_uri": "/api/v1/namespaces/default/secrets",
    "actor_id": "system:serviceaccount:default:demo",
    "source_ip": "206.123.145.70"
  }
}
```

After processing, the record becomes a source of fields for event classification (code/category/severity/outcome), as well as for building context (`actor`, network attributes, and source metadata).

Transformation and enrichment

Transformation is implemented in two steps:

1. **Transform**: Mapping fields from the original log to the fields of the target event model.
2. **Enrich**: Adding or refining fields from additional context sources (for example, static environment attributes, subject roles, and service indicators).

The order is fixed: `Transform` is applied first, then `Enrich`. In case of a conflict for a target field, the final value is determined by the `Enrich` stage.

Filtering and delivery

After the event is formed, a delivery policy is applied:

- Source filtering
- Filtering by minimum severity
- Routing to one or more destinations

Filtering rules can use both exact source identifiers and source masks, which makes it possible to manage flows at the level of individual services or entire groups.

Destinations can be storage and processing systems such as cluster Loki, external SIEM/log platforms, and streaming buses. The delivery scheme supports parallel delivery to multiple target systems.

Security event model

Below is the structure of the event that is sent to storage.

Required fields:

- `id`, `timestamp`
- `source.component`
- `event.code`, `event.category`, `event.severity`, `event.outcome`
- `eventMetadata.cluster`

Optional fields:

- `eventMetadata.sourceIPs`
- `actor.*`
- `object.*`

```
{
  "id": "2f0de5c2-2e58-4d3f-b4fe-5ec6f1935b9f",
  "timestamp": "2026-05-10T14:21:03Z",
  "source": {
    "component": "kube-apiserver"
  },
  "event": {
    "code": "UNAUTHORIZED_ACCESS",
    "category": "Rbac",
    "severity": "High",
    "outcome": "Failure"
  },
  "eventMetadata": {
    "cluster": "prod-cluster",
    "sourceIPs": [
      "206.123.145.70"
    ]
  },
  "actor": {
    "id": "system:serviceaccount:default:demo",
    "type": "ServiceAccount"
  },
  "object": {
    "id": "/api/v1/namespaces/default/secrets",
    "type": "KubernetesResource"
  }
}
```

Minimal sufficient lifecycle

In a practical scenario, the architecture works along the following chain:

1. Log sources are connected to the collection pipeline.
2. An initial selection of potentially relevant records is performed.
3. Records are processed and transformed into unified events.
4. Events are enriched with contextual attributes.
5. Filtering and routing rules are applied.
6. Events are delivered to target storages and analytics systems.

The result is a unified and manageable flow of security events suitable for monitoring, investigations, and long-term auditing.

Supported security events

The `security-events-manager` module ships with a built-in set of security event detection rules covering authentication, configuration, RBAC, runtime, and other categories. For the up-to-date list of implemented security events, their codes, severity levels, and descriptions, refer to the module documentation.

Additional resources

- Module `log-shipper` documentation
- Module `security-events-manager` documentation

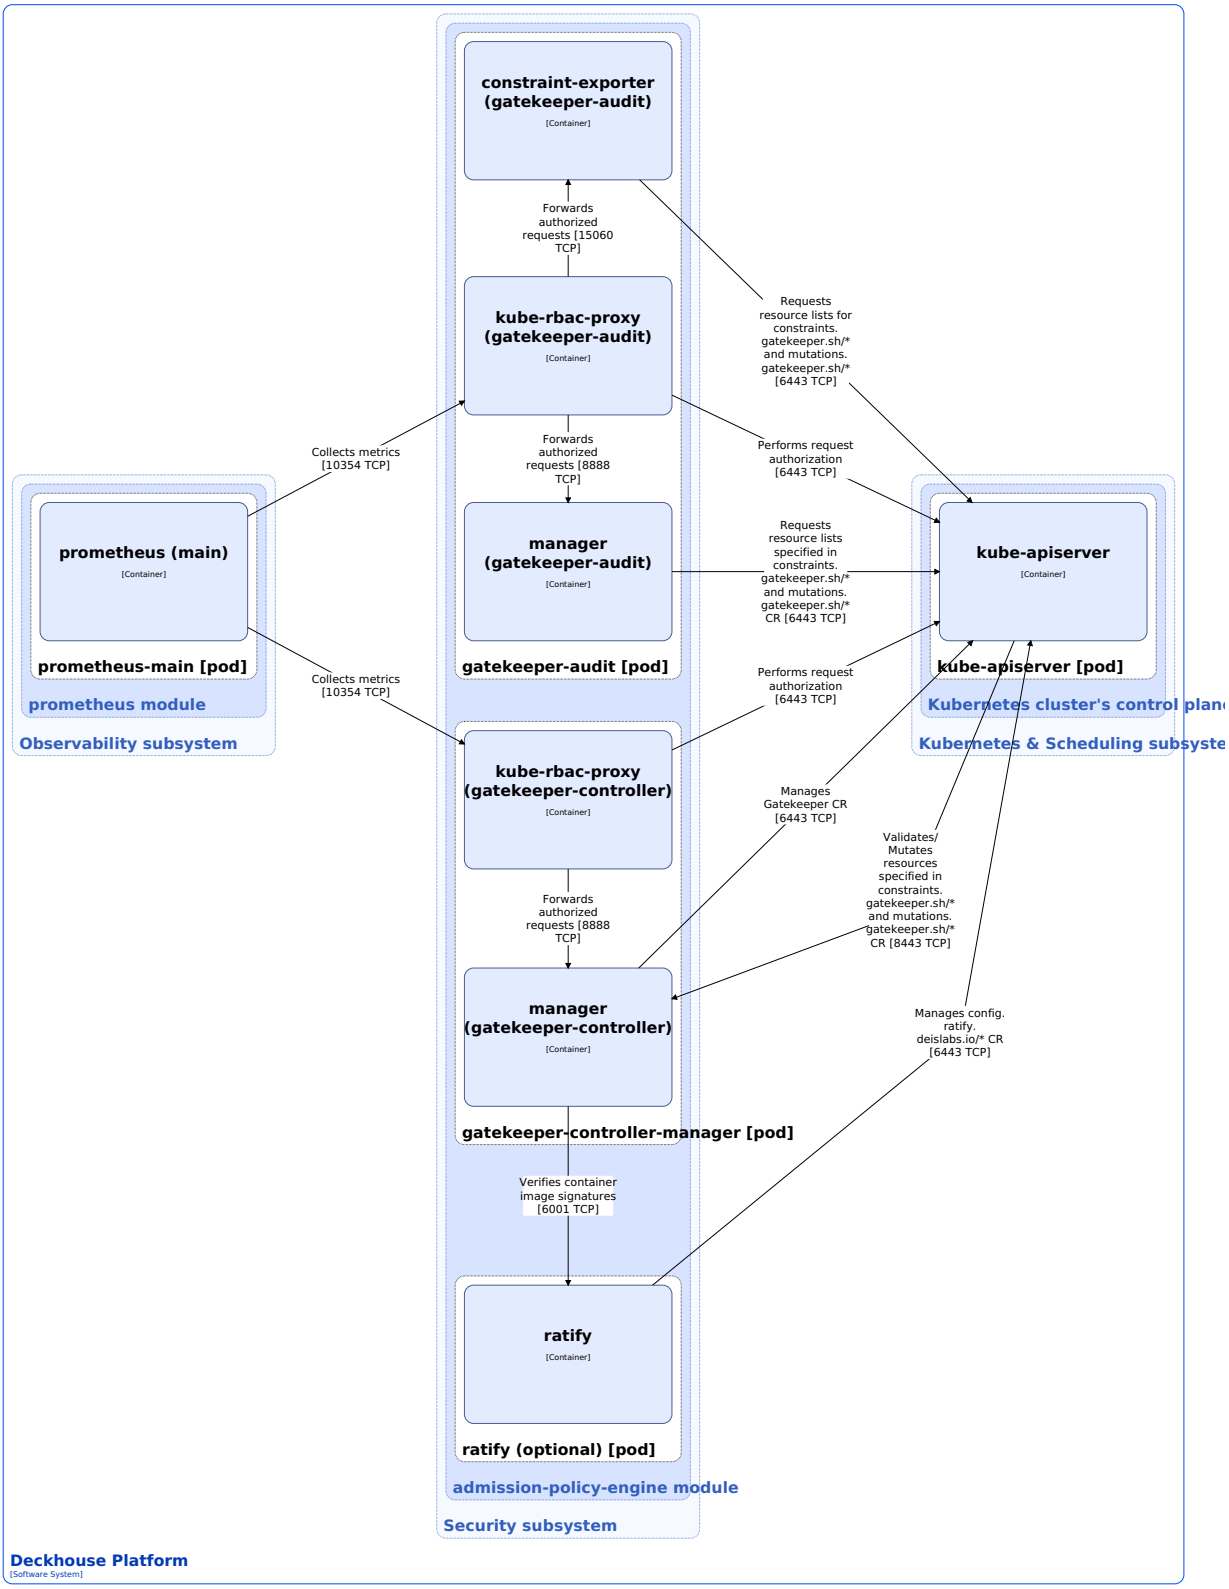
> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Admission-policy-engine module

The `admission-policy-engine` module enforces security policies and operational restrictions in a Kubernetes cluster. Policies are applied based on Pod Security Standards checks and rules from the following custom resources:

- OperationPolicy: Describes the operational policy of the cluster.

- SecurityPolicy: Describes the security policy of the cluster.
- SecurityPolicyException: Describes exceptions to the cluster security policy.



> **i** The `deckhouse` module processes the OperationPolicy and SecurityPolicy resources. The Deckhouse controller of the `deckhouse` module uses addon-operator and module hooks to create custom resources for Gatekeeper based on OperationPolicy and SecurityPolicy. Gatekeeper uses the resulting custom resources to validate newly created or updated Kubernetes resources.
>
> For details on the hooks concept, refer to the addon-operator documentation.

For a detailed description of the module, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `admission-policy-engine` module and its interaction with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Gatekeeper-controller-manager**: A Gatekeeper controller that performs the following operations:
   - Manages Gatekeeper custom resources.
   - Validates Kubernetes resources specified in custom resources from the `constraints.gatekeeper.sh/*` API group.
   - Mutates Kubernetes resources specified in the AssignMetadata, Assign, ModifySet, and AssignImage custom resources.

   Security rules are defined using the ConstraintTemplate custom resource and custom resources from the `constraints.gatekeeper.sh/*` API group. A ConstraintTemplate defines new policy types, based on which specific security policies are created to validate resources.

It consists of the following containers:

- **manager**: Main container.
- **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to controller metrics.

2. **Gatekeeper-audit**: Implements periodic checks of existing Kubernetes resources for compliance with security policies.

   It consists of the following containers:

   - **manager**: Main container.
   - **constraint-exporter**: Sidecar container that exposes additional metrics for the `constraints.gatekeeper.sh/*` and `mutations.gatekeeper.sh/*` custom resources.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to metrics from `manager` and `constraint-exporter`.

3. **Ratify**: An optional component consisting of a single **ratify** container. It provides a Gatekeeper provider implementation for validating metadata of used artifacts. In DP, this provider is used to verify container image signatures and is available in the SE+, EE, CSE Lite, and CSE Pro editions.

> **i** Gatekeeper uses the Provider custom resource to extend resource validation capabilities in Kubernetes. The Provider resource describes the service endpoint to which Gatekeeper sends requests during ValidationWebhook execution. Some DP modules, such as `operator-trivy`, can create Provider custom resources and thereby extend the verification capabilities.

Module interactions

The module interacts with the following components:

- **Kube-apiserver**:
  - Monitors Kubernetes resources specified in custom resources of the `constraints.gatekeeper.sh/*` and `mutations.gatekeeper.sh/*` API groups.
  - Manages ConstraintTemplate, Assign, AssignImage, AssignMetadata, ModifySet, as well as resources from the `constraints.gatekeeper.sh/*` and `config.ratify.deislabs.io/*` API groups.

The following external components interact with the module:

1. **Kube-apiserver**: Validates Kubernetes resources and checks their compliance with the defined security rules.
2. **Prometheus-main**: Collects module metrics.

Cert-manager module

The `cert-manager` module automates the full certificate management lifecycle in a cluster: from issuing and renewing self-signed certificates to integration with external certificate authorities such as Let’s Encrypt, HashiCorp Vault, and Venafi. This significantly simplifies service security and provides centralized control over all certificate-related processes.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cert-manager` module and its interactions with other DP components are shown in the following diagram:

Module components

The `cert-manager` module consists of the following components:

1. **Cert-manager**: A controller that provides the full certificate management lifecycle in Deckhouse Platform (DP). `Cert-manager` manages the following custom resources:
   - Issuer: Describes settings and parameters for obtaining certificates from a specific source, such as a CA or an external service. It is used within a selected namespace.
   - ClusterIssuer: Similar to Issuer, but applies to the entire cluster and is available in all namespaces.
   - Certificate: Defines the required certificate and specifies parameters such as the subject, validity period, the Issuer or ClusterIssuer used, and additional options.
   - CertificateRequest: A request to issue or renew a certificate.
   - Challenge: Describes a task used to complete domain validation, such as an HTTP-01 or DNS-01 challenge for Let’s Encrypt.
   - Order: Groups related Challenges into a sequence for obtaining a certificate from an ACME server, such as Let’s Encrypt.

   The component includes the following containers:
   - **cert-manager**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the cert-manager container metrics.

> **i** To complete the DNS-01 challenge, `cert-manager` supports a number of popular DNS providers, such as AzureDNS, Cloudflare, DigitalOcean, and others. For the full list of supported DNS providers, refer to the cert-manager documentation. For providers that are not supported out of the box, webhook issuer types are used as external components. To work correctly, such providers must be installed in the `d8-cert-manager` system namespace. When making changes to this namespace, it is recommended to always account for such extensions so they remain operational.

2. **Webhook**: A component consisting of a single webhook container and performing the following operations:
   - validates the Issuer, ClusterIssuer, Certificate, CertificateRequest, Challenge, and Order custom resources
   - mutates CertificateRequest custom resources by adding the user identity created the certificate request

   In DP, validation is disabled for resources in the `d8-cert-manager` namespace and for namespaces with the `cert-manager.io/disable-validation=true` label.
3. **Cainjector**: An additional component consisting of a single cainjector container. Cainjector automatically injects or updates root certificate authority (CA) certificates in all relevant Kubernetes resources: ValidatingWebhookConfiguration, MutatingWebhookConfiguration, CustomResourceDefinition, and APIService. This keeps trusted root certificates up to date for services that use webhooks and API extensions.

   Cainjector is enabled using the `.spec.settings.enableCAInjector` parameter in the `cert-manager` module settings. DP does not use cainjector, so enable it only if your services use custom CA injections.

   Cainjector processes only resources with the `cert-manager.io/inject-ca-from`, `cert-manager.io/inject-ca-from-secret`, or `cert-manager.io/inject-apiserver-ca` annotations, depending on the resource type.
4. **Cm-acme-http-solver**: A temporary pod with the acmesolver container that is launched to complete an HTTP-01 Challenge during domain validation through ACME, such as Let’s Encrypt. This pod is automatically created by `cert-manager` controller for the duration of the HTTP-01 Challenge and is deleted after the procedure is complete. This approach provides secure temporary publication of the resource that confirms domain ownership for certificate issuance.

Module interactions

The `cert-manager` module interacts with the following components:

1. **Kube-apiserver**:
   - Manages the Issuer, ClusterIssuer, Certificate, CertificateRequest, Challenge, and Order custom resources.
   - Watches and updates ValidatingWebhookConfiguration, MutatingWebhookConfiguration, CustomResourceDefinition, and APIService resources.
2. **ACME service**: Handles requests for domain verification and certificate issuance.
3. **PKI service**: Handles requests for issuing and renewing certificates.
4. **DNS provider**: Handles requests to add and delete records in DNS services to complete DNS-01 Challenge during domain validation through ACME server.

The following external components interact with the module:

1. **Kube-apiserver**:
   - validates the Issuer, ClusterIssuer, Certificate, CertificateRequest, Challenge, and Order custom resources;
   - mutates CertificateRequest custom resources.
2. **Prometheus-main**: Collects `cert-manager` metrics.
3. **Nginx Controller**: Forwards requests from ACME server to `cm-acme-http-solver`.

Additional resources

Module operator-trivy

The `operator-trivy` module scans user images at runtime for known CVEs (Common Vulnerabilities and Exposures), including vulnerabilities specific to Astra Linux, ALT Linux, and RED OS. It is based on the Trivy project. Scanning uses public vulnerability databases, enriched with Astra Linux, ALT Linux, RED OS databases, and BDU FSTEC (Data Bank of Information Security Threats by the Federal Service for Technical and Export Control of Russia).

The module also analyzes Kubernetes cluster compliance with the CIS (Center for Internet Security) Kubernetes Benchmark requirements.

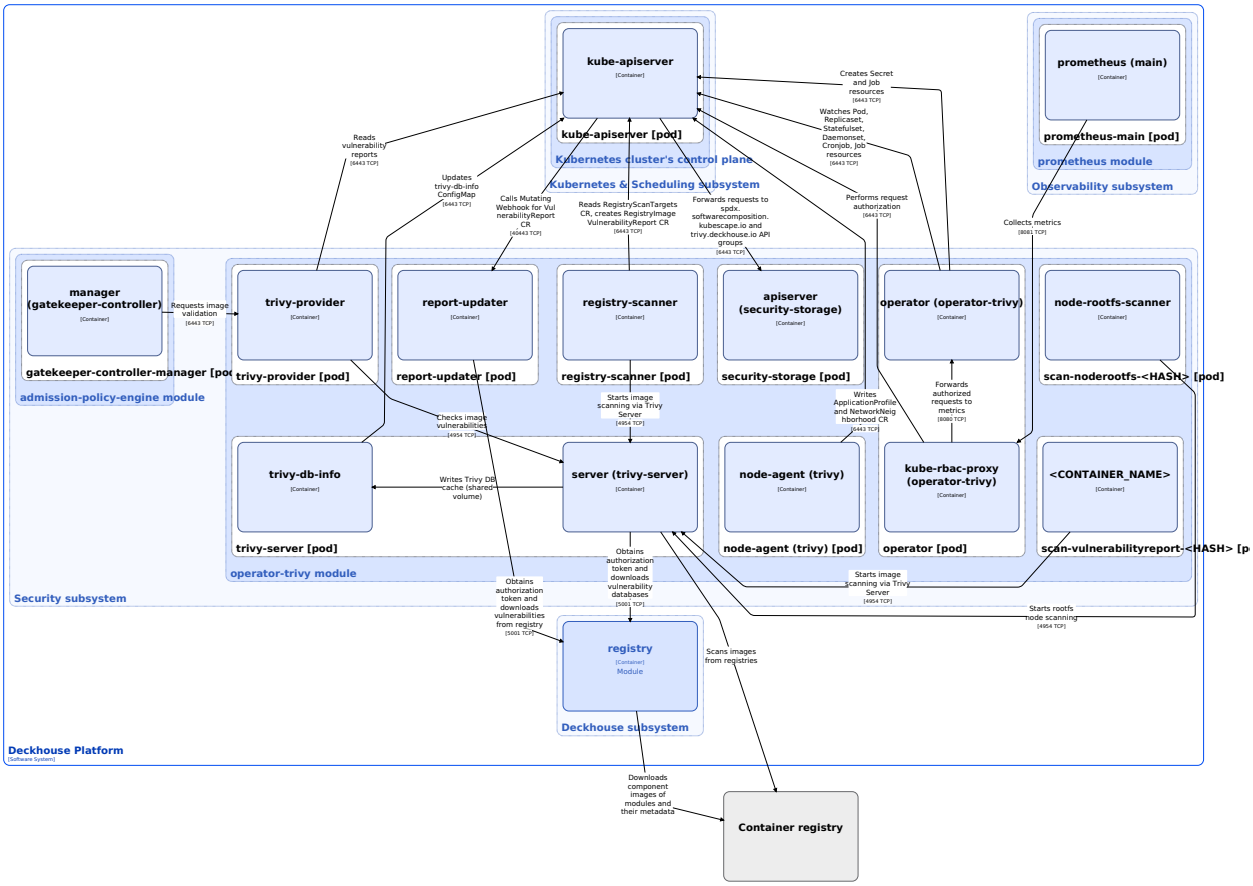
Additionally, the `operator-trivy` module can collect workload behavior models when the optional node-agent component is enabled.

The `operator-trivy` module works with custom resources from the `trivy.deckhouse.io` and `spdx.softwarecomposition.kubescape.io` API groups.

The `trivy.deckhouse.io` API group includes the following resources:

- ClusterComplianceReport: Stores an aggregated cluster compliance report for security requirements (for example, CIS Kubernetes Benchmark).
- ClusterConfigAuditReport: Stores cluster-level audit results for Kubernetes object configuration.
- ClusterInfraAssessmentReport: Stores cluster-level Kubernetes infrastructure security assessment results.
- ClusterRbacAssessmentReport: Stores cluster-level role-based access control (RBAC) settings assessment results.
- ClusterSbomReport: Stores an aggregated cluster-level SBOM (Software Bill of Materials) for software components.
- ClusterVulnerabilityReport: Stores aggregated cluster-level vulnerability scanning results.
- ConfigAuditReport: Stores audit results for Kubernetes object configuration.
- ExposedSecretReport: Stores results of searching for potential secrets in container images.
- InfraAssessmentReport: Stores security assessment results for Kubernetes infrastructure objects.
- NodeVulnerabilityReport: Stores vulnerability scanning results for node `rootfs` (the root filesystem).
- RbacAssessmentReport: Stores RBAC settings assessment results for excessive privileges and other risks.
- RegistryImageVulnerabilityReport: Stores CVE scanning results for a specific image tag in a registry.
- RegistryScanTarget: Defines a target registry, repositories, and periodic scanning parameters.
- SbomReport: Stores an SBOM, that is, the software and dependency composition of a container image.
- VulnerabilityReport: Stores vulnerability scanning results for container images.

The `spdx.softwarecomposition.kubescape.io` API group includes the following resources:



- ApplicationProfiles: Stores an application behavior profile at runtime (system calls, executed processes, file access, HTTP endpoints).
- CollapseConfigurations: Defines dynamic path, endpoint, and network address aggregation parameters to reduce runtime profile size.
- ConfigurationScanSummaries: Stores a summary of configuration scan results for a workload group within a specified scope (for example, a namespace).
- ContainerProfiles: Stores an individual container profile, including runtime behavior and network interactions.
- GeneratedNetworkPolicies: Stores NetworkPolicy objects generated from observed traffic.
- KnownServers: Stores a catalog of known servers and IP address ranges to enrich generated network policies.
- NetworkNeighborhoods: Stores an observed map of incoming and outgoing workload network interactions.
- OpenVulnerabilityExchangeContainers: Stores OpenVEX documents with vulnerability statuses for components.
- SbomSyftFiltereds: Stores a filtered Syft SBOM with only relevant vulnerable components.
- SbomSyfts: Stores SBOM in Syft format.
- SeccompProfiles: Stores container seccomp profiles (allowed system calls and filtering rules).
- VulnerabilityManifestSummaries: Stores VulnerabilityManifest summaries by severity level with links to related objects.
- VulnerabilityManifests: Stores a detailed manifest of discovered vulnerabilities.
- VulnerabilitySummaries: Stores an aggregated vulnerability summary for a specified scope.
- WorkloadConfigurationScans: Stores detailed configuration scan results for a specific workload.
- WorkloadConfigurationScanSummaries: Stores a summary of WorkloadConfigurationScan results.

For more details, see the module documentation section.

Module architecture

> The following assumptions are made to simplify the diagram:
>
> - The diagram shows direct interaction between containers from different pods. In practice, they communicate through corresponding Kubernetes Services (internal load balancers). Service names are omitted when they are clear from context. In other cases, the service name is shown above the arrow.
> - Pods can run with multiple replicas, but all pods are shown as a single replica in the diagram.

The level 2 C4 architecture of the `operator-trivy` module and its interactions with other Deckhouse Platform (DP) components are shown in the following diagram:

Module components

The module consists of the following components:

1. **Operator** (Deployment): A component based on Trivy Operator that watches Pod, ReplicaSet, ReplicationController, StatefulSet, DaemonSet, CronJob, and Job resources, and starts a Job task for scanning when their specifications change.

   Operator analyzes Job execution results and generates the following reports as custom resources:

   - ClusterComplianceReport.
   - ClusterConfigAuditReport.
   - ClusterInfraAssessmentReport.
   - ClusterRbacAssessmentReport.
   - ClusterVulnerabilityReport.
   - ConfigAuditReport.
   - ExposedSecretReport.
   - InfraAssessmentReport.
   - NodeVulnerabilityReport.
   - RbacAssessmentReport.
   - SbomReport.
   - VulnerabilityReport.

   Includes the following containers:

   - **operator**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to controller metrics.

2. **Trivy-server** (StatefulSet): This component implements a security scanning service and is based on the Open Source Trivy project.

   Trivy-server updates its vulnerability database from an Open Container Initiative (OCI) image at startup and then periodically.

   Trivy-server processes requests from other module components (operator, registry-scanner, trivy-provider, and scanning tasks), performs the requested scan, and returns the result.

   Includes the following containers:

   - **server**: Main container.
   - **trivy-db-info**: Sidecar container that synchronizes Trivy cache metadata with the `trivy-db-info` ConfigMap resource in the `d8-operator-trivy` namespace.

3. **Trivy-provider** (StatefulSet): This component includes a single **trivy-provider** container and provides an image verification interface for the Gatekeeper component of the `admission-policy-engine` module.

   When the module is installed, a Provider resource is created to register trivy-provider as a provider in Gatekeeper. For details about the integration, see the relevant Gatekeeper documentation section.

The Deckhouse controller deploys this component if the `.settings.denyVulnerableImages.enabled` parameter of the ModuleConfig custom resource is set to `true` (default is `false`) and the Gatekeeper component of the `admission-policy-engine` module is enabled.

4. **Report-updater** (Deployment): An optional controller that includes a single **report-updater** container, implements a MutatingWebhook, and enriches the VulnerabilityReport custom resource with BDU identifiers. The BDU dictionary is regularly updated from an OCI image every six hours.

   The Deckhouse controller deploys this component if the `.settings.linkCVEtoBDU` parameter of the ModuleConfig custom resource is set to `true` (default is `false`).

5. **Registry-scanner** (StatefulSet): An optional component that includes a single **registry-scanner** container and regularly scans images located in arbitrary container registries specified by the user. Scanning of workloads in the cluster itself is performed by the operator component.

   The Deckhouse controller deploys this component if the `.settings.registryScanning.enabled` parameter of the ModuleConfig custom resource is set to `true` (default is `false`).

   Registry-scanner reads RegistryScanTarget custom resources, runs image scans through the trivy-server component, and stores processed results in the RegistryImageVulnerabilityReport custom resource.

6. **Security-storage** (Deployment): A controller that includes a single **apiserver** container, extends Kubernetes API, and processes requests for custom resources from the `trivy.deckhouse.io` and `spdx.softwarecomposition.kubescape.io` API groups.

   Security-storage also implements the backend for storing these resources:

   - Metadata is stored in an SQLite database.
   - Object body is stored in gob format in the `/data` directory.

7. **Node-agent** (DaemonSet): An optional component with a single **node-agent** container that runs on all cluster nodes in privileged mode, observes container behavior by using eBPF programs, and builds runtime profiles.

   Node-agent stores runtime profiles in ApplicationProfile and NetworkNeighborhood custom resources (in the security-storage component). For details about node-agent behavior, see the module documentation section.

   > ⚠ The node-agent component has privileged access to the operating system of each node. In Linux, this requires the following capabilities:
   >
   > - SYS_ADMIN
   > - SYS_PTRACE
   > - NET_ADMIN
   > - SYSLOG
   > - SYS_RESOURCE
   > - IPC_LOCK
   > - NET_RAW
   >
   > This is required to observe container behavior by using eBPF programs.
   >
   > Node-agent runs in profiling mode and does not perform active rule-based attack detection.

   The Deckhouse controller deploys this component if the `.settings.nodeAgent.enabled` parameter of the ModuleConfig custom resource is set to `true` (default is `false`).

8. **Scan-noderootfs-<HASH>** (Job): A component that includes a single **node-rootfs-scanner** container and implements a task to scan the node root filesystem (scan-noderootfs). The task is created and managed by the operator component.

9. **Scan-vulnerabilityreport-<HASH>** (Job): A component that launches tasks for security scanning of Pod, ReplicaSet, ReplicationController, StatefulSet, DaemonSet, CronJob, and Job resources by using the trivy-server component. The task is created and managed by the `operator` component.

   Consists of a set of **<CONTAINER_NAME>** containers, each responsible for scanning the corresponding workload container. Their base image is Trivy with an added trivy-wrapper. The target container image from the workload specification is passed in arguments. Trivy-wrapper authenticates to the registry storage by using the `trivy registry login` command and then hands control over to Trivy.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Authorizes requests to operator metrics.
   - Works with custom resources from the `trivy.deckhouse.io` API group.
   - Works with RegistryScanTarget and RegistryImageVulnerabilityReport custom resources.
   - Watches Pod, ReplicaSet, ReplicationController, StatefulSet, DaemonSet, CronJob, and Job resources.
   - Creates, updates, and deletes Secret, ConfigMap, and Job resources.
2. **Registry**: Pulls OCI images with the vulnerability database and the BDU database.
3. **Container registry**: Scanning images.

The following external components interact with the module:

1. **Kube-apiserver**:

    - Forwards API requests for custom resources from the `trivy.deckhouse.io` and `spdx.softwarecomposition.kubescape.io` API groups.
    - Mutates VulnerabilityReport custom resources.

2. **Prometheus-main**: Collects module metrics.

Additional resources

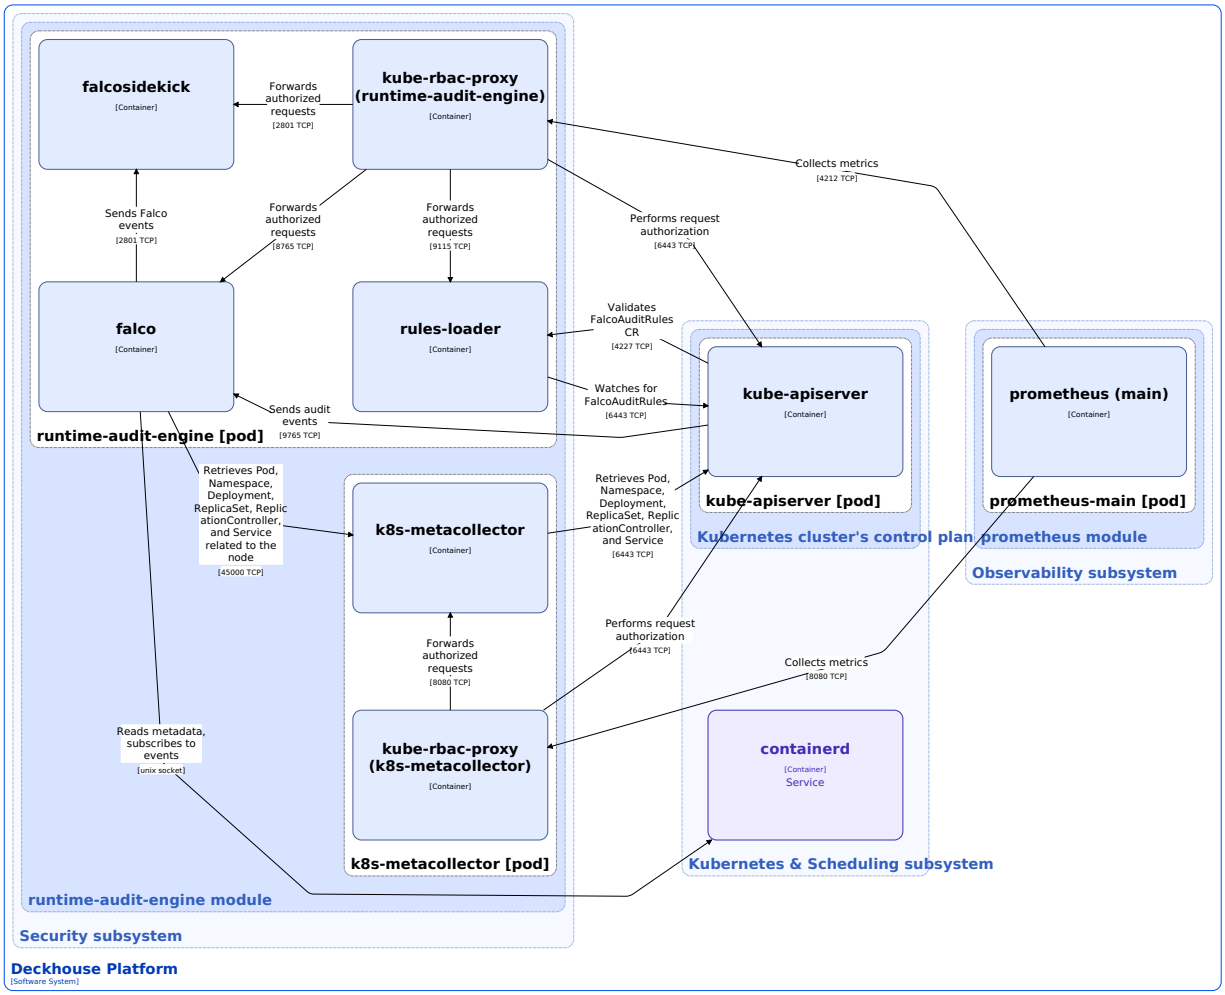
Runtime-audit-engine module



The `runtime-audit-engine` module implements runtime auditing in Deckhouse Platform (DP) based on the Falco threat detection system. The module collects Linux kernel events and Kubernetes API audit events (using the `k8saudit` plugin), enriches them with Kubernetes Pod metadata, and generates security events according to configured rules. Audit rules are defined using the FalcoAuditRules custom resource.

When the module is enabled, the `control-plane-configurator` ConfigMap is created in the `d8-runtime-audit-engine` namespace with the audit webhook URL and CA. The `control-plane-manager` module detects this ConfigMap and configures the control plane to send Kubernetes API audit events to the `runtime-audit-engine` module.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `runtime-audit-engine` module and its interactions with other DP components are shown in the following diagram:

Module components

The `runtime-audit-engine` module consists of the following components:

1. **Runtime-audit-engine** (DaemonSet): A component deployed on each cluster node. It collects audit events, evaluates rules, outputs triggered rules to stdout, and exports them as Prometheus metrics. Data is received from the Linux kernel via interception of system calls (syscalls) and from `containerd` via a Unix socket.

   The component includes the following containers:

   - **falco**: Main container that collects security events from cluster nodes and containerized applications in DP based on the Falco threat detection system.
   - **falcosidekick**: Sidecar container that receives events from the `falco` component and exports audit events as Prometheus metrics.
   - **rules-loader**: Sidecar container that performs the following operations:
     - Watches FalcoAuditRules custom resources and stores them in the shared `/etc/falco/rules.d/` Pod directory for processing by the `falco` component.
     - Validates the FalcoAuditRules custom resource.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC (Role-Based Access Control) that provides secure access to component metrics.

   > ⚠ The `falco` container has privileged access to each node operating system. The container security context includes the `BPF`, `SYS_RESOURCE`, `PERFMON`, `SYS_PTRACE`, and `SYS_ADMIN` capabilities.

2. **K8s-metacollector** (Deployment): A component that proxies requests to `kube-apiserver` to reduce control plane load. It also reduces the amount of metadata passed to `falco` by keeping only node-related data. K8s-metacollector collects metadata from `kube-apiserver` about Pod, Namespace, Deployment, ReplicaSet, ReplicationController, and Service resources.

   The component includes the following containers:

   - **k8s-metacollector**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to k8s-metacollector metrics.

Module interactions

The `runtime-audit-engine` module interacts with the following components:

1. **Kube-apiserver**:

    - Manages FalcoAuditRules custom resources.
    - Monitors Pod, Namespace, Deployment, ReplicaSet, ReplicationController, and Service resources.
    - Authorizes module component requests.

2. **Containerd**:

    - Provides container metadata.
    - Provides `containerd` events.

3. **Linux kernel**: Intercepts Linux kernel system calls (syscalls) in real time.

The following external components interact with the module:

1. **Kube-apiserver**:

    - Sends webhook requests to validate the FalcoAuditRules custom resource.
    - Sends audit events.

2. **Prometheus-main**: Collects module metrics.

Secrets-store-integration module

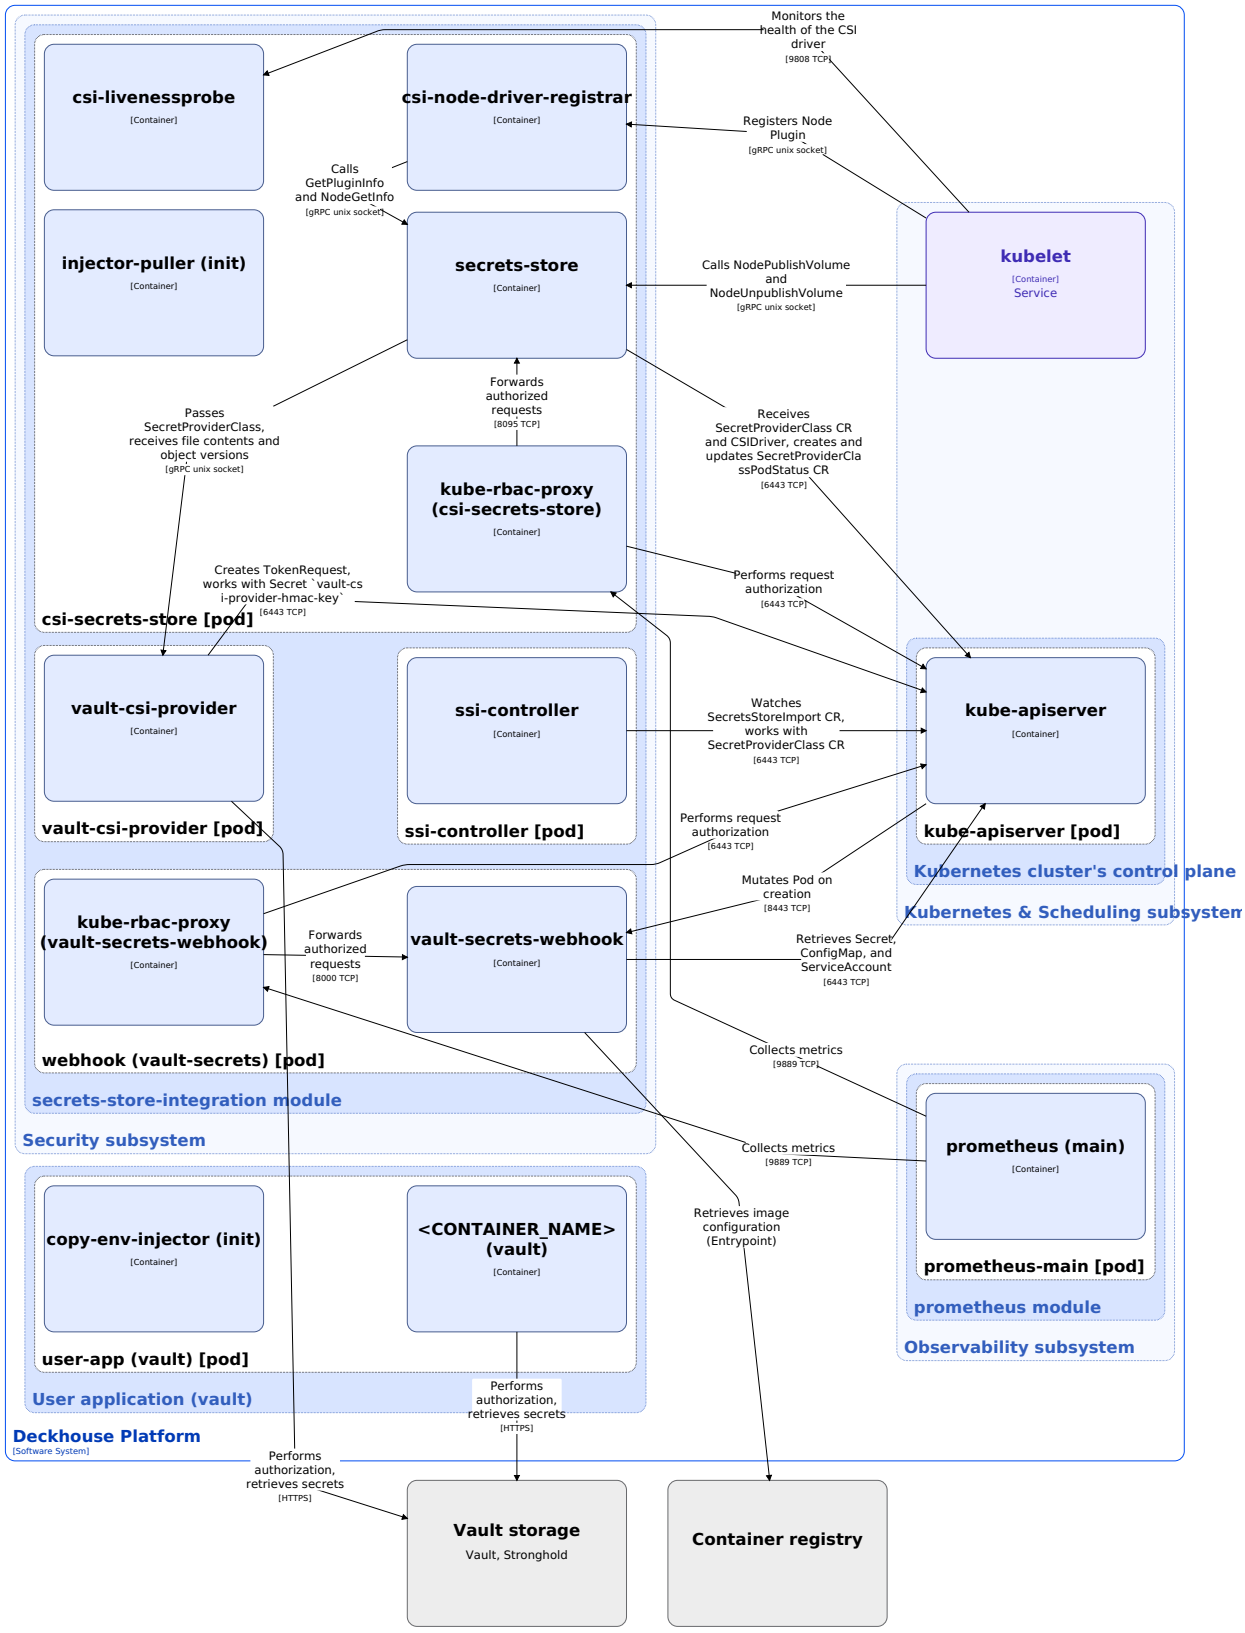
The `secrets-store-integration` module delivers secrets to applications in Deckhouse Platform (DP) from an external store compatible with the HashiCorp Vault API.

The module provides the following capabilities:

- Delivers secrets to pods as mounted files or environment variables without storing them in etcd.
- Automatically connects to an internal Deckhouse Stronghold instance without manual configuration (`DiscoverLocalStronghold` mode).
- Works with any Vault-compatible secrets store in `Manual` mode.
- Automatically refreshes mounted secrets every two minutes when the value in the store changes.
- Injects an entrypoint for applications that cannot be modified to read secrets directly from the store.
- Delivers Base64-encoded binary secrets (for example, JKS keystores or Kerberos keytab files) with automatic decoding.

The operating mode (`Manual` or `DiscoverLocalStronghold`) is specified by the `settings.connectionConfiguration` parameter in the module settings.

The module works with the following custom resources:



- SecretProviderClass: Describes which secrets to deliver to a pod and from which external store. The resource specification also defines connection parameters for the secrets source and path mappings in the container.
- SecretProviderClassPodStatus: Contains the status of the secret mounting process in a pod and diagnostic information.
- SecretsStoreImport: Stores the mapping of secrets between a Vault-compatible store and files in containers.

For more details about the module, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `secrets-store-integration` module and its interactions with other DP components are shown in the following diagram:

Module components

The `secrets-store-integration` module consists of the following components:

1. **Csi-secrets-store** (DaemonSet): Runs on all cluster nodes and implements the Container Storage Interface (CSI) standard to deliver secrets to a pod as mounted files.

   Csi-secrets-store performs the following actions:

   - Registers the ephemeral CSI driver `secrets-store.csi.deckhouse.io` in kubelet.
   - Interacts with vault-csi-provider to retrieve data from the secrets store.
   - Mounts secrets as files in a pod.
   - Rotates secrets.
   - Watches the Pod and CSIDriver resources and the SecretProviderClass custom resource.
   - Works with the SecretProviderClassPodStatus custom resource.

The component includes the following containers:

- **injector-puller**: Init container that performs a one-time launch of the injector binary (an executable that securely injects secrets from an external store into the application environment inside the pod) from the `secrets-store-integration/env-injector` service image. This one-time launch is necessary to preload the image onto every cluster node. The webhook component uses this image to deliver secrets to user applications as environment variables.
- **csi-node-driver-registrar**: Sidecar container that registers the CSI Node Plugin in kubelet. Calls the `GetPluginInfo` and `NodeGetInfo` RPCs in the secrets-store container to get plugin and node information.
- **secrets-store**: Main container.
- **csi-livenessprobe**: Sidecar container that monitors the CSI driver Unix socket and exposes the `/healthz` HTTP endpoint monitored by kubelet. If the `livenessProbe` check fails, kubelet restarts the csi-secrets-store pod.
- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to secrets-store container metrics.

2. **Vault-csi-provider** (DaemonSet): Runs on all cluster nodes and consists of a single **vault-csi-provider** container. Vault-csi-provider authenticates with the secrets store, retrieves data from it, and passes the data to csi-secrets-store.
3. **Ssi-controller** (Deployment): Consists of a single **ssi-controller** container. The controller watches SecretsStoreImport custom resources and creates SecretProviderClass custom resources based on them.
4. **Webhook** (Deployment): Implements mutating webhooks for Pod resources using Mutating Admission Controllers.

   The component mutates a pod if the pod has the `secrets-store.deckhouse.io/role` annotation. In this case, the component makes the following modifications to the pod manifest:

   - Adds an init container that copies a statically built injector binary from the `secrets-store-integration/env-injector` service image into a temporary directory shared by all containers in the pod.
   - If the pod manifest has the `secrets-store.deckhouse.io/env-from-path` annotation or a container uses secrets from the secrets store, then for each such container, including init containers, the component replaces the original startup command with a command that starts the injector binary.

     The injector receives the original startup command as an argument. If the container in the pod manifest has no startup command, the component retrieves the startup command from the image in the container registry.

   The component includes the following containers:

   - **vault-secrets-webhook**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to vault-secrets-webhook container metrics.

The following components are not part of the module, but the module affects them:

- **User-app**: Represents a typical user application that needs secrets delivered as environment variables.

  The component includes the following containers:

  - **copy-env-injector**: Init container added by the webhook component. It copies the injector binary from the `secrets-store-integration/env-injector` service image.
  - **<CONTAINER_NAME>**: One or more containers (including init containers) of the original user application whose startup command was changed by the webhook component to start the injector binary.

  The injector authenticates with the secrets store, retrieves data, passes secrets to the application as environment variables, and starts the original container command. If the `secrets-store.deckhouse.io/restart-on-secret-change` annotation is set to `watch-for-lease` or `watch-for-data`, the injector rotates secrets when they change in the store.

Module interactions

The `secrets-store-integration` module interacts with the following components:

1. **Kube-apiserver**:
   - Authorizes requests.
   - Retrieves CSIDriver, Secret, ConfigMap, and ServiceAccount.
   - Works with the SecretsStoreImport, SecretProviderClass, and SecretProviderClassPodStatus custom resources.
2. **Container registry**: Retrieves the startup command from the user container image.
3. **Secrets store**: Authorizes requests and retrieves secrets.

The following external components interact with the module:

1. **Kube-apiserver**: Invokes the mutating webhook when a Pod resource is created.
2. **Kubelet**:
   - Registers the Node Plugin.
   - Checks the CSI driver `livenessProbe`.
   - Calls the `NodePublishVolume` and `NodeUnpublishVolume` RPCs in the Node Plugin.
3. **Prometheus-main**: Collects metrics from the csi-secrets-store and webhook components.

Additional resources

- Module `secrets-store-integration` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Network subsystem

This subsection describes the architecture of the Network subsystem of Deckhouse Platform (DP).

The Network subsystem includes the following modules:

- `kube-dns`: Installs CoreDNS components for DNS management in the Kubernetes cluster.
- `node-local-dns`: Deploys a caching DNS server on each cluster node and exports DNS metrics to Prometheus for analyzing DNS operation in the cluster on the Grafana dashboard.
- `kube-proxy`: Manages the kube-proxy components responsible for networking and load balancing within the cluster.
- `cni-cilium`: Provides cluster networking using the CNI Cilium plugin.
- `cni-flannel`: Provides a network between multiple nodes in a cluster using the Flannel project.
- `cni-simple-bridge`: Provides basic networking for pods, with limited functionality compared to the platform's other CNI modules.
- `cilium-hubble`: Provides visualization of the cluster network stack if the Cilium CNI is enabled.
- `ingress-nginx`: Installs and manages the Ingress NGINX Controller using custom resources.
- `metallb`: Implements the LoadBalancer mechanism for Services in bare-metal clusters.
- `istio`: Implements a Service Mesh based on Istio for centralized management of network traffic in the cluster.
- `alb`: Implements an Application Load Balancer (ALB) based on the Kubernetes Gateway API.
- `sdn`: Provides software-defined networking (SDN) functions in the cluster — node network interface configuration, additional networks for pods and VMs, underlay networks, and system networks.
- `service-with-healthchecks`: Provides an internal load balancer with independent health checks for each port, unlike the standard Kubernetes Service load balancer.
- `static-routing-manager`: Manages static routes and `ip rule` entries on cluster nodes.

The subsection also describes:

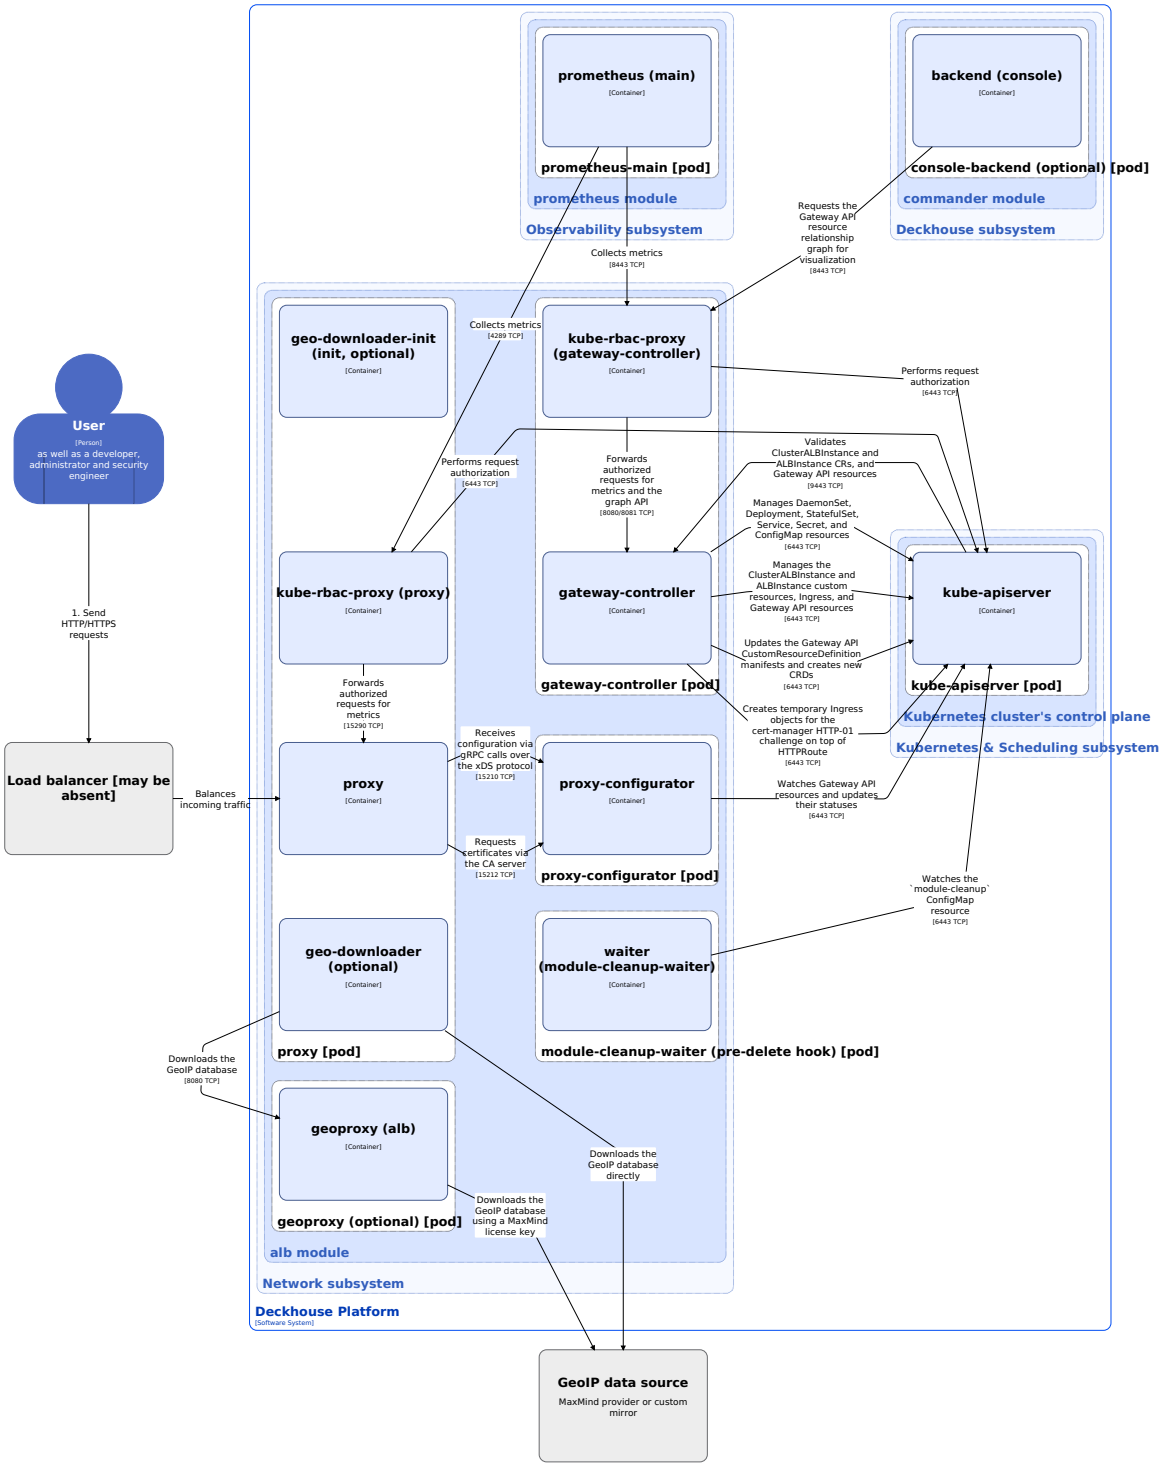
- Cluster architecture with Istio enabled
- Application service architecture with Istio enabled

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Alb module

The `alb` module implements an application load balancer (ALB, Application Load Balancer) in Deckhouse Platform (DP) and lets you publish applications using the Kubernetes Gateway API. It deploys and configures the infrastructure for accepting and routing external requests, and validates the user's Gateway API configuration. ALB is based on the Envoy Open Source project.

The module works with the following custom resources of the `network.deckhouse.io` API group:



- ClusterALBInstance: Defines a cluster-wide ALB (data plane) instance, used for shared or platform-level Gateways.
- ALBInstance: Defines an ALB instance within a user namespace, used for application- or project-level Gateways.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `alb` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Gateway-controller** (Deployment): the module's central controller, which performs the following actions:
   - Manages the ClusterALBInstance and ALBInstance custom resources.
   - Installs Gateway API CRDs (the `gateway.networking.k8s.io` API group).
   - Implements the Gateway API controller for the `d8-alb` GatewayClass and creates a Gateway for every instance.
   - Validates the ClusterALBInstance and ALBInstance custom resources and the `gateway.networking.k8s.io` API group resources using the Validating Admission Controllers mechanism.
   - Creates temporary Ingress objects for the cert-manager HTTP-01 challenge on top of HTTPRoute when migrating from `ingress-nginx`.
   - Creates and removes the proxy and geoproxy components for every ClusterALBInstance/ALBInstance.
   - Provides a Graph API interface for retrieving the Gateway API resource relationship graph, used by the console module.

   It consists of the following containers:

   - **gateway-controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to gateway-controller metrics and the graph API.

2. **Proxy-configurator** (Deployment): the Gateway API control-plane component, built from Istio Pilot (istiod) configured to work with Gateway API only (sidecar injection and istiod's built-in Gateway API infrastructure-provisioning mechanism are disabled).

   The component provides the following capabilities:

   - Implements the traffic management control plane.
   - Builds and validates the Envoy proxy configuration based on Gateway, HTTPRoute, GRPCRoute, TCPRoute, UDPRoute, TLSRoute, and ListenerSet resources.
   - Issues and renews certificates for the Envoy proxies using a built-in CA server.
   - Distributes the Envoy proxy configuration to the proxy components using the xDS protocol (a family of standardized API protocols for dynamically configuring data-plane components).
   - Updates the status of Gateway, HTTPRoute, GRPCRoute, TCPRoute, UDPRoute, TLSRoute, and ListenerSet resources.

   It consists of a single **proxy-configurator** container.

3. **Proxy** (Deployment or DaemonSet): an Envoy instance that implements the traffic management data plane, accepting and routing external traffic according to configuration received from proxy-configurator over the xDS protocol.

   The gateway-controller creates this component dynamically (not via a Helm template) for every ClusterALBInstance or ALBInstance custom resource. The workload kind depends on the resource type: a ClusterALBInstance is deployed as a DaemonSet, an ALBInstance as a Deployment behind a Service.

   It consists of the following containers:

   - **geo-downloader-init**: Optional init container that downloads the GeoIP database before Envoy starts.
   - **geo-downloader**: Optional sidecar container that periodically refreshes the local copy of the GeoIP database.
   - **proxy**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to the main container's metrics.

   The gateway-controller adds the first two containers only if the `spec.geoIP` parameter is set on the ClusterALBInstance/ALBInstance resource.

4. **Geoproxy** (StatefulSet): a caching proxy server for the proxy component that provides fast access to the GeoIP database downloaded from the MaxMind provider. The component also provides access to already-downloaded databases in clusters without internet access, which improves the stability of the Gateway API controller's work with GeoIP databases.

   The component provides the following benefits:

   - Saves MaxMind licenses (databases are downloaded from a single point once a day).
   - Persistent data storage (restarting components does not cause repeated requests to MaxMind servers).
   - The ability to specify your own mirror for downloading the databases.

   The gateway-controller creates this component programmatically for every ClusterALBInstance/ALBInstance, only if the `spec.geoIP.licenseKeySecretRef` parameter — a reference to the Secret holding the MaxMind license key — is set on the resource.

   It consists of a single **geoproxy** container.

5. **Module-cleanup-waiter** (Job): a Helm `pre-delete` hook of the module, launched by the Deckhouse controller before the `alb` module is removed. It waits for the gateway-controller to finish cleaning up the module's resources, and only then allows the release removal to complete. It does not take part in the module's normal operation.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Installs resources of the `gateway.networking.k8s.io` API group.
   - Manages DaemonSet, Deployment, StatefulSet, Service, Secret, and ConfigMap resources.
   - Reads and updates Node and Namespace resources.
   - Manages the ClusterALBInstance and ALBInstance custom resources, Ingress resources, and Gateway API resources (the `gateway.networking.k8s.io` API group).
   - Authorizes requests for the gateway-controller component's metrics and graph API, and for the proxy component's metrics.

2. **GeoIP data source** (MaxMind provider or mirror): Downloads the GeoIP database.

The following external components interact with the module:

1. **Kube-apiserver**: Validates the ClusterALBInstance and ALBInstance custom resources and Gateway API resources (the `gateway.networking.k8s.io` API group).
2. **Prometheus-main**: Collects metrics from the gateway-controller and proxy components.
3. **Load balancer**: Balances incoming traffic between instances of the proxy component.
4. **Deckhouse web UI**: Requests the Gateway API resource relationship graph for visualization.

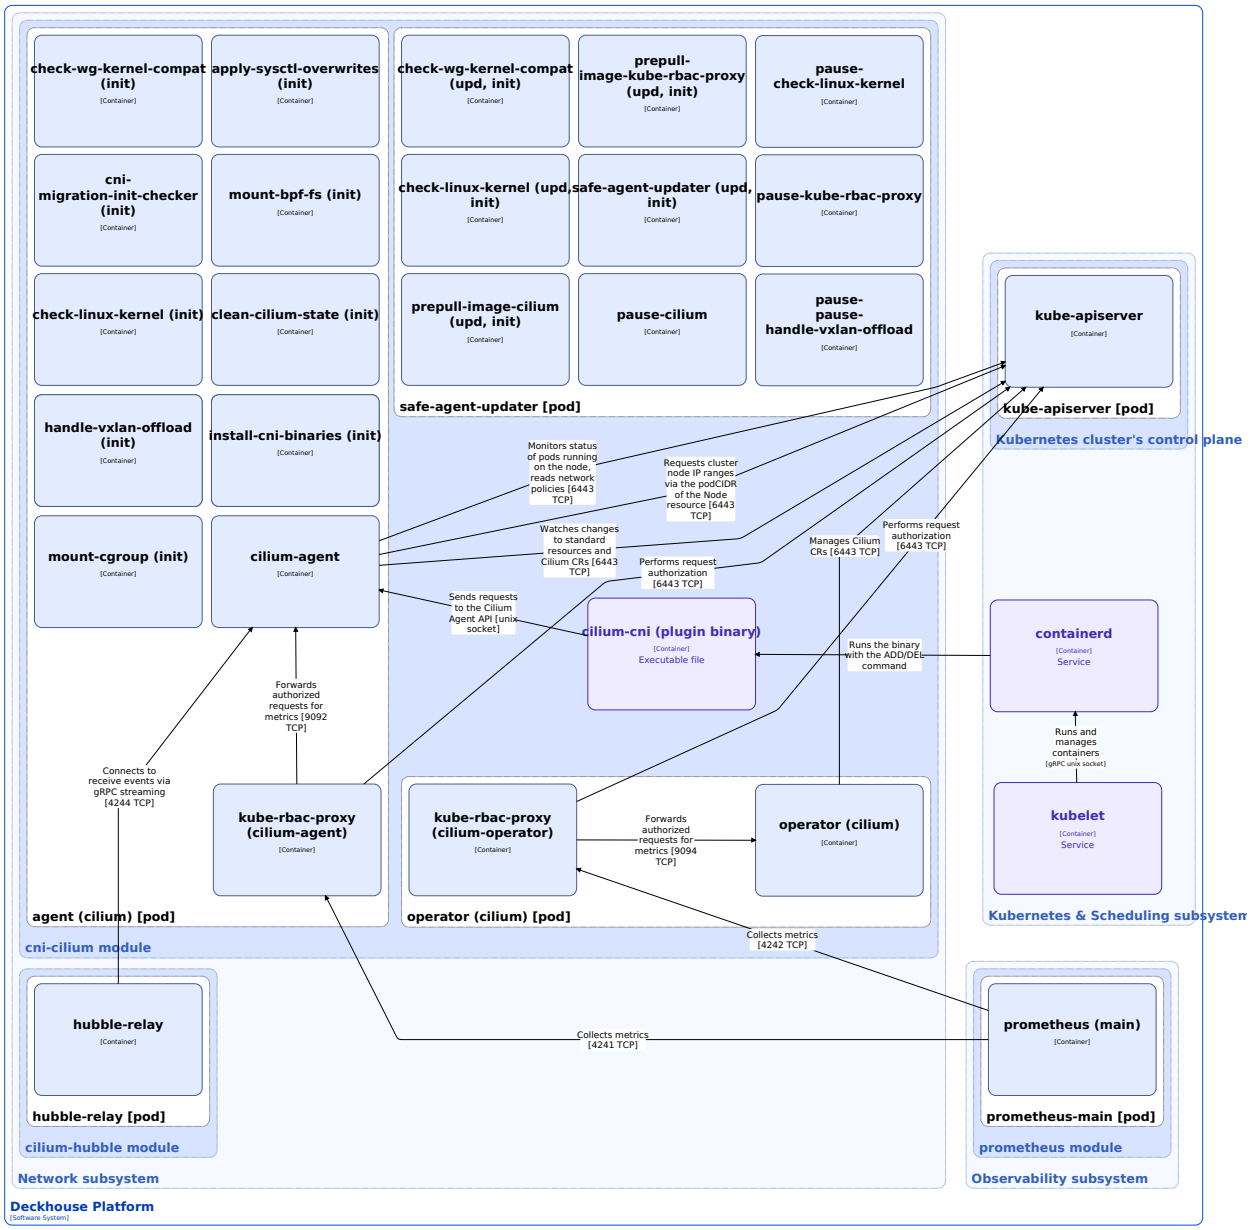
Cni-cilium module



The `cni-cilium` module provides a network in a cluster. It is based on the Cilium project.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cni-cilium` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Operator** (Deployment): A component in the Cilium architecture that takes over the centralized management of global tasks in a Kubernetes cluster. Operator component performs the following functions:

   - **Custom resources management**: Automatically registers the Custom Resource Definitions (CRD) required for Cilium operation in the Kubernetes API, for example, CiliumEndpoint, CiliumEndpointSlice, CiliumNetworkPolicy. The full list of CRDs can be found in the Cilium documentation.
   - **Garbage collection for security identifiers**: Maintains a local cache of active identifiers (CiliumIdentity) and periodically scans it, deleting records about identifiers that have stopped signaling activity (heartbeat). This is important because identifiers are represented by a 16-bit integer, and running out of them (maximum 65536) can lead to problems.
   - **CiliumEndpointSlices (CES) Management**: Maintains up-to-date information about endpoints in the cluster, which is critical for the correct operation of network policies and load balancing.

   It consists of the following containers:

   - **operator**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to operator metrics. It is an open source project.

2. **Agent** (DaemonSet): Agent running on each node of the Kubernetes cluster. It is the main management component in the Cilium architecture. It is responsible for translating high-level configurations from the Kubernetes API into low-level settings for network interfaces and eBPF programs that actually handle traffic. Agent component performs the following functions:

   - **Endpoints management**: Monitors the status of all endpoints on its node. Each pod is assigned a unique IP

address and a security identity (numeric identifier), which is generated based on Kubernetes labels.

- **Network policies enforcement**: Calculates and applies network policies rules set in the cluster. Cilium uses the identity-based policies concept: the rules are based not on IP addresses, but on the security identity of the pod. The agent converts these rules into data structures (BPF maps) that the Linux kernel uses to filter traffic.
- **IP Address Management (IPAM)**: Allocates IP addresses for pods scheduled on its node using IP address ranges from the `spec.podCIDRs` or `spec.PodCidr` fields of the specification of the corresponding Node resource.
- **Datapath Orchestration**: Compiles, loads eBPF programs into the Linux kernel and binds them to network interfaces. It is these programs in the kernel that perform real packet processing: forwarding, policy filtering, connection tracking, NAT and load balancing.
- **Service Load Balancing**: Configures load balancing rules for services in a cluster using eBPF capabilities.
- **Cluster event handling**: The Agent works according to the event model: it constantly monitors changes in the Kubernetes API (creating pods, updating services, changing Endpoints, updating custom resources) and updates the configuration of eBPF programs on the fly.
- **Oservability**: The agent runs a local Hubble server (embedded in the agent process), which collects metrics and data on network flows. This allows you to monitor the network status, identify problems, and analyze traffic between pods. The Hubble server starts when the `cilium-hubble` module is enabled. The hubble-relay component of the `cilium-hubble` module connects to Cilium agents to receive events via a gRPC streaming.

How it works: when an event occurs in the cluster (for example, a new pod starts), the agent receives a notification about it and, based on the current cluster status and policies, configures eBPF programs so that traffic for this pod passes correctly.

It consists of the following containers:

- **cni-migration-init-checker**: Init container waiting for the migration process from another CNI plugin to complete, if such a migration has been started.
- **check-wg-kernel-compat**: Init container checking the Linux kernel version for compliance with the minimum requirements for working with WireGuard used in CNI Cilium.
- **check-linux-kernel**: Init container checking the Linux kernel version for compliance with the minimum requirements for working with CNI Cilium.
- **clearing-unnecessary-iptables**: Init container running script for cleaning up unnecessary `iptables` rules.
- **handle-vxlan-offload**: Init container correcting UDP segmentation settings (if tunnel mode is set to `VXLAN`).
- **config**: Init container generating configuration file used to configure the agent.
- **mount-cgroup**: Init container configuring Linux cgroups (control groups).
- **apply-sysctl-overwrites**: Init container configuring the Linux kernel parameters.
- **mount-bpf-fs**: Init container mounting the BPF file system.
- **clean-cilium-state**: Init container running a script for clearing the CNI Cilium state.
- **install-cni-binaries**: Init container running a script for installing binary files used by the Agent.
- **agent**: Main container.
- **kube-rbac-proxy**: Sidecar container providing authorized access to agent metrics (described above).

3. **Cilium-cni**: Executable file run by the containerd component that passes certain commands as an argument in accordance with the CNI specification, for example, ADD when starting the container and DEL when deleting it. Cilium-cni executable interacts with the Cilium agent API via a Unix socket and initiates a datapath configuration to provide network connectivity, load balancing, and network policies for pod. Datapath in Cilium is a component that runs in the Linux kernel and is responsible for real low-level processing of network packets in a Kubernetes cluster. Simply put, this is the “road” along which data travels: how packets travel from one pod to another, how they are routed, how network policies and load balancing are applied.
4. **Safe-agent-updater** (DaemonSet): A special application designed to eliminate disruptive situations that may occur when updating the version of the Cilium agent and lead to problems with the network availability of DP components.

   It consists of the following containers:

   - **check-wg-kernel-compat**: Init container checking the Linux kernel version for compliance with the minimum requirements for working with WireGuard used in CNI Cilium.
   - **check-linux-kernel**: Init container checking the Linux kernel version for compliance with the minimum requirements for working with CNI Cilium.
   - A set of init containers for prepulling new versions of images of the corresponding containers of the agent component:
     - **prepull-image-cilium**.
     - **prepull-image-kube-rbac-proxy**.
   - **safe-agent-updater**: Init container that compares the values of special annotations in the DaemonSet manifest of the updated Cilium agent with the values of the corresponding annotations in the metadata of the agent pod running on the node. In particular, the `safe-agent-updater-daemonset-generation` annotation stores the hash sum of the agent image. If the hash sums do not match, safe-agent-updater deletes the running pod and waits until the pod with the new agent version enters the `Ready` state.
   - A set of sidecar containers for prepulling new versions of images of the corresponding containers of the agent component. Containers are on pause and perform only the function of storing images:
     - **pause-cilium**.
     - **pause-check-linux-kernel**.
     - **pause-kube-rbac-proxy**.
     - **pause-pause-handle-vxlan-offload**.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Manages Cilium custom resources.
   - Watches changes to standard Kubernetes API resources and Cilium custom resources.
   - Monitors status of pods running on the node, reads network policies.
   - Requests the IP ranges of cluster nodes via the `PodCidr`/`podCIDRs` attributes of the Node resource specification.
   - Authorizes requests for agent and operator metrics.

The following external components interact with the module:

1. **Hubble-relay**: Connects to Cilium agents to receive events via gRPC streaming.
2. **Prometheus-main**: Collects metrics from agent and operator.
3. **Containerd**: Runs the cilium-cni executable file with certain commands according to the CNI specification, for example, ADD when starting the container and DEL when deleting it.

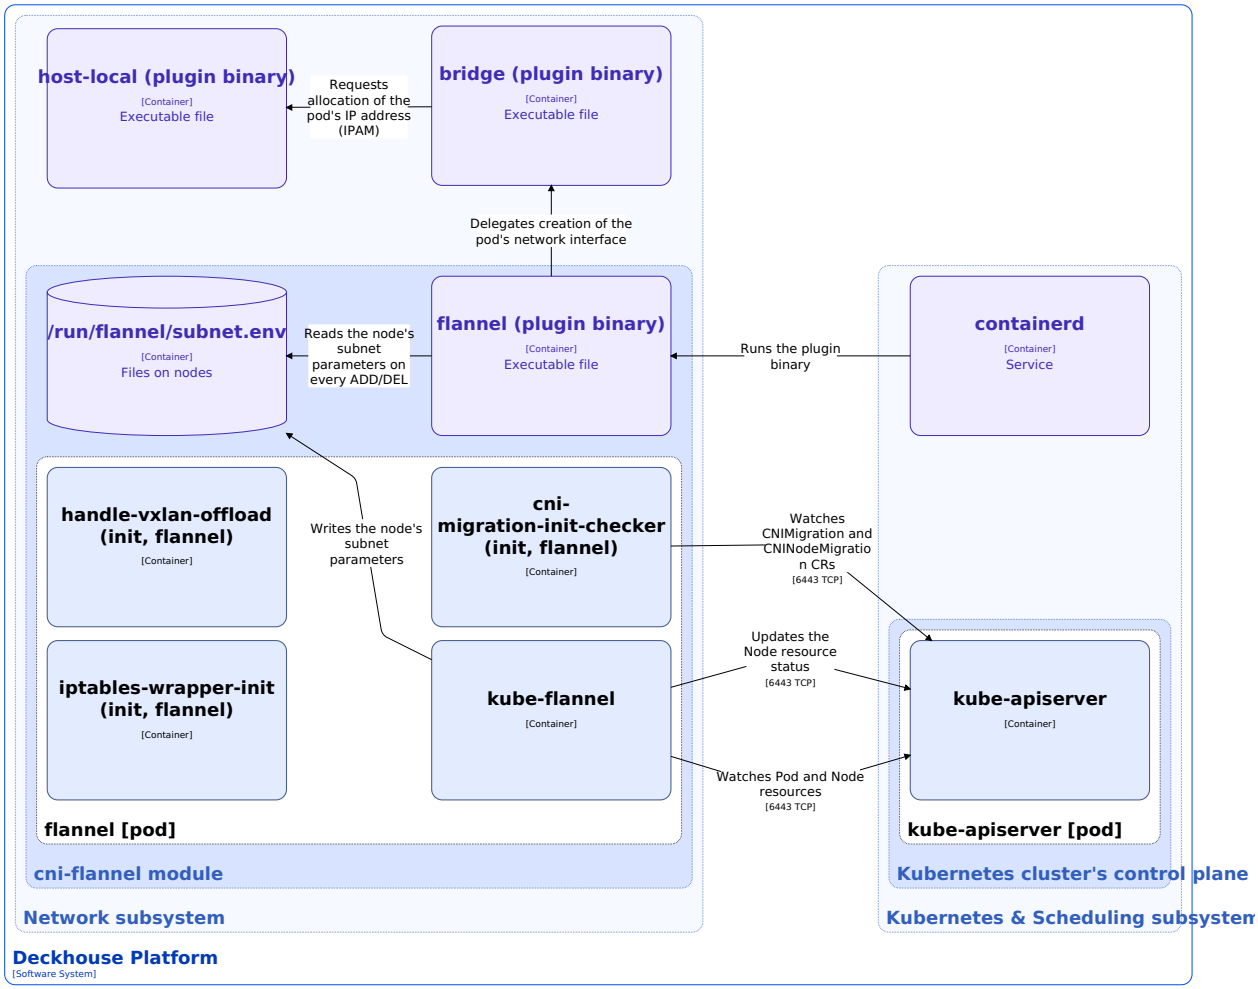
Cni-flannel module



The `cni-flannel` module provides a network between nodes in a Deckhouse Platform cluster. It is based on the Flannel project and implements the Container Network Interface (CNI).

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cni-flannel` module and its interactions with other components of platform are shown in the following diagram:

Module components

The module consists of the following components:

1. **Flannel** (DaemonSet): Runs on every cluster node and implements Flannel's Layer 3 overlay network between nodes.

   Depending on the `podNetworkMode` parameter, it uses the host-gw or VXLAN backend.

   The component takes the pod subnet from the `spec.podCIDR` field of the Node resource and writes the resulting subnet parameters (network, subnet, MTU) to the `/run/flannel/subnet.env` file on the node. The Flannel CNI plugin uses this file on every pod creation or removal.

   It consists of the following containers:

   - **cni-migration-init-checker**: Init container waiting for the migration process from another CNI plugin to complete, if such a migration has been started.
   - **iptables-wrapper-init**: Init container that prepares executables required for working with iptables.
   - **handle-vxlan-offload**: Optional init container that corrects UDP segmentation settings on the node's network interface. It is created by the Deckhouse controller if the `podNetworkMode` parameter is set to `VXLAN`.
   - **kube-flannel**: Main container.

2. **Flannel (CNI plugin)**: An executable file run by the containerd component according to the CNI specification, for example ADD when creating a pod's network namespace and DEL when removing it.

   On startup, the component reads the subnet parameters from the `/run/flannel/subnet.env` file and delegates creation of the pod's network interface to the `bridge` CNI plugin, which in turn requests an IP address from the `host-local` IP Address Management (IPAM) plugin. Both `bridge` and `host-local` are standard Open Source CNI plugins, installed on every cluster node independently of this module, as part of kubelet installation.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches CNIMigration and CNINodeMigration custom resources, and Pod and Node resources.
   - Updates the status of the Node resource.

2. **Bridge (CNI plugin)**: Creates the pod's network interface.

The following external components interact with the module:

1. **Containerd**: Runs the flannel executable file with certain commands according to the CNI specification, for example, ADD when creating a pod’s network namespace and DEL when removing it.

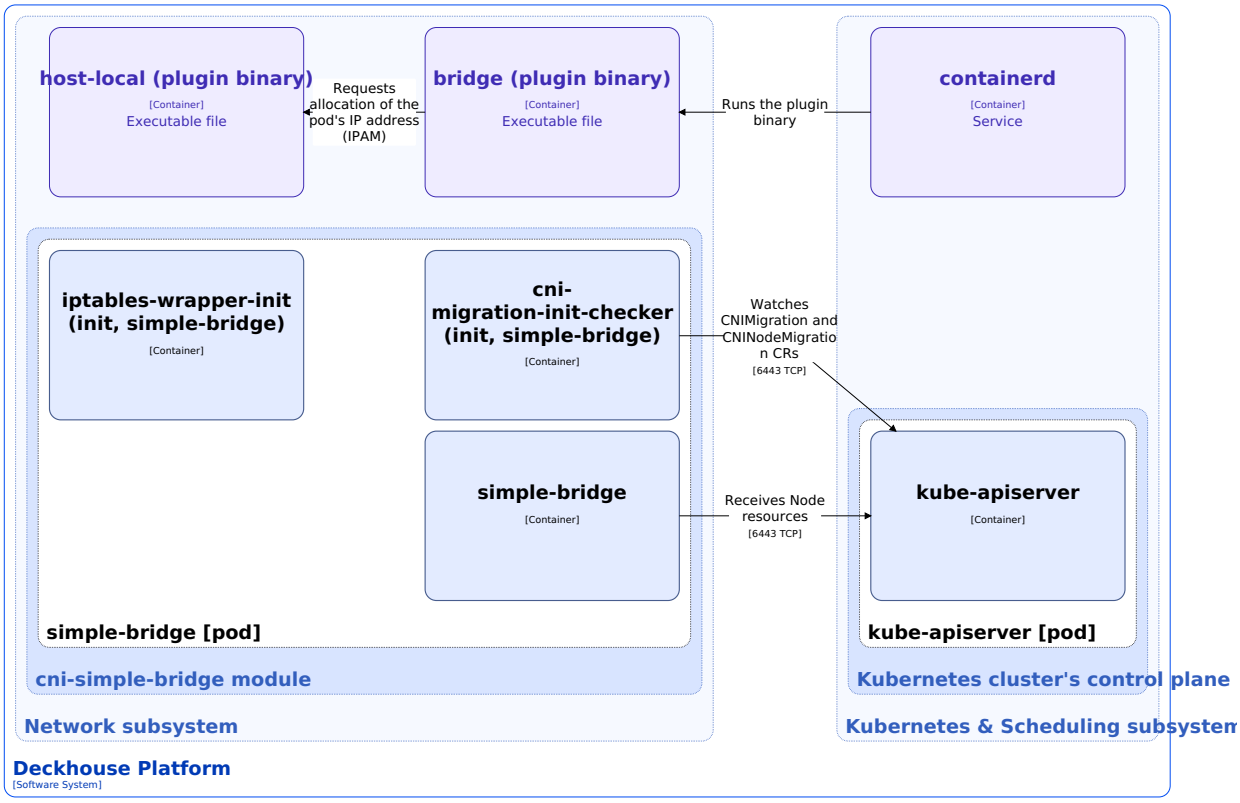
Additional resources

- Global custom resources
- Module `cni-flannel` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Cni-simple-bridge module

The `cni-simple-bridge` module provides basic networking for pods in Deckhouse Platform and implements the Container Network Interface (CNI).



> The `cni-simple-bridge` CNI plugin was used by default for the `cloud-provider-aws`, `cloud-provider-azure`, `cloud-provider-gcp`, and `cloud-provider-yandex` modules in Deckhouse platform versions earlier than 1.77.0. Starting with platform 1.77.0, these modules use Cilium CNI provided by the `cni-cilium` module by default.

The module has no configurable parameters.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cni-simple-bridge` module and its interactions with other components of Deckhouse Platform are shown in the following diagram:

Module components

The module consists of the following components:

1. **Simple-bridge** (DaemonSet): Runs on every cluster node and prepares the CNI plugin for operation. To do this, it obtains the pod subnet from the `spec.podCIDR` field of the Node resource and builds the configuration for running the `bridge` executable, which containerd invokes on every creation or removal of a pod's network namespace. When invoked, `bridge` requests an IP address from the `host-local` IP Address Management (IPAM) plugin.

   `bridge` and `host-local` are standard Open Source CNI plugins, installed on every cluster node independently of this module, as part of kubelet installation.

   It consists of the following containers:

   - **cni-migration-init-checker**: Init container waiting for the migration process from another CNI plugin to complete, if such a migration has been started.
   - **iptables-wrapper**: Init container that prepares executables required for working with iptables.
   - **simple-bridge**: Main container.

Module interactions

The module interacts with the **Kube-apiserver** component:

- Reads Node resources.
- Watches CNIMigration and CNINodeMigration custom resources.

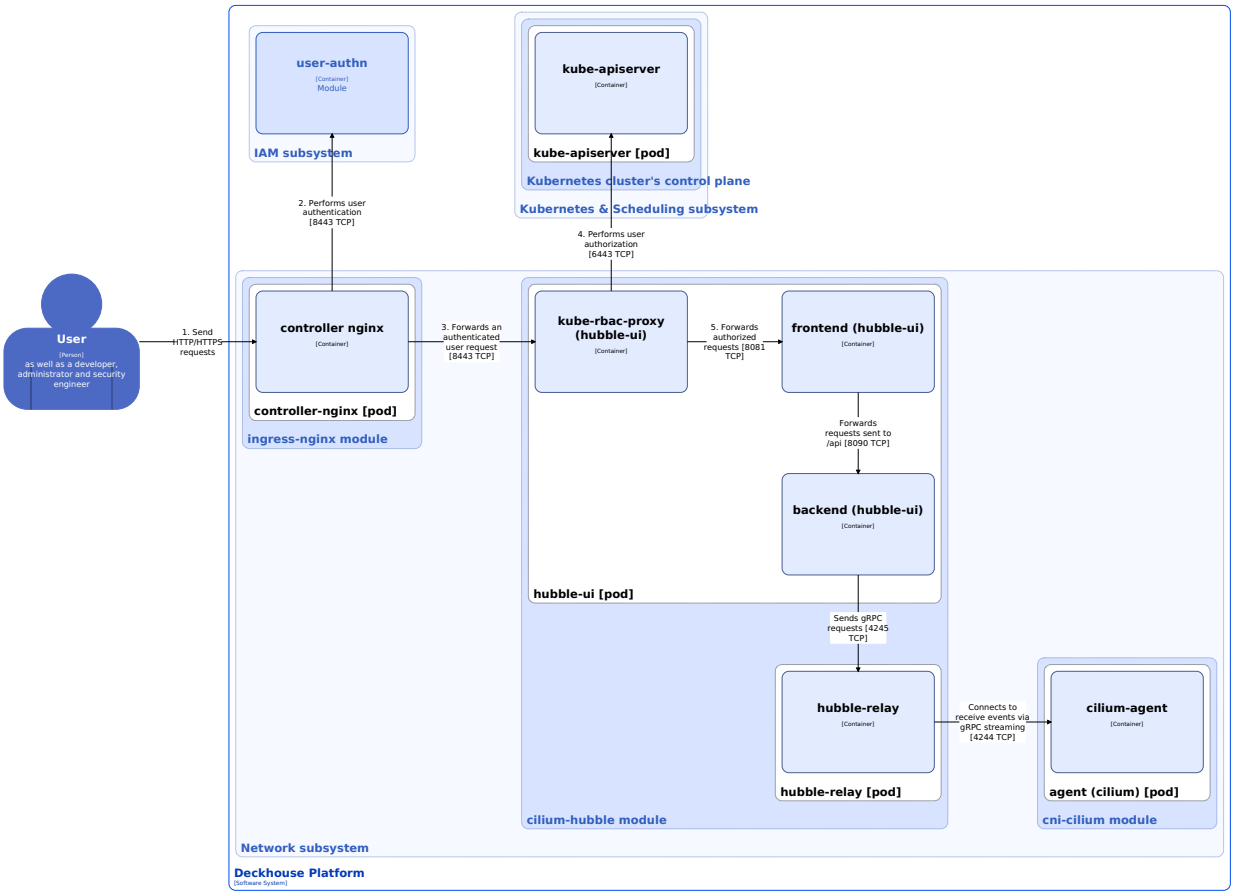
Cilium-hubble module



The `cilium-hubble` module provides visualization of the cluster network stack if the Cilium CNI is enabled.

For more details about module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `cilium-hubble` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

> **i** The numbers in the diagram indicate the sequence of steps that a user request goes through before reaching the hubble-ui component:
>
> - In steps 1, 2, and 3, the request passes through the Ingress NGINX Controller, where mandatory user authentication is performed using the `user-authn` module;
> - In steps 4 and 5, the user is authorized based on Kubernetes RBAC to provide secure access.

Module components

The module consists of the following components:

1. **Hubble-relay**: Component that aggregates events from all cluster nodes into a single view. Hubble-relay establishes a permanent connection to each Cilium Agent on the nodes and, through the gRPC stream, receives events, deduplicates them, and provides a single gRPC endpoint for the Hubble CLI and Hubble UI (web interface). While doing this, hubble-relay does not store history, it broadcasts an event stream in real time.

   It consists of a single container:

   - **hubble-relay**: Main container. It is a part of Cilium project.

2. **Hubble-ui**: Component that implements the web interface. Hubble-ui connects to hubble-relay and provides convenient access to data that comes from Cilium agents. Hubble-ui builds an interactive Service Map and a flow table with filters.

   It consists of the following containers:

   - **frontend**: Container that is an NGINX proxy server, which distributes static files of the hubble-ui web interface and forwards requests to the `/api` endpoint to the **backend** container of the component.
   - **backend**: Container implementing the hubble-ui API that sends requests to the hubble-relay component to receive in real time data coming from Cilium agents.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to Hubble UI. It is an open source project.

   Frontend and backend containers are built based on Hubble-UI, which is an Open Source project.

Module interactions

The module interacts with the following components:

1. **Cilium-agent**: Receives in real time an event stream from Cilium agents.
2. **Kube-apiserver**: Authorizes requests to Hubble UI.

The following external components interact with the module:

- **Controller nginx**: Forwards external user requests to the module web interface.

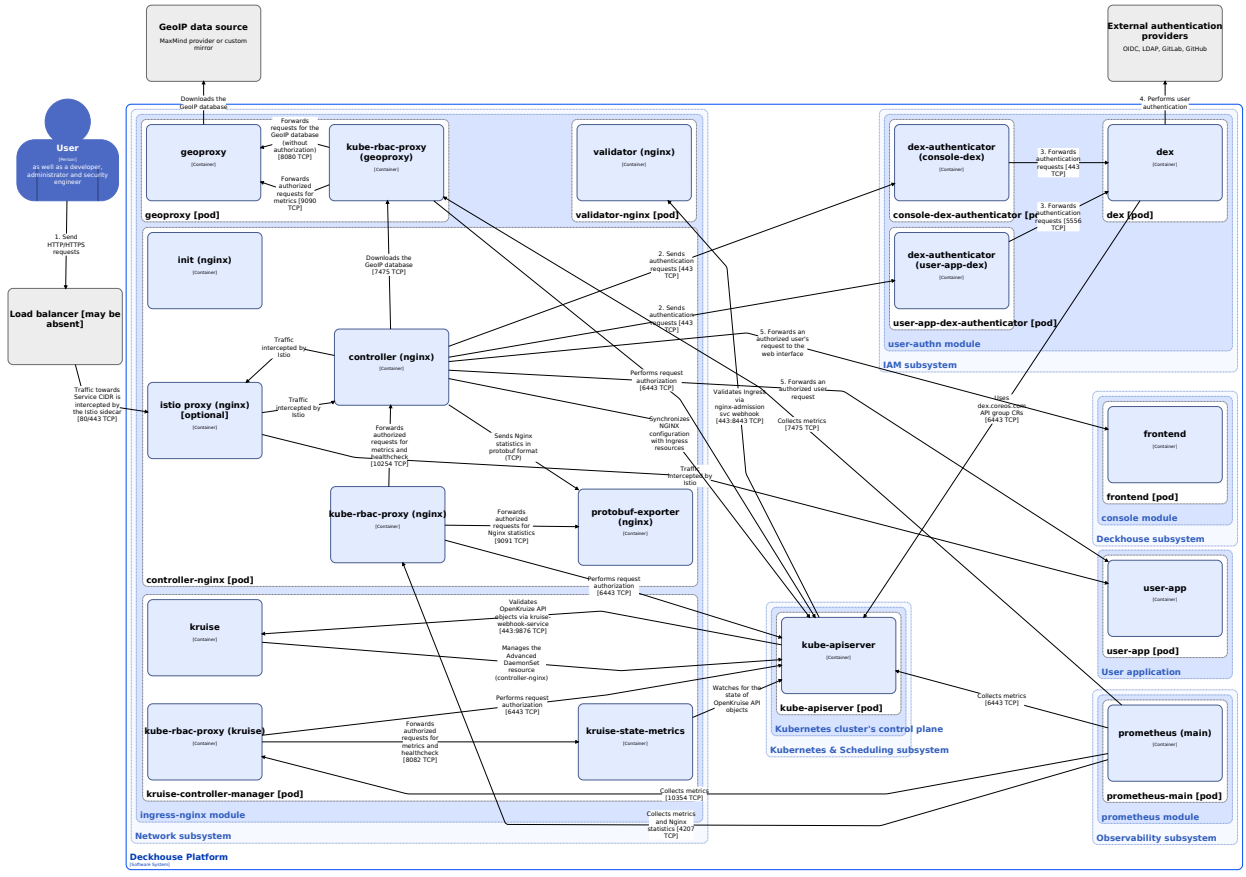
Ingress-nginx module

The `ingress-nginx` module installs and manages the Ingress NGINX Controller using the IngressNginxController custom resource.

The module can operate in high availability (HA) mode and provides flexible configuration for placing Ingress controllers on cluster nodes, as well as tuning controller behavior according to the specifics of the underlying infrastructure.



The module supports running and configuring multiple instances of the Ingress NGINX Controller independently. This allows, for example, separating external and intranet application Ingress resources.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `ingress-nginx` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller-nginx** (Advanced DaemonSet): Non-standard DaemonSet with advanced capabilities managed by kruise-controller-manager.

It consists of the following containers:

- **init**: Init container configuring a file system for the Ingress controller.
- **controller**: Main container running Ingress NGINX Controller and implementing the core module logic. It is an open source project.
- **protobuf-exporter**: Sidecar container in the ingress-controller pod that receives NGINX statistics in protobuf format. It parses and aggregates the messages according to predefined rules and exports metrics in Prometheus format. This exporter is developed by Flant.
- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to controller metrics and status as well as to `protobuf-exporter`. It is an open source project.
- **istio-proxy**: Istio sidecar container added to the pod when the `spec.enableIstioSidecar` parameter of the IngressNginxController custom resource is enabled. In this case, part of the user traffic passes through it.

2. **Validator-nginx** (Deployment): Consists of a single container. Validator is an Ingress NGINX Controller running in validation mode with a reduced set of privileges. It implements a webhook server used to validate Ingress resources via the Validating Admission Controllers mechanism.

3. **Kruise-controller-manager** (Deployment): Controller that manages the Advanced DaemonSet custom resource. This DaemonSet extension provides advanced update capabilities for the Ingress NGINX Controller that are not available in the standard Kubernetes DaemonSet controller.

   It consists of the following containers:

   - **kruise**: Main container running kruise-controller-manager.
   - **kruise-state-metrics**: Sidecar container that monitors the state of OpenKruise API objects and exposes corresponding metrics (but not metrics of the kruise-controller-manager itself).
   - **kube-rbac-proxy**: Sidecar container providing authorized access to controller metrics and status (described above).

4. **Geoproxy** (StatefulSet): Caching proxy server for the Ingress controller that provides quick access to the GeoIP database downloaded from the MaxMind provider. This component also grants access to already downloaded bases in clusters that have no internet access, improving the stability of the Ingress NGINX Controller when working with GeoIP databases.

   This component provides the following features:

   - MaxMind license saving (databases are downloaded from a single point once a day).
   - Persistent data storage (if components are restarted, it doesn't require accessing the MaxMind servers again).
   - It lets you specify a custom mirror for downloading databases.

   It consists of the following containers:

   - **geoproxy**: Proxy server. This server is developed by Flant.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to geoproxy metrics (the GeoIP databases are available without authorization). This container is described in detail above.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Synchronizes the NGINX configuration when Ingress resources change.
   - Authorizes requests for metrics, statistics, and controller status checks.
   - Forwards external HTTP requests to the Kubernetes API endpoint.

2. **GeoIP database source** (MaxMind provider or custom mirror): The module downloads the GeoIP database.

3. **Dex-authenticator of platform services and user applications**: Used to authenticate requests in dex via dex-authenticator, which acts as an OAuth2 proxy.

4. **DP platform services** (such as `console`, `dashboard`, Grafana, and others): The module forwards HTTP requests that have been authenticated via Dex.

5. **User services deployed in DP**: The module forwards external HTTP requests to user services. To enable this, the user must create the corresponding Ingress resources and, if authentication via Dex is required, the DexAuthenticator custom resource.

> **i** To keep the diagram simple, it shows interactions between ingress-controller and only one DP service, the frontend component of the `console` module and its corresponding console-dex-authenticator.

The following external components interact with the module:

1. **Kube-apiserver**: Uses a validation webhook to validate created or updated Ingress resources.
2. **Prometheus-main**: Collects metrics from ingress and kruise controllers, geoproxy, as well as NGINX statistics.
3. **Load balancer**: Distributes HTTP/HTTPS traffic across healthy ingress-controller instances.

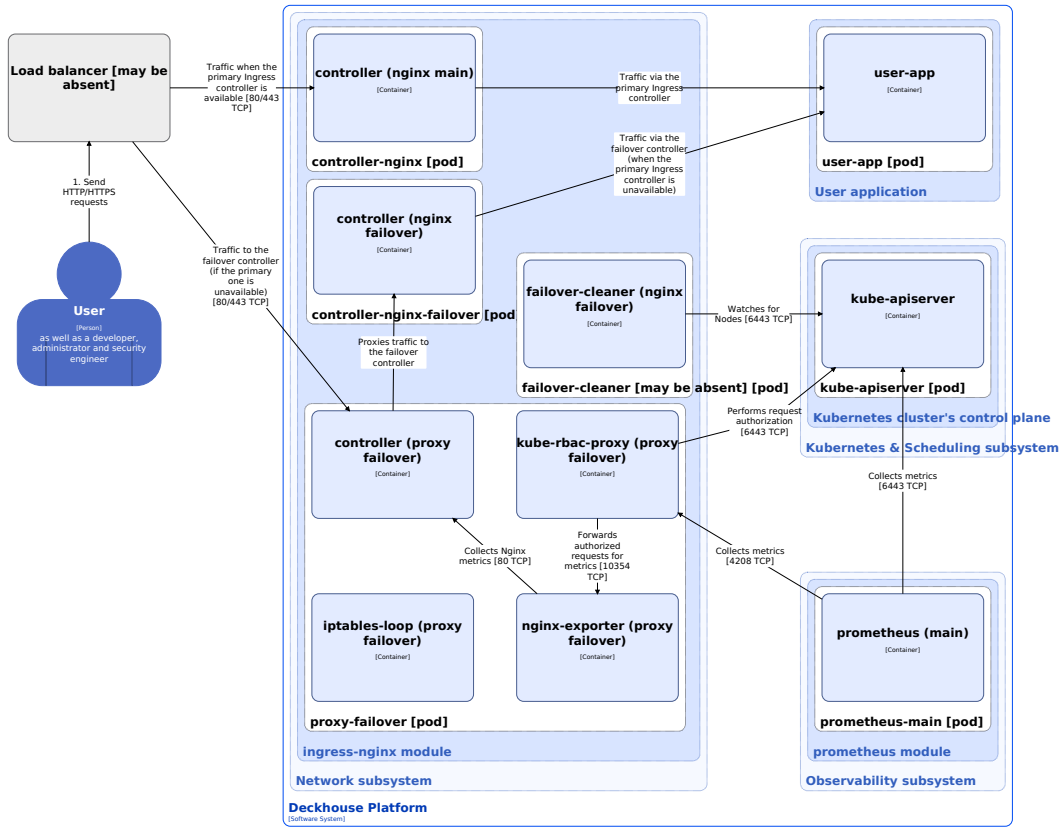
Receiving traffic from external networks

Methods for receiving traffic from external networks are described in the `spec.inlet` parameter of the IngressNginxController custom resource.

For inlet types LoadBalancer, LoadBalancerWithProxyProtocol, and LoadBalancerWithSSLPassthrough, the load balancer shown in the diagram is automatically provided by the cloud provider (when DP is deployed in a cloud environment) or can be implemented using the MetalLB controller (for bare-metal installations). For configuration details, refer to the

`metallb` module documentation.

For inlet types HostPort, HostPortWithProxyProtocol, HostPortWithSSLPassthrough, and HostWithFailover, the load balancer is deployed by the user or may be absent. In this case, the user must configure the load balancer backends or otherwise ensure network connectivity to the ingress-controller. The ingress-controller entry point in this case is the ports on the cluster nodes where the controller is running.



Architecture of Ingress controller with HostWithFailover inlet type

When the value `HostWithFailover` of the `spec.inlet` parameter of the IngressNginxController custom resource is set, two Ingress controllers are installed in the cluster: the primary controller and the failover controller, as well as a proxy-failover controller that coordinates traffic switch between them.

The primary controller starts in `hostNetwork`, while the failover controller starts in `podNetwork`. If the main controller pod is unavailable on the node, the proxy failover starts proxying traffic to the failover controller pod using the `PROXY PROTOCOL` to save information about the client's IP address.

> **i** The following diagram does not show the architecture of the main Ingress controller, as well as the module interactions, as they are described in detail in the diagram above.

The Level 2 C4 architecture of Ingress controller with HostWithFailover inlet type and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Components of failover Ingress controller

1. **Controller-nginx-failover** (Advanced DaemonSet): Failover Ingress-controller deployed on the same nodes as the main one. Failover controller has the same containers on the pod with the same purpose as the main Ingress controller.
2. **Proxy-failover** (Advanced DaemonSet): Proxy server.

   It consists of the following containers:

   - **controller**: Server that performs the following functions:
     - Monitors a performance of the main Ingress controller and returns its status.
     - Monitors the NGINX configuration file on the node and reboots Ingress controller if this configuration is changed.
     - Starts a NGINX instance that proxies traffic to the failover controller in case the main one is unavailable. Traffic is switched to the failover controller and back to the main controller with the use of `iptables` rules, that are configured by the iptables-loop container depending on the availability of the `80` and `443` TCP ports on the main controller.

     This controller is developed by Flant.
   - **iptables-loop**: Sidecar container that updates the `iptables` rules on the node that are necessary for the

Ingress controller to work. It is developed by Flant.

- **nginx-exporter**: Sidecar container that connects to NGINX over HTTP and exports metrics in the Prometheus format. It is an open source project.
- **kube-rbac-proxy**: Sidecar container providing authorized access to controller metrics and status (described above).

3. **Failover-cleaner** (DaemonSet): Component deployed to the cluster nodes that are labeled with `ingress-nginx-controller.deckhouse.io/need-hostwithfailover-cleanup=true`. It cleans up the `iptables` rules. If the Ingress controller operates normally, the failover-cleaner component doesn't run on any node.

Failover Ingress controller interactions

Failover Ingress controller interacts with the following components:

1. **Kube-apiserver**:
   - Watches Node resources for `ingress-nginx-controller.deckhouse.io/need-hostwithfailover-cleanup=true` labels.
   - Authorizes requests for metrics, statistics, and controller status checks.
   - Forwards external HTTP requests to the Kubernetes API endpoint.
2. **GeoIP database source** (MaxMind provider or custom mirror): Failover Ingress controller downloads the GeoIP database.
3. **Dex-authenticator of platform services and user applications**: Used to authenticate requests in dex via dex-authenticator, which acts as an OAuth2 proxy.
4. **DP platform services** (such as `console`, `dashboard`, Grafana, and others): The module forwards HTTP requests that have been authenticated via Dex.
5. **User services deployed in DP**: The module forwards external HTTP requests to user services. To enable this, the user must create the corresponding Ingress resources and, if authentication via Dex is required, the DexAuthenticator custom resource.

The following external components interact with the failover Ingress controller:

1. **Prometheus-main**: Collects failover Ingress controller metrics.
2. **Load balancer**: Routes HTTP/HTTPS traffic in case the main Ingress controller is unavailable.

Istio module

The `istio` module implements a Service Mesh based on Istio for centralized management of network traffic in Deckhouse Platform (DP). The module provides mTLS (Mutual Transport Layer Security), request authorization, traffic routing, load balancing, and observability of interactions between applications.

The `istio` module allows several Istio versions to run at the same time. The module's `globalVersion` parameter specifies which Istio version is used by default for namespaces labeled `istio-injection: enabled`. If a namespace needs to use an Istio version other than the default one, it is labeled with the label corresponding to the Istio revision instead, for example, `istio.io/rev: v1x27`.

The module works with the following custom resources.

Resources managed directly by the module (the `deckhouse.io` group):

- IngressIstioController: Describes an Istio ingress gateway instance serving the selected gateway class.
- IstioFederation: Marks one or more remote clusters as trusted for mesh federation (available in the Enterprise Edition and Ultimate).
- IstioMulticluster: Marks one or more remote clusters as trusted for a multicluster configuration (available in the Enterprise Edition and Ultimate).
- WaypointInstance: Describes a waypoint ambient proxy created by the waypoint-controller component (available in the Enterprise Edition and Ultimate).

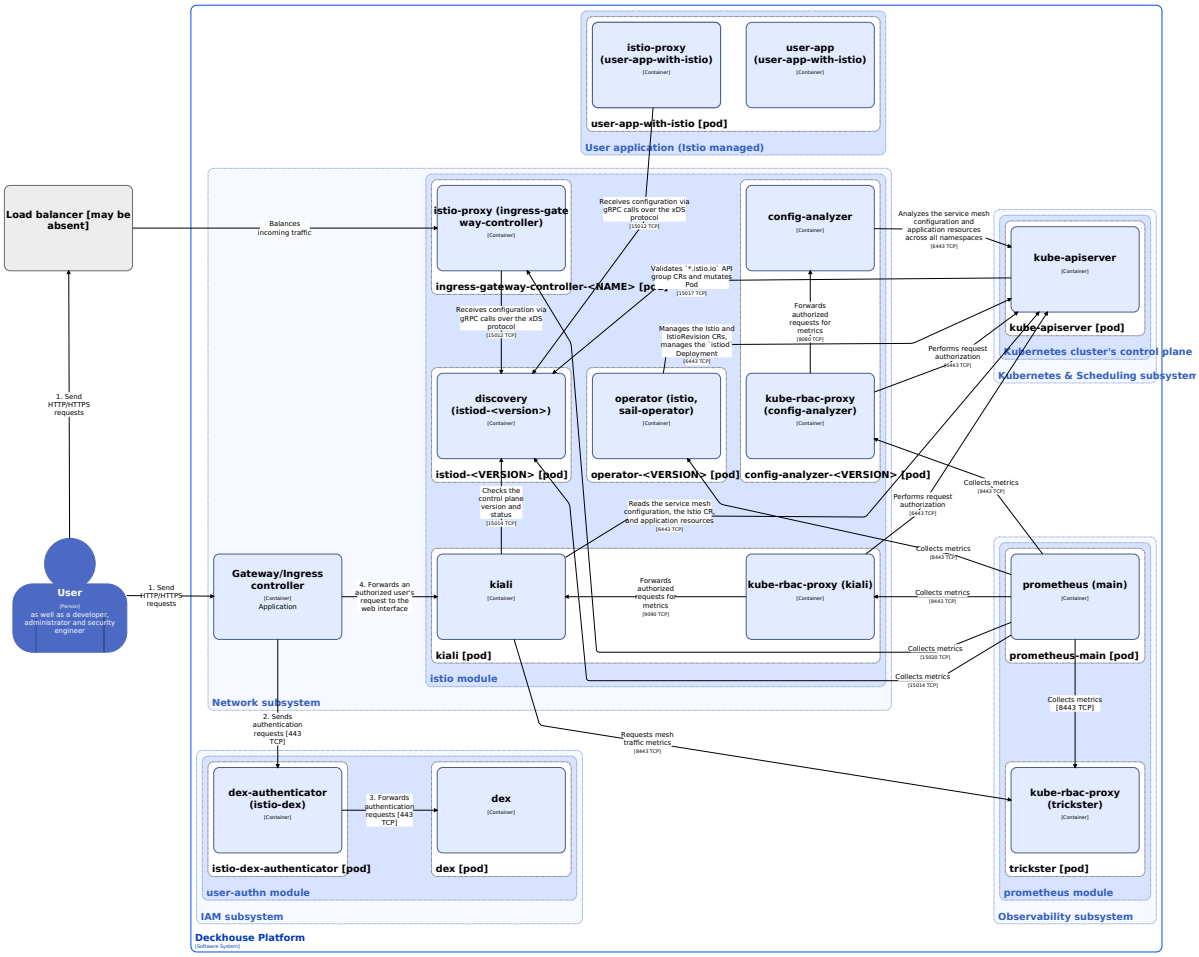
The module also installs and uses the standard Istio custom resources (the `networking.istio.io`, `security.istio.io`, `telemetry.istio.io`, and `extensions.istio.io` groups — VirtualService, DestinationRule, Gateway, PeerAuthentication, and others). For more details, see the Istio custom resource reference.

> ⚠ DP only supports operator-based management for Istio version 1.25. All later versions run without the operator. Istio 1.25 is deprecated and will be removed in a future update.

If an Istio version with operator support is requested, the following Sail Operator custom resources of the `sailoperator.io` group are installed and used:

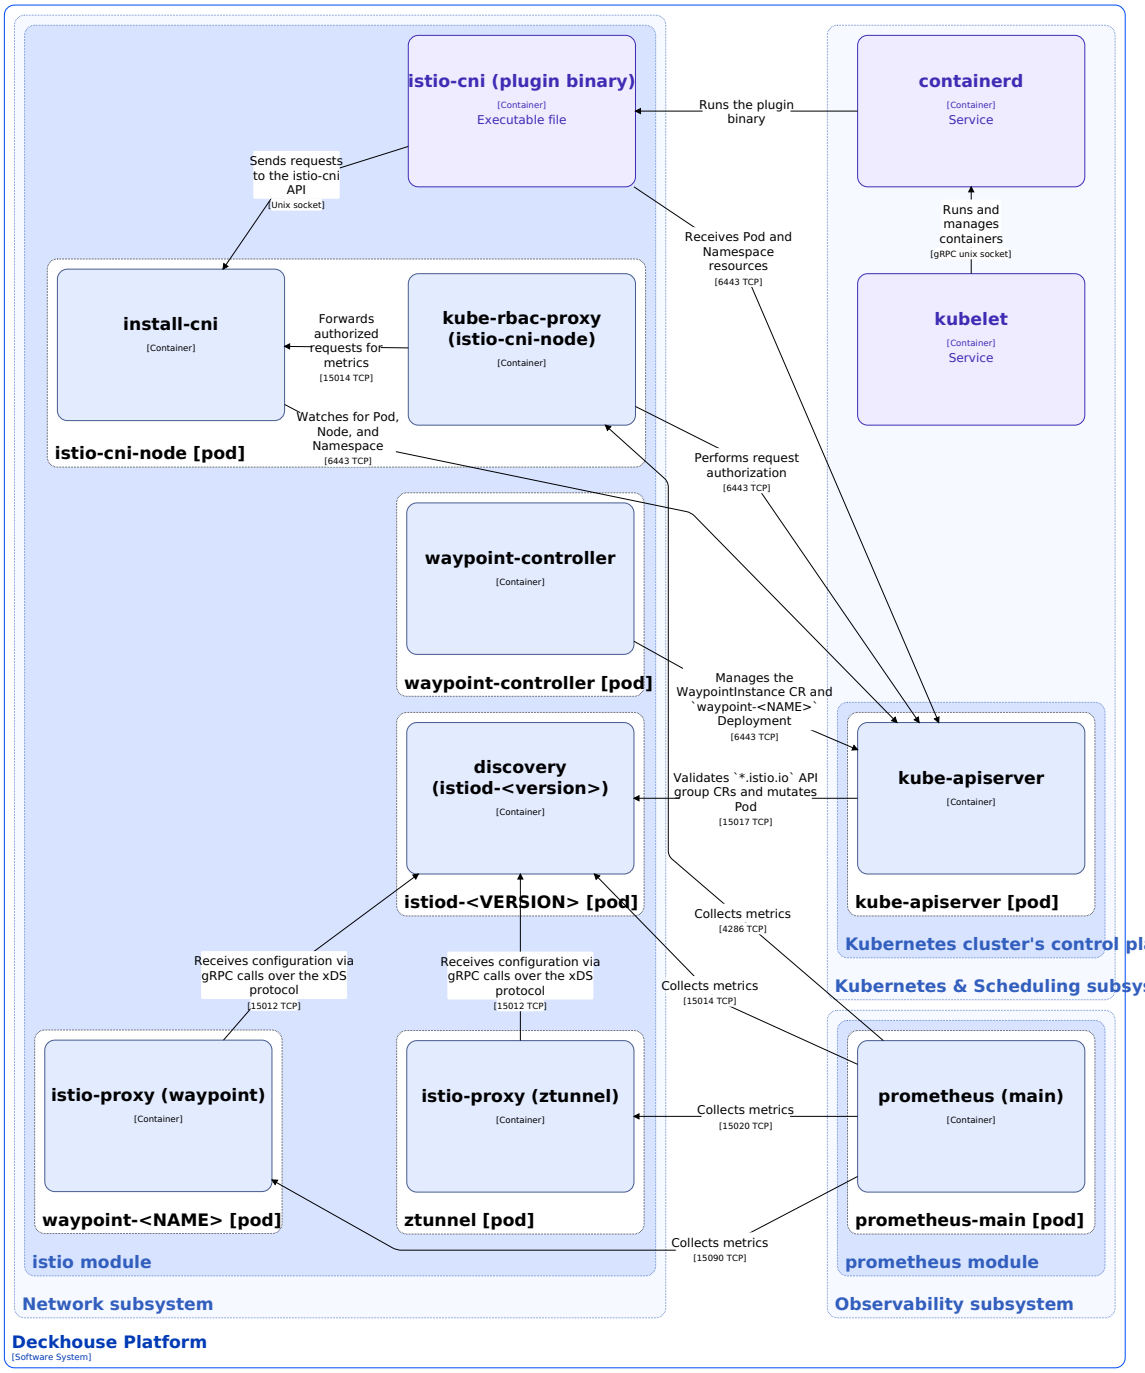
- Istio: Represents an Istio Service Mesh deployment consisting of one or more control planes.
- IstioRevision: Represents a single revision of the Istio control plane.

The set of module components and its architecture depend on the DP edition. The Enterprise Edition (EE) and Ultimate adds cross-cluster service mesh federation, periodic service mesh configuration analysis, and support for Istio ambient mode.



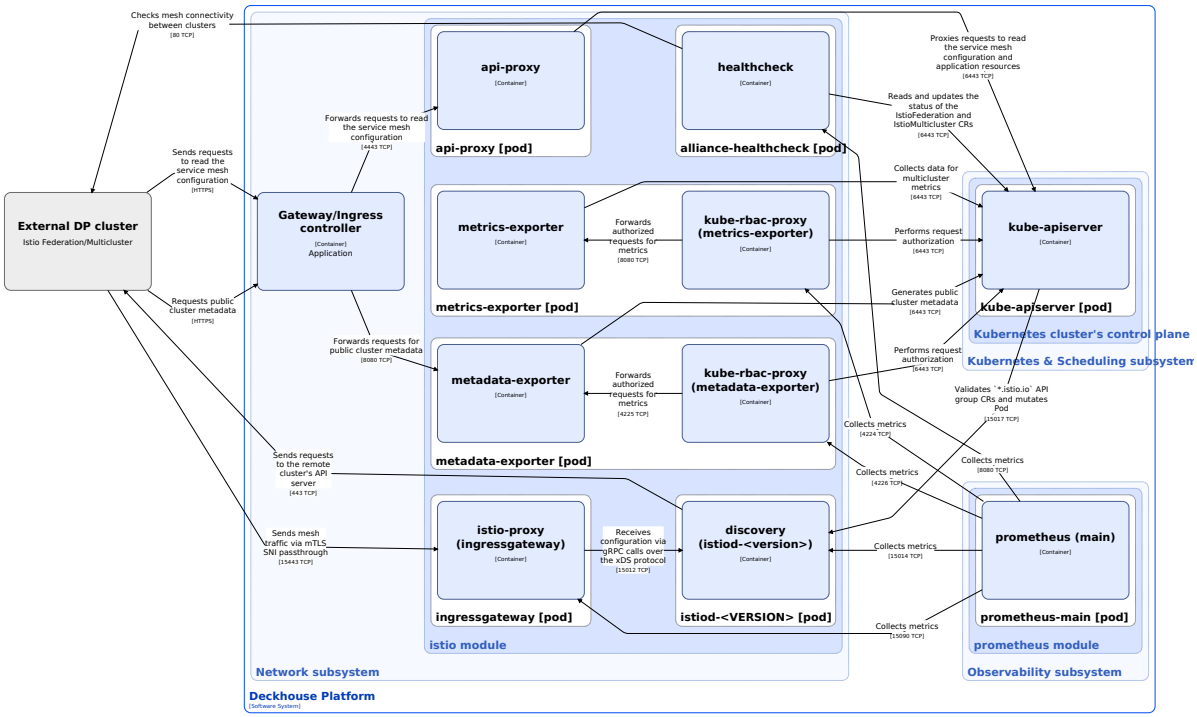
For more details about module configuration, refer to the corresponding documentation section.

Module architecture



The Level 2 C4 architecture of the `istio` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagrams:

> **i** The following simplifications are made in the diagrams:
>
> - The diagrams show containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagrams.



- Base module functionality (control plane, CNI, ingress gateway, Kiali, config-analyzer):

- Ambient mode (ztunnel, waypoint-controller; available only in the Enterprise Edition and Ultimate, disabled by default — the diagram shows only the differences from the base configuration):

- Federation and multicluster configuration (available only in the Enterprise Edition and Ultimate, disabled by default — the diagram shows only the differences from the base configuration):

Module components

Main module components

The module consists of the following components:

1. **Operator-<VERSION>** (Deployment): an implementation of the Sail Operator that manages the Istio control plane lifecycle. The component is responsible for installing all the resources required for a given control plane version to work.

   DP only supports the operator for Istio version 1.25.

   The component watches the Istio and IstioRevision custom resources and uses them to create the `istiod-<VERSION>` Deployment, a Service, and a ConfigMap. Webhook management for validation and mutation is deliberately disabled in the operator; it is handled by the Deckhouse controller of the `deckhouse` module when the module's Helm chart is applied.

   It consists of a single container:

   - **operator**: Main container.

2. **Istiod-<VERSION>** (Deployment): the Istio control plane component that:

   - Distributes sidecar proxy routing configuration via xDS.
   - Issues certificates for workloads managed by Istio.
   - Validates user application pods and mutates them to inject sidecar containers, via Validating/Mutating Admission Controllers.
   - Validates custom resources of the `*.istio.io` API groups via Validating Admission Controllers.

   For Istio 1.25 (deprecated and scheduled for removal), the component is created and managed by the operator-<VERSION> component through the Istio and IstioRevision custom resources. For other Istio versions supported in DP, it is deployed directly by the module's Helm chart.

   It consists of a single container:

   - **discovery**: Main container.

3. **Ingress-gateway-controller-<NAME>** (DaemonSet): controller that handles incoming mesh traffic from applications. Created by the Deckhouse controller of the `deckhouse` module for each IngressIstioController custom resource. The `<NAME>` placeholder is the name of the IngressIstioController resource.

   It consists of a single container:

   - **istio-proxy**: Main container based on the open-source Envoy project, which handles incoming traffic and receives configuration via xDS from the istiod controller.

4. **Kiali** (Deployment): Kiali web interface for managing and observing Istio resources and user services running under Istio, allowing you to:

   - Visualize connections between services.
   - Diagnose problematic connections between services.
   - Diagnose the state of the Istio control plane.

   It consists of the following containers:

   - **kiali**: Main container.

- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to the Kiali web interface.

Authentication of Kiali web interface users is performed by the `user-authn` module through a dedicated dex-authenticator.

5. **Istio-config-analyzer-<VERSION>** (Deployment): component that performs periodic service mesh configuration analysis (`istioctl analyze`) and exports the analysis results as Prometheus metrics.

   The component is created by the Deckhouse controller of the `deckhouse` module for each Istio revision if the `.settings.configAnalysis.enabled` module parameter is set to `true` (enabled by default).

   It consists of the following containers:

   - **istio-config-analyzer**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to metrics.

Ambient mode components

The following additional components are created when Istio runs in ambient mode:

1. **Istio-cni-node** (DaemonSet): Istio component that installs the CNI plugin on each cluster node and, in Istio ambient mode, sets up traffic interception for pods.

   The component prepares the `istio-cni` binary and appends it as an additional plugin to the first CNI config found in the `/etc/cni/net.d/` directory on each cluster node. In the standard DP configuration this is the `05-cilium.conflist` file, created by the Cilium CNI plugin of the `cni-cilium` module. When creating each pod, kubelet (via containerd) calls both CNI plugins in sequence — first cilium, then istio-cni. The result produced by the first plugin is passed to the second.

   In Istio ambient mode, the component handles API requests from the `istio-cni` CNI plugin and configures routing to the ztunnel component.

   The component is created by the Deckhouse controller if the `.settings.dataPlane.trafficRedirectionSetupMode` module parameter is set to `CNIPlugin` (the default is `InitContainer`).

   It consists of the following containers:

   - **install-cni**: Main container that installs and configures the CNI plugin on the node.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to install-cni metrics.

2. **Istio-cni**: binary invoked by containerd, which receives the command (for example, ADD when a container starts and DEL when it is removed) and other parameters via environment variables, per the CNI specification, and the JSON configuration via stdin.

   On each invocation, istio-cni performs the following actions:

   - Processes the input from containerd: the JSON configuration, and the pod's name and namespace.
   - Retrieves pod and namespace information from kube-apiserver.
   - Stops processing if the namespace is in `exclude_namespaces` (a configuration parameter in the `cni-config` ConfigMap).
   - In ambient mode, checks whether the pod is enabled for ambient via labels and, if so, notifies the istio-cni-node component via a Unix socket.
   - In sidecar mode, checks that the pod has no `istio-init` container, has an `istio-proxy` container, and checks annotations; if the conditions are met, it enters the pod's network namespace (netns) and sets up interception of inbound and outbound traffic by running `iptables` or `nftables` commands.

3. **Ztunnel** (DaemonSet): Istio ambient mode component that provides the L4 data plane (mTLS, L4-level authorization) without adding a sidecar to the user's application. Runs on every cluster node.

   The component is created by the Deckhouse controller if the `.settings.ambient.enabled` module parameter is set to `true` (disabled by default).

   It consists of a single container:

   - **istio-proxy**: Main container that receives configuration via xDS from the istiod controller.

4. **Waypoint-controller** (Deployment): controller for the ambient mode L7 layer. The controller manages the WaypointInstance custom resource and creates or updates the corresponding `waypoint-<NAME>` Deployment.

   Created under the same conditions as ztunnel.

   It consists of a single container:

   - **waypoint-controller**: Main container.

5. **Waypoint-<NAME>** (Deployment): proxying service that handles L7 traffic (HTTP routing and authorization) for the services or workloads of the given namespace. Created dynamically by the waypoint-controller component for each WaypointInstance resource.

   It consists of a single container:

   - **istio-proxy**: Main container that receives configuration via xDS from the istiod controller.

Federation or multicluster mode components

> ⚠ Cross-cluster interaction (federation or multicluster) is only available between DP clusters, since DP installs a modified version of Istio that is not compatible with vanilla Istio in other clusters.

The following additional components are created when Istio runs in federation or multicluster mode:

1. **Metadata-exporter** (Deployment): component that provides public cluster metadata (the CA root certificate, public keys, endpoint addresses) to remote clusters for configuring cross-cluster interaction (federation or multicluster).

   The component is created by the Deckhouse controller if the `.settings.federation.enabled` or the `.settings.multicluster.enabled` module parameter is enabled (both disabled by default).

   It consists of the following containers:

   - **metadata-exporter**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to metrics.

2. **Alliance-healthcheck** (Deployment): component that checks the availability of the mesh connection with remote clusters and updates the status of the IstioFederation and IstioMulticluster custom resources.

   Created under the same conditions as metadata-exporter.

   It consists of a single container:

   - **healthcheck**: Main container.

3. **Ingressgateway** (DaemonSet): component that accepts mesh traffic from remote clusters via mTLS with SNI passthrough. A separate component from ingress-gateway-controller-<NAME>, dedicated exclusively to federation and multicluster traffic.

   The component is created by the Deckhouse controller if either:

   - The `.settings.federation.enabled` module parameter is enabled.
   - The `.settings.multicluster.enabled` module parameter and the `.spec.enableIngressGateway` parameter of the IstioMulticluster custom resource are both enabled.

   It consists of a single container:

   - **istio-proxy**: Main container that receives configuration via xDS from the istiod controller.

4. **Metrics-exporter** (Deployment): component that collects data for multicluster configuration metrics.

   The component is created by the Deckhouse controller if the `.settings.multicluster.enabled` module parameter is enabled.

   It consists of the following containers:

   - **metrics-exporter**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to metrics.

5. **Api-proxy** (Deployment): component that provides remote clusters with read access to this cluster's service mesh configuration and application resources. Used by the remote cluster's istiod for multicluster service discovery.

   The component is created by the Deckhouse controller if the `.settings.multicluster.enabled` module parameter is enabled.

   It consists of a single container:

   - **api-proxy**: Main container.

Component that is not part of the `istio` module:

- **User application**: workload created by the user and modified by istiod when the pod is mutated.

  It consists of the following containers:

  - **istio-init**: optional init container that sets up iptables rules to intercept application traffic. Added if the `.settings.dataPlane.trafficRedirectionSetupMode` module parameter is set to `InitContainer`. When it is set to `CNIPlugin`, this function is performed by the istio-cni-node component instead.
  - **istio-proxy**: sidecar container that lets the user application participate in the Istio mesh network. Added if the `.settings.ambient.enabled` module parameter is set to `false` (disabled by default).
  - **user-app**: the user application's own set of init and sidecar containers.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Authorizes requests for the module components' metrics.
   - Manages the Istio, IstioRevision, IngressIstioController, IstioFederation, IstioMulticluster, and WaypointInstance custom resources.
   - Manages custom resources of the `networking.istio.io`, `security.istio.io`, `telemetry.istio.io`, and `extensions.istio.io` API groups.
   - Creates and manages the `istiod-<VERSION>` and `waypoint-<NAME>` Deployments and the `ingress-`

`gateway-controller-<NAME>` DaemonSet.
    - Reads Pod, Namespace, Node, Service, Secret, ConfigMap, Job, CronJob, Deployment, DaemonSet, ReplicaSet, and StatefulSet resources.
2. **The `user-authn` module**: Authenticates Kiali web interface users.
3. **Trickster**: Queries service mesh traffic metrics for the Kiali web interface.
4. **Remote DP cluster**:
    - Checks the availability of the mesh connection between clusters.
    - Retrieves the remote cluster's service mesh and application parameters.

The following external components interact with the module:

1. **Kube-apiserver**:
    - Validates custom resources of the `networking.istio.io`, `security.istio.io`, `telemetry.istio.io`, and `extensions.istio.io` API groups.
    - Mutates pods to add init and sidecar containers.
2. **Prometheus-main**: Collects metrics from all module components.
3. **Containerd**: Runs CNI plugin binaries.
4. **Load balancer**: Balances incoming traffic to ingress-gateway-controller.
5. **Gateway/Ingress controller**: Forwards the authenticated user request to the Kiali web interface. Depends on the chosen method of publishing resources: using the Ingress controller of the `ingress-nginx` module or the Gateway controller of the `alb` module.
6. **Remote DP cluster**:
    - Requests the cluster's public metadata.
    - Sends mesh traffic via mTLS SNI passthrough.
    - Reads the cluster's service mesh and application parameters.
7. **User application**: Receives configuration via xDS from the istiod controller.

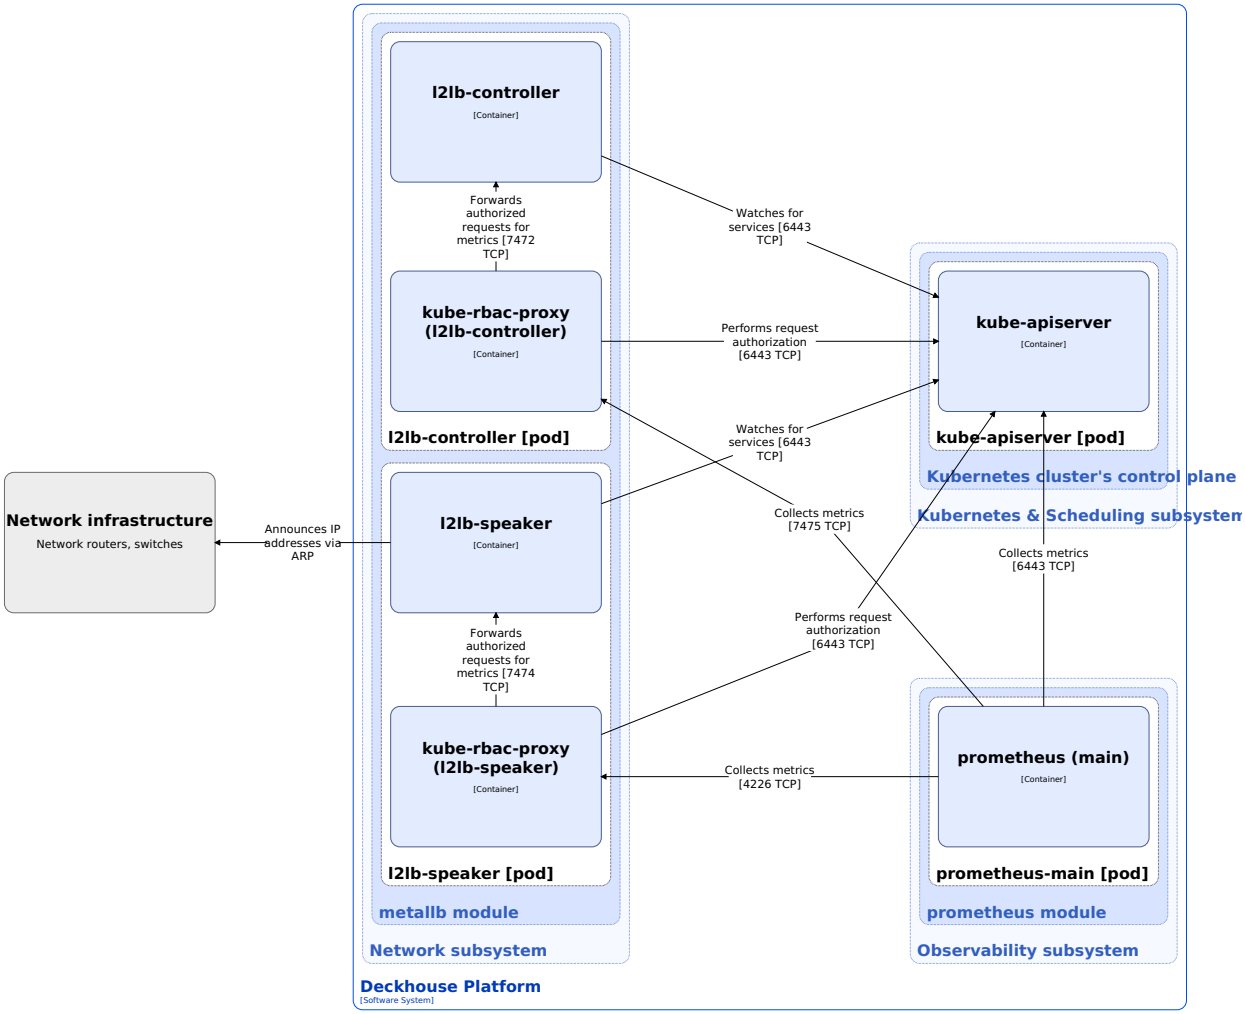
Metallb module

The `metallb` module implements the LoadBalancer mechanism for services in bare-metal clusters.

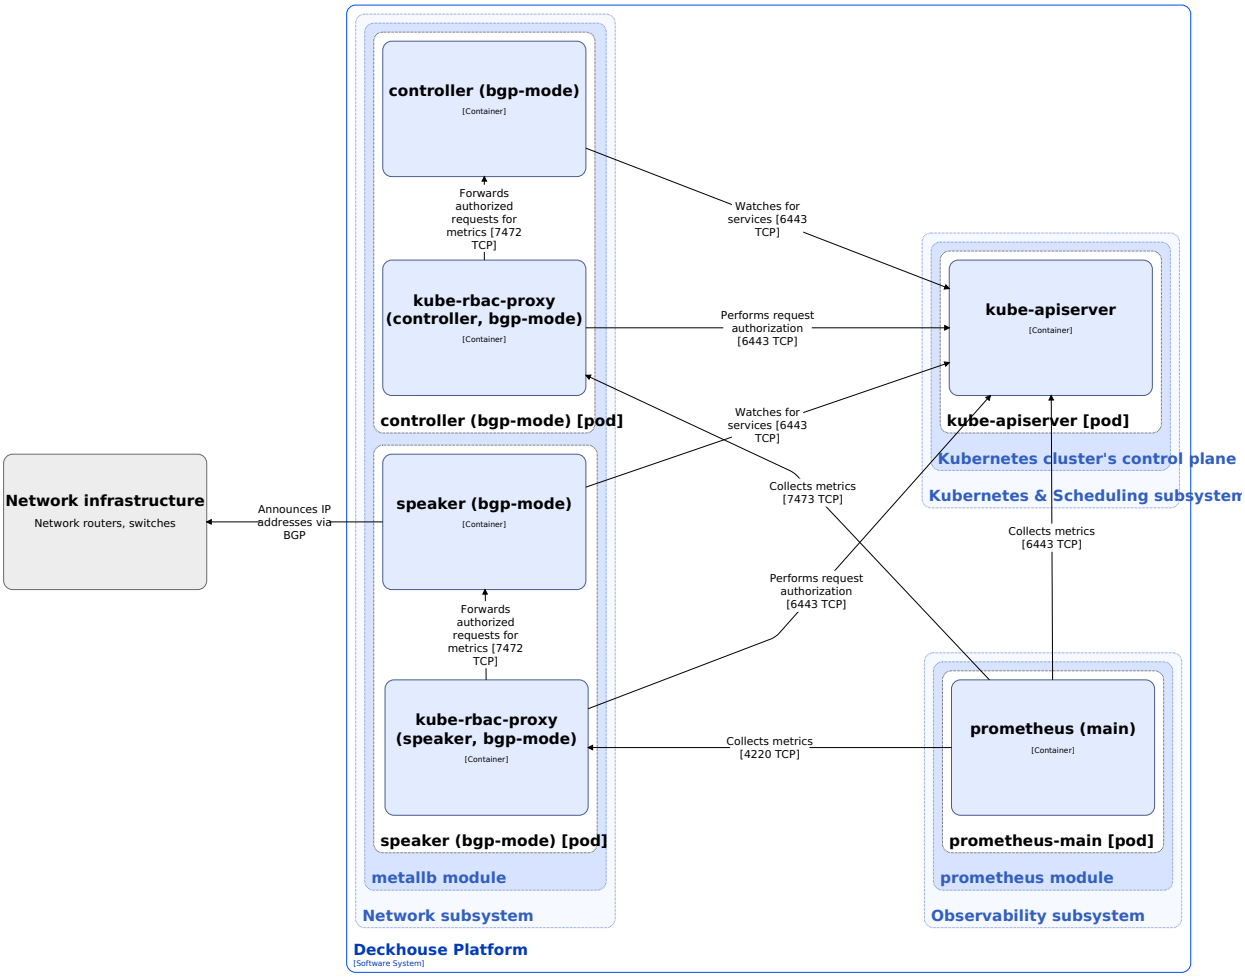
The following operating modes are supported:

- **Layer 2**: Implements an improved load balancing mechanism (compared to the standard L2 mode in MetalLB) for bare-metal clusters. It allows using multiple "public" IP addresses for services and distributing them evenly across available cluster nodes.
- **BGP**: Fully based on the MetalLB solution and uses the BGP protocol to create routes.



For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture



> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `metallb` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagrams.

MetalLB in Layer 2 mode:

MetalLB in BGP mode:

Module components

The module consists of the following components:

1. **Controller/l2lb-controller** (Deployment): MetalLB controller responsible for assigning IP addresses to LoadBalancer services.

   The controller monitors changes in Kubernetes services and applies IP address configuration based on a predefined address pool specified in the module configuration.

   It consists of the following containers:

   - **controller/l2lb-controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to controller metrics. It is an open-source project.

2. **Speaker/l2lb-speaker** (DaemonSet): MetalLB speaker running on each cluster node that participates in load balancing. It is responsible for implementing the load balancing mechanism at the network level.

   Depending on the operating mode, it performs the following functions:

   - In **Layer 2 mode**, it uses ARP to associate virtual IP addresses of services with the physical addresses of cluster nodes.
   - In **BGP mode**, it announces routes to virtual IP addresses via the BGP protocol, making services accessible from outside the cluster.

   It consists of the following containers:

   - **speaker/l2lb-speaker**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to speaker metrics.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Monitors changes in Kubernetes services and applies IP address configuration.
   - Authorizes requests for metrics.

2. **Network equipment**: Ensures the availability of virtual IP addresses outside the cluster:

   - In **BGP mode**, it advertises routes to virtual IP addresses using the BGP protocol.

    - In **Layer 2 mode**, it uses ARP/GARP to notify upstream routers that the virtual IP addresses are associated with the MAC addresses of specific nodes.

The following external components interact with the module:

- **Prometheus-main**: Collects metrics from the MetalLB controller and speaker.

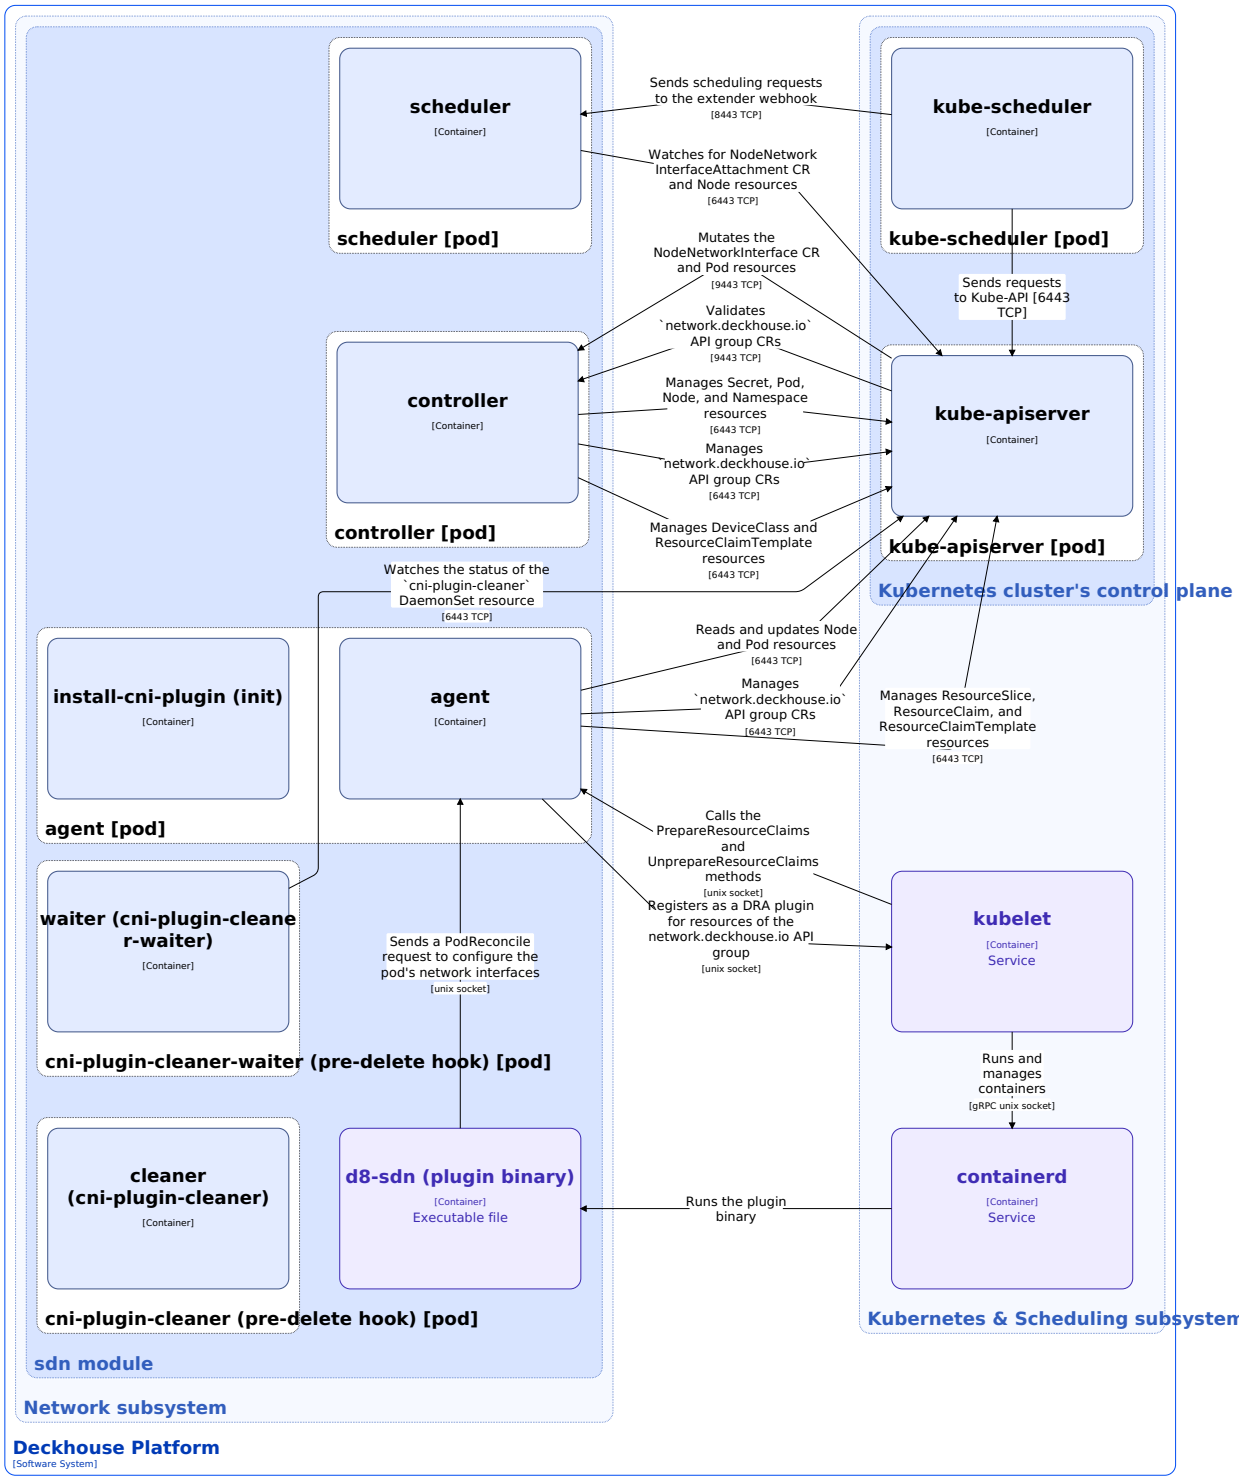
Sdn module

The `sdn` module provides software-defined networking (SDN) functions in Deckhouse Platform (DP):

- Configuring network interfaces on nodes.
- Additional networks for pods and virtual machines.
- IPAM (IP Address Management) for additional networks. The IPAM mechanism allocates IPv4 addresses from pools and assigns them to additional network interfaces of pods connected to cluster networks (ClusterNetwork) and project networks (Network).
- Underlay networks for passing through hardware network devices.
- System networks for node-level service traffic.

The module works with the following custom resources of the `network.deckhouse.io` API group:



- ClusterIPAddress: Represents a request for an IPv4 address at the cluster scope, for a network interface connected to a ClusterNetwork or SystemNetwork.
- ClusterIPAddressPool: Defines a cluster-scoped pool of IPv4 addresses used for IPAM in cluster networks.
- ClusterNetwork: Defines a publicly available network at the cluster scope.
- IPAddress: Represents a request for an IPv4 address for an additional network interface of a pod connected to a project network.
- IPAddressLease: A reservation record for an allocated IP address that prevents it from being assigned again.
- IPAddressPool: Defines a pool of IPv4 addresses within a user namespace, used for IPAM in a project network.
- Network: A namespaced resource that creates a dedicated project network based on a network class provided by the administrator in a NetworkClass resource.
- NetworkClass: Defines a range of VLAN tags and node network interfaces that users can base their own Network resources on.
- NodeNetworkInterface: Describes a network interface on a node, used both to discover existing interfaces and to create new ones (VLAN, Bond).
- SystemNetwork: Creates an additional service network on cluster nodes on top of an existing underlay network for node-level service traffic.
- UnderlayNetwork: Provides direct pass-through of physical and virtual node network interfaces (PF/VF) to pods via Dynamic Resource Allocation (DRA), in Shared or Dedicated mode.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `sdn` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller** (Deployment): the controller manages software-defined networks in DP, performing the following actions:

   - Manages custom resources of the `network.deckhouse.io` API group.
   - Validates custom resources of the `network.deckhouse.io` API group using the Validating Admission Controllers mechanism.
   - Mutates NodeNetworkInterface custom resources using the Mutating Admission Controllers mechanism.
   - Mutates Pod resources in namespaces labeled `direct-nic-access.network.deckhouse.io/enabled` to inject a ResourceClaim for hardware network device pass-through.

   It consists of a single **controller** container.

2. **Agent** (DaemonSet): a component that runs on every cluster node and performs the following operations:

   - Configures node network interfaces (port bonding, bridging, VLAN interface configuration).
   - Brings up additional, underlay, and system networks.
   - Implements a CNI server that the d8-sdn component connects to over a Unix socket.
   - Implements a Dynamic Resource Allocation (DRA) driver for the `network.deckhouse.io` API group,

registering itself as a DRA plugin with kubelet, for passing physical and virtual network devices through to a pod. This functionality is available in the DP Ultimate/EE, Certified Core/CSE Lite (1.73), and Certified Pro/CSE Pro (1.73) editions.

The agent translates cluster node and pod configurations into low-level network interface and eBPF program settings that actually process traffic.

It consists of the following containers:

- **install-cni-plugin**: Init container that copies the `d8-sdn` CNI plugin executable to the `/opt/cni/bin` directory on the node.
- **agent**: Main container.

> ⚠ The agent component has privileged access to the operating system of each node. On Linux, this requires the following capabilities:
>
> - NET_ADMIN
> - SYS_ADMIN
> - BPF
>
> The container also runs as the root user (`runAsUser: 0`), uses `hostNetwork: true`, and the `Unconfined` AppArmor profile. This is required to configure node network interfaces, network namespaces, and to load BPF programs.

3. **D8-sdn**: A CNI plugin executable run by the containerd component according to the CNI specification, for example, ADD when creating a pod's network namespace and DEL when removing it. D8-sdn communicates with the agent's API over a Unix socket and triggers the low-level network configuration for pods.
4. **Scheduler** (Deployment): a kube-scheduler extender that suggests nodes for pod placement according to the pods' network interface settings.
5. **Cni-plugin-cleaner** (DaemonSet): a Helm `pre-delete` module hook, triggered by the Deckhouse controller before the `sdn` module is removed. It runs on every node and deletes the CNI plugin files (the executable in `/opt/cni/bin` and the configuration in `/etc/cni/net.d`) installed by the agent component. It does not take part in the module's normal operation.
6. **Cni-plugin-cleaner-waiter** (Job): a Helm `pre-delete` module hook, triggered by the Deckhouse controller before the `sdn` module is removed, that waits for the `cni-plugin-cleaner` DaemonSet to finish on every cluster node before Helm is allowed to complete removing the module release.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Manages custom resources of the `network.deckhouse.io` API group.
   - Manages Secret, Pod, Node, Namespace, DeviceClass, ResourceSlice, ResourceClaim, and ResourceClaimTemplate resources.
2. **Kubelet**: Registers itself as a DRA plugin for resources of the `network.deckhouse.io` API group.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Validates custom resources of the `network.deckhouse.io` API group.
   - Mutates NodeNetworkInterface and Pod resources.
2. **Kube-scheduler**: Sends requests to the `sdn-scheduler-extender` webhook for scheduling pods that use software-defined networks.
3. **Containerd**: Runs the d8-sdn executable file with certain commands according to the CNI specification, for example, ADD when creating a pod's network namespace and DEL when removing it.
4. **Kubelet**: Calls the `PrepareResourceClaims` and `UnprepareResourceClaims` RPC-methods to configure a pod's DRA resources.

Service-with-healthchecks module

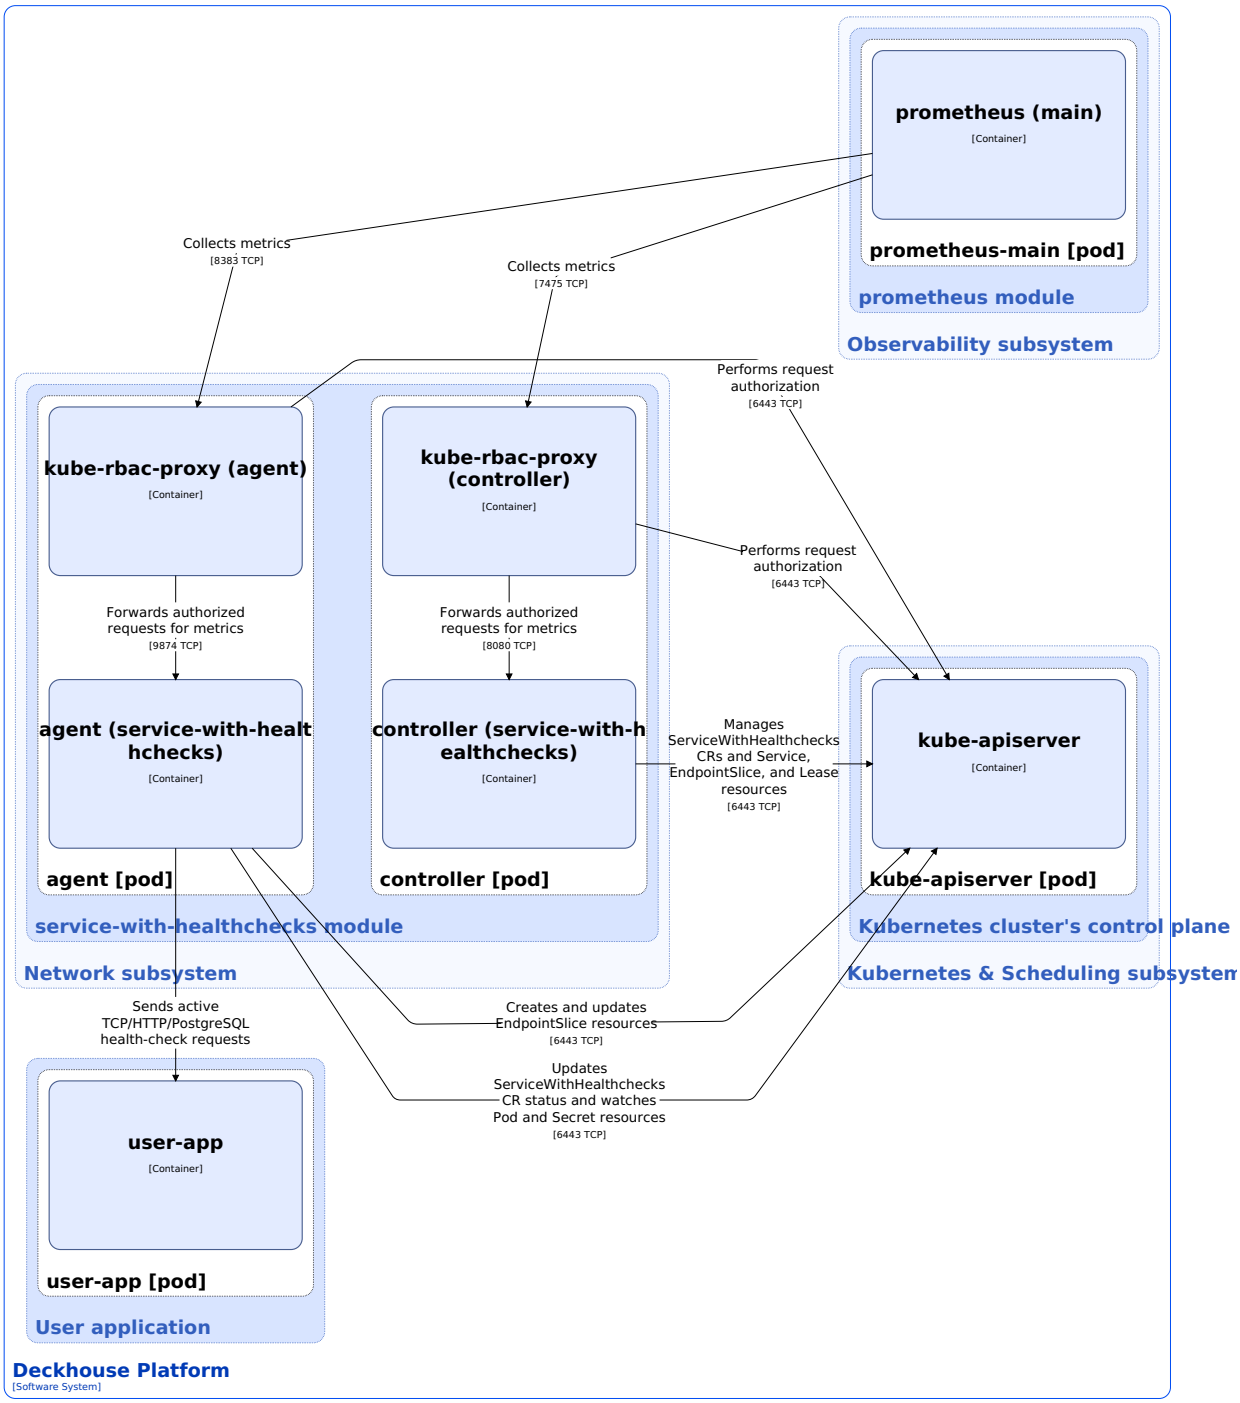
The `service-with-healthchecks` module provides an internal load balancer with per-port health checks.

The module works with the ServiceWithHealthchecks custom resource, which defines a Service load balancer with an

independent TCP, HTTP, or PostgreSQL health check for each port.

Unlike the regular load balancer, in which readiness probes are tied to the container state, ServiceWithHealthchecks custom resource allows you to set up active probes on individual TCP ports. In this way, each of the load balancers dealing with the same pod can operate independently of the others: a pod that fails the probes of one balancer is still published by the others.

Probes are grouped by the port they check, not by the resource. When a probe fails, the pod stops receiving traffic on that port only, and the other ports of the same resource keep working. When several probes check the same port, all of them have to pass for that port to receive traffic.



The module is CNI-agnostic: the controller and agent only manage standard Kubernetes Service and EndpointSlice objects, so traffic is still routed by the cluster's existing kube-proxy or CNI implementation, exactly as for a regular Service.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `service-with-healthchecks` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller** (Deployment): Reconciles ServiceWithHealthchecks resources and performs the following actions:

   - Creates and maintains a Service resource with an empty `selector` for each custom `ServiceWithHealthchecks` resource. Load balancing is determined entirely by the EndpointSlice resources created by the agent component for the corresponding Service resources.
   - Removes obsolete EnpointSlice resources after cluster node removal.

   It consists of the following containers:

   - **controller**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to controller metrics.

2. **Agent** (DaemonSet): Runs on every cluster node and performs active TCP, HTTP, or PostgreSQL health checks against the pods scheduled to its own node according to the specification of the corresponding ServiceWithHealthchecks custom resource. Based on the check results, agent creates and updates an EndpointSlice bound to the child Service maintained by the controller. Component also watches Secret resources of the `network.deckhouse.io/postgresql-credentials` type, used to authenticate PostgreSQL health checks.

   It consists of the following containers:

  - **agent**: Main container.
  - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to component metrics.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches and updates the status of ServiceWithHealthchecks custom resources.
   - Watches Pod resources on its own node and Secret resources of the `network.deckhouse.io/postgresql-credentials` type.
   - Manages Service, EndpointSlice, and Lease resources.
   - Authorizes requests for metrics.
2. **User services deployed in DP**: Sends active TCP, HTTP, or PostgreSQL health checks to the ports of pods on its node specified in the ServiceWithHealthchecks resource.

The following external components interact with the module:

1. **Prometheus-main**: Collects metrics from the agent and controller components.

Additional resources

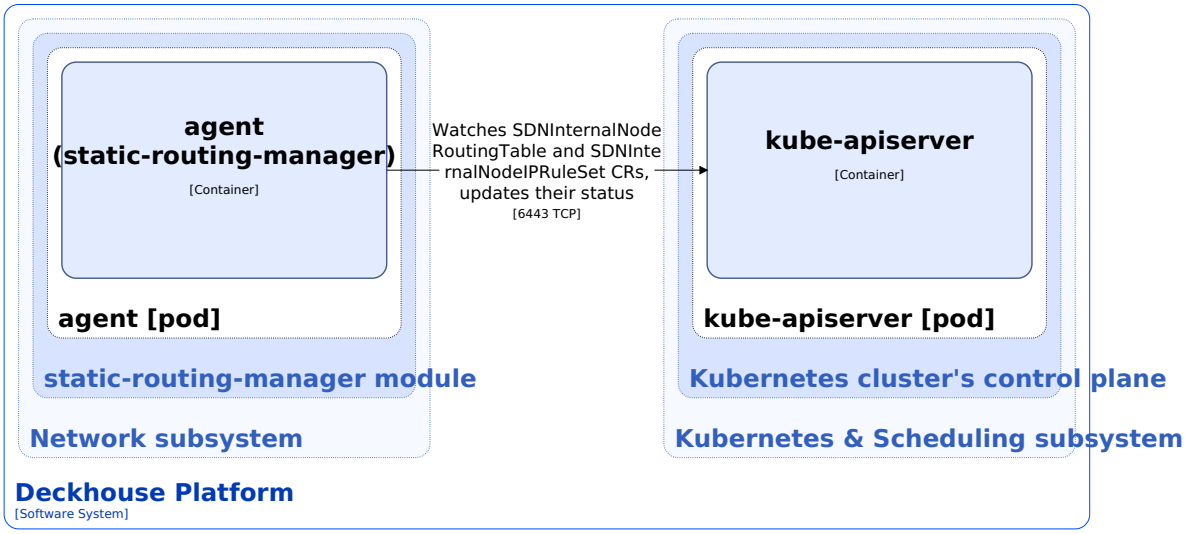
Static-routing-manager module

The `static-routing-manager` module manages static routes and `ip rule` entries on cluster nodes.

The module works with the following custom resources of the `network.deckhouse.io` API group:

- IPRuleSet: Describes a set of `ip rule` entries to be created on nodes matching a `nodeSelector`.
- RoutingTable: Describes a routing table and the routes it contains, for nodes matching a `nodeSelector`.

The module also works with the following internal custom resources of the `internal.network.deckhouse.io` API group:



- SDNInternalNodeIPRuleSet: Contains the set of `ip rule` entries for a specific cluster node.
- SDNInternalNodeRoutingTable: Contains the routing table for a specific cluster node.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `static-routing-manager` module and its interactions with other components of Deckhouse Platform are shown in the following diagram:

Module components

The module consists of one **agent** (DaemonSet) component and one **agent** container. Agent runs on every cluster node and performs the following actions:

- Watches SDNInternalNodeRoutingTable and SDNInternalNodeIPRuleSet custom resources and updates their status.
- Applies the static routes and `ip rule` entries to the node's kernel routing table.

The SDNInternalNodeRoutingTable and SDNInternalNodeIPRuleSet custom resources are created by the Deckhouse controller of the `deckhouse` module for each cluster node matching the `nodeSelector` of the IPRuleSet and RoutingTable resources.

Module interactions

The module interacts with **kube-apiserver**:

- Manages the SDNInternalNodeRoutingTable and SDNInternalNodeIPRuleSet custom resources.
- Watches the IPRuleSet and RoutingTable custom resources and updates their status.

Additional resources

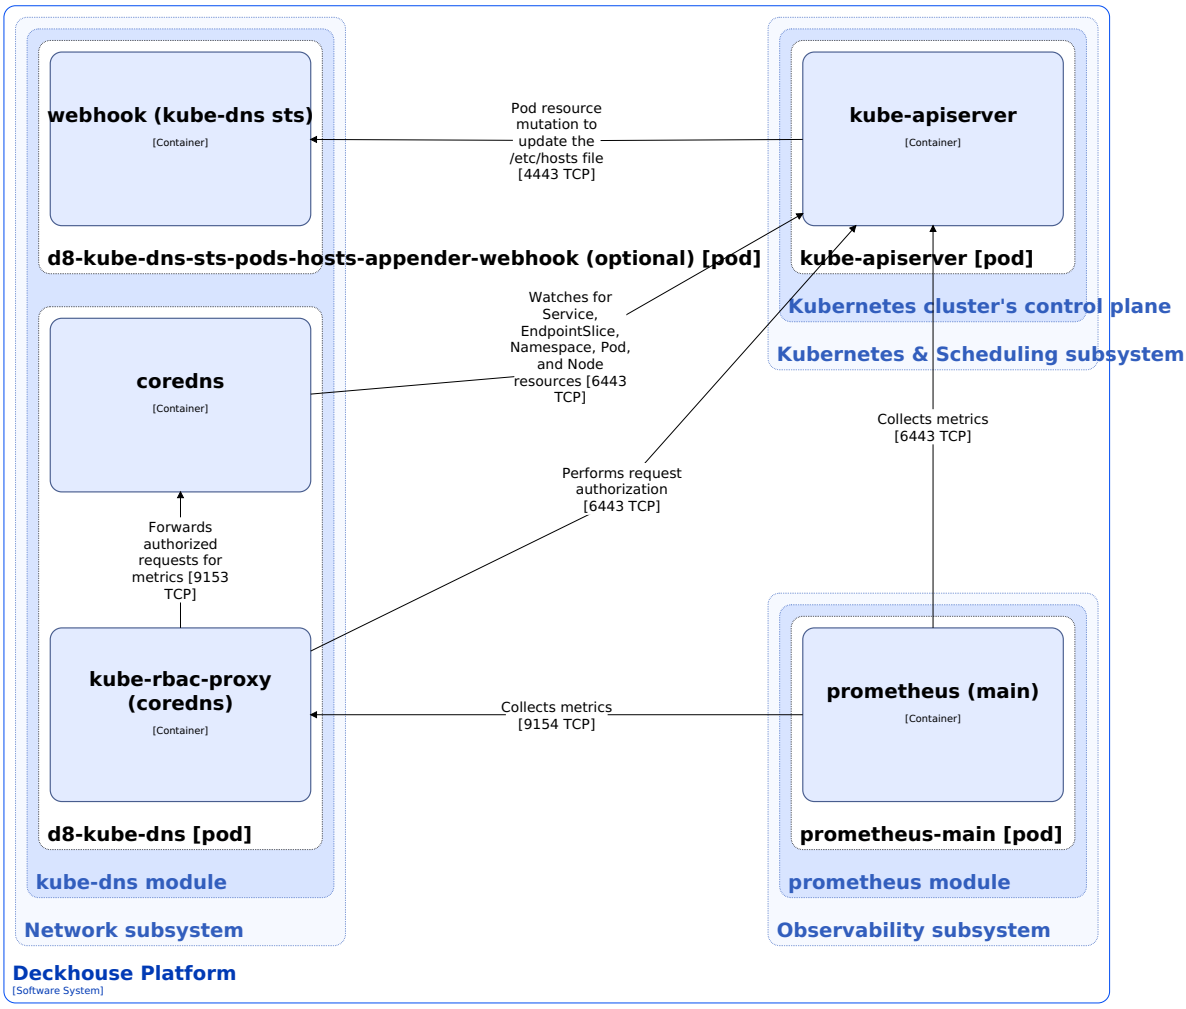
DNS modules

The `kube-dns` module provides domain name resolution based on CoreDNS in Deckhouse Platform (DP).



For more details about module configuration and usage examples, refer to the corresponding documentation section.

kube-dns module

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `kube-dns` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The `kube-dns` module consists of the following components:

1. **D8-kube-dns** (Deployment): Main module component implementing a DNS server in the Kubernetes cluster.

   The d8-kube-dns component watches changes in standard Service, EndpointSlice, Namespace, and Pod resources, and periodically requests Node resources. Based on the data it receives, d8-kube-dns updates records in the local object database.

   It consists of the following containers:

   - **coredns**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to coredns metrics. It is an Open Source project.

2. **D8-kube-dns-sts-pods-hosts-appender-webhook** (Deployment): Optional component that consists of a single **webhook** container.

   The Deckhouse controller of the `deckhouse` module creates this component if the `.spec.settings.clusterDomainAliases` parameter is set in ModuleConfig.

   The component implements a mutating webhook server that adds the **render-etc-hosts-with-cluster-domain-aliases** init container to a pod created by a StatefulSet controller if the `.spec.subdomain` option is specified in the pod spec.

   The init container modifies the `/etc/hosts` file so that the name resolution subsystem works correctly with cluster domain aliases.

Module interactions

The module interacts with the following components:

- **Kube-apiserver**:
  - Watches standard Service, Endpoint, EndpointSlice, Namespace, Pod, and Node resources.
  - Authorizes requests for metrics.

The following external components interact with the module:

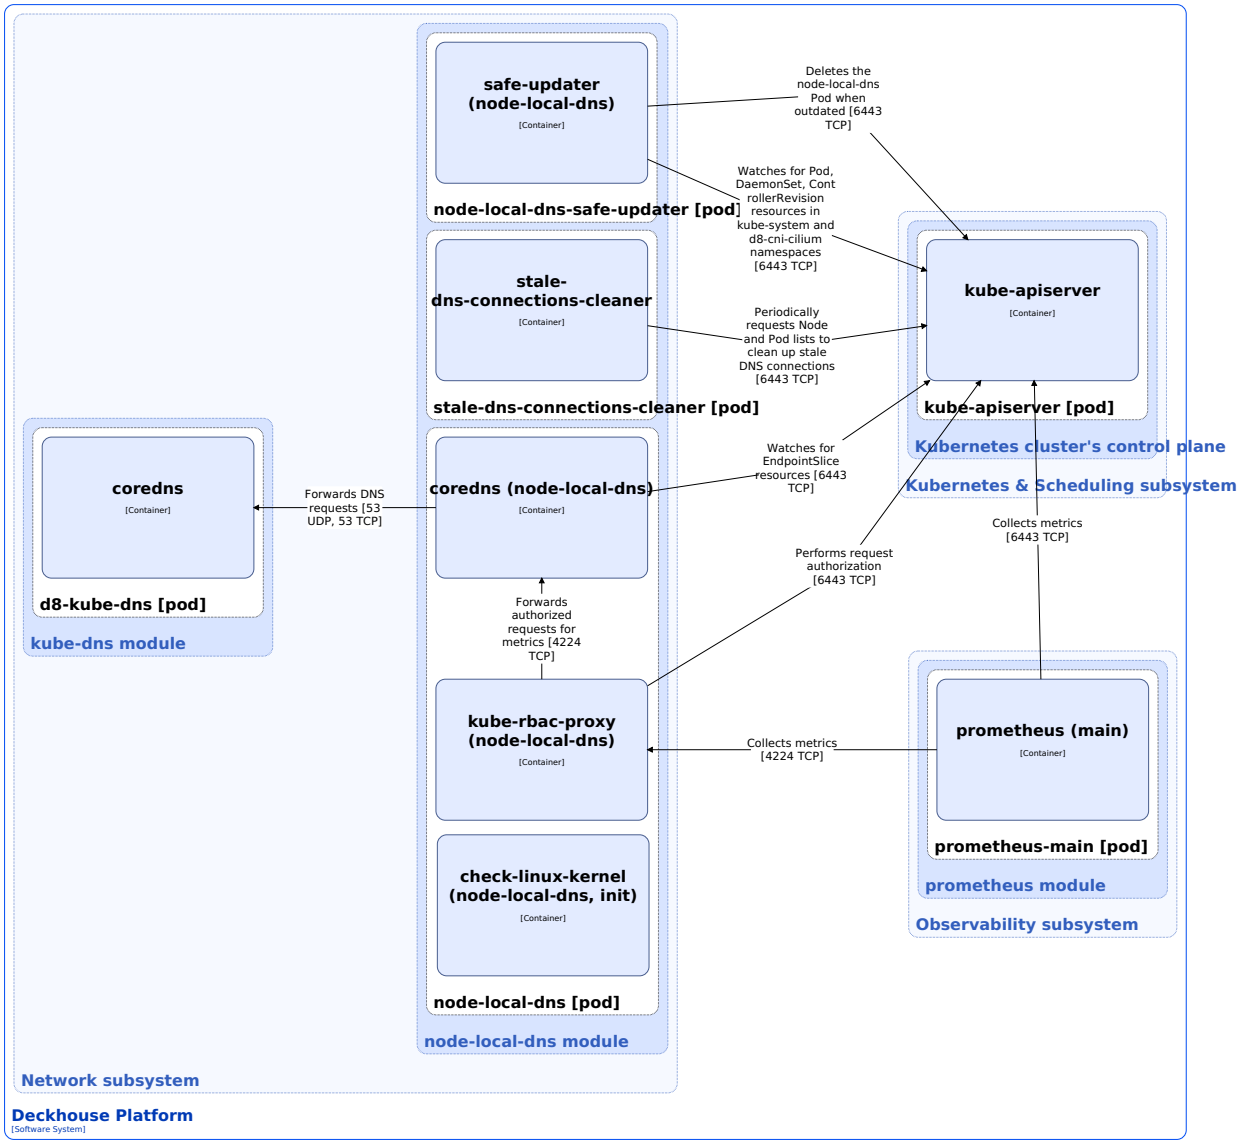
1. **Kube-apiserver**: Modifies Pod resources created by the StatefulSet controller.
2. **Prometheus-main**: Collects module metrics.

node-local-dns module

The `node-local-dns` module provides a caching DNS service and a DNS request forwarding mechanism on each cluster node, reducing the load on `coredns` of the `kube-dns` module.

Depending on the CNI plugin used, the `node-local-dns` module implements different DNS request forwarding mechanisms:

- When using `cni-cilium`, Cilium handles DNS request forwarding using the CiliumLocalRedirectPolicy custom resource.
- When using `cni-flannel` or `cni-simple-bridge`, iptables handles DNS request forwarding.



For more details about module configuration and usage examples, refer to the corresponding documentation section.

When using cni-cilium

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `node-local-dns` module when using Cilium as the CNI plugin and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The `node-local-dns` module consists of the following components:

1. **Node-local-dns** (DaemonSet): Main module component implementing a caching DNS server in the Kubernetes cluster.

   The node-local-dns component watches changes in standard EndpointSlice resources and uses them to update the list of DNS servers for forwarding requests.

   It consists of the following containers:

   - **check-linux-kernel**: Init container that checks the Linux kernel version.
   - **coredns**: Main container.
   - **cube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to coredns metrics. It is an Open Source project.

2. **Stale-dns-connections-cleaner** (DaemonSet): Component that removes stale UDP connections left after the `node-local-dns` Pod is restarted. It consists of a single **stale-dns-connections-cleaner** container.

   > ⚠ The component has privileged access to the network subsystem of each node. On Linux, this requires the `CAP_NET_ADMIN` capability. This access is required to perform network connection operations at the Linux kernel level.

3. **Safe-updater** (Deployment): Component that provides safe restarts of node-local-dns when the DaemonSet spec changes.

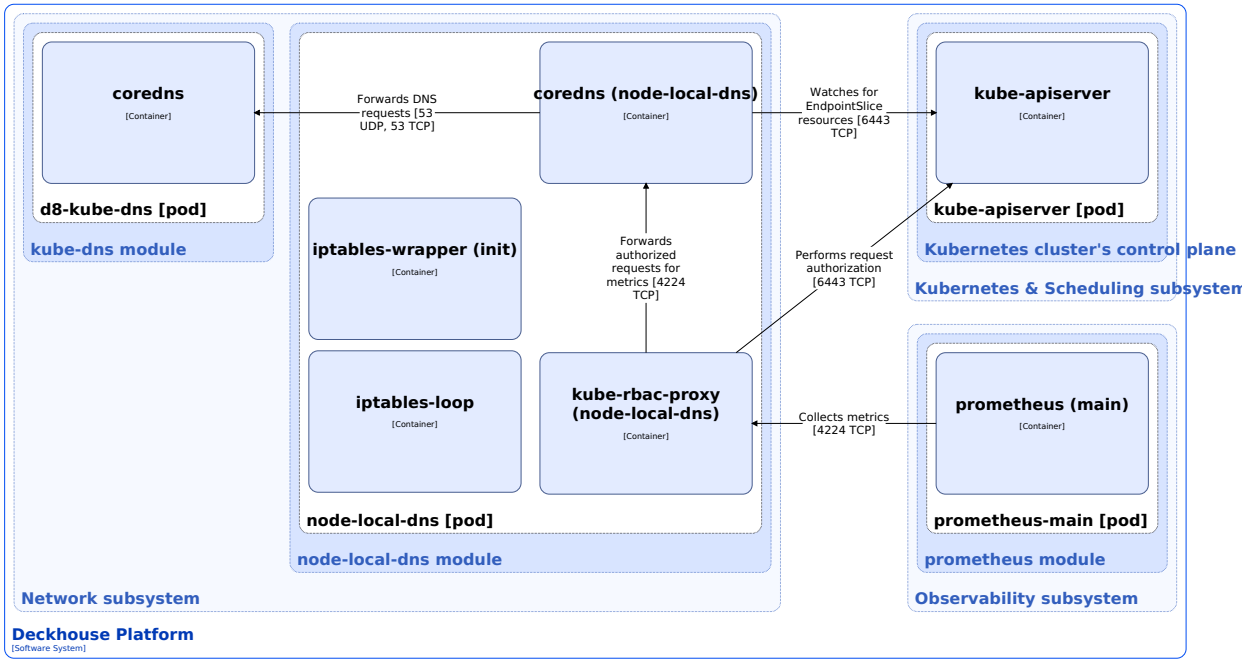
   Safe-updater checks that Cilium is running on the node and is in a correct state, and only then sends a command to delete the `node-local-dns` Pod.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches standard EndpointSlice, DaemonSet, ControllerRevision, and Pod resources.
   - Periodically retrieves Node resources.
   - Deletes the `node-local-dns` Pod when the DaemonSet configuration becomes outdated.
   - Authorizes requests for metrics.
2. **D8-kube-dns**: Executes DNS requests.

The following external components interact with the module:



- **Prometheus-main**: Collects module metrics.

When using cni-flannel or cni-simple-bridge

Module architecture

> **i** The following simplifications are made in the diagram:
>

Cluster-level Istio architecture

> **i** Compatibility between Istio versions and Kubernetes versions is defined by the compatibility table in the `istio` module documentation. Before using Istio, refer to the current versions and their status in that section.

The Istio components are divided into two categories:

- **Control plane**: Managing and maintaining services. The control plane usually refers to istiod Pods.
- **Data plane**: Istio application part composed of a set of sidecar-proxy containers.

All data plane services are grouped into a service mesh with the following features:

- It has a common namespace for generating service ID in the following format: `<TrustDomain>/ns/<Namespace>/sa/<ServiceAccount>`. Each service mesh has a TrustDomain ID (in this case, it matches the cluster domain), for example, `mycluster.local/ns/myns/sa/myapp`.
- Authentication of services within a single service mesh using trusted root certificates.

Control plane components:

- **Istiod**: Main service working through the following tasks:
  - Continuous connection to the Kubernetes API and collecting information about services.
  - Processing and validating all Istio-related custom resources using the Kubernetes Validating Webhook mechanism.
  - Configuring each sidecar proxy individually:
    - Generating authorization, routing, balancing rules, etc.
    - Distributing information about other application services in the cluster.
    - Issuing individual client certificates for implementing Mutual TLS. These certificates are unrelated to the certificates that Kubernetes uses for its own service needs.
  - Automatic tuning of manifests that describe application Pods via the Kubernetes Mutating Webhook mechanism:
    - Injecting an additional sidecar-proxy service container.
    - Injecting an additional init container for configuring the network subsystem (configuring DNAT to intercept application traffic).
    - Routing readiness and liveness probes through the sidecar-proxy.
- **Operator**: Installs all the resources required to operate a specific version of the control plane.
- **Kiali**: Dashboard for monitoring and controlling Istio resources as well as user services managed by Istio:
  - Visualizing relationships between services.
  - Diagnosing problematic relationships.

    - Diagnosing control plane health.

With Istio enabled, the Ingress controller behavior is changed as follows:

- A sidecar proxy is added to the controller Pods. It only handles traffic from the controller to the application services (the `enableIstioSidecar` parameter of the IngressNginxController resource).
- Services not managed by Istio continue to function as before, requests to them are not intercepted by the controller sidecar.
- Requests to services running under Istio are intercepted by the sidecar and processed according to Istio rules. For details on enabling Istio for applications, refer to the corresponding documentation page.

The istiod controller and sidecar-proxy containers export their own metrics that the cluster-wide Prometheus collects.

Estimating overhead

Using Istio will incur additional resource costs for both control plane (istiod controller) and data plane (istio sidecars).

Control plane

The istiod controller continuously monitors the cluster configuration, compiles the settings for the data plane istio sidecars and distributes them over the network. Therefore, the more applications and their instances, the more services, and the more frequently this configuration changes, the more computational resources are required and the greater the load on the network.

Two approaches are supported to reduce the load on controller instances:

- Horizontal scaling (the `controlPlane.replicasManagement` parameter of the `istio` module). The more controller instances, the fewer instances of istio sidecars to serve for each controller and the less CPU and network load.
- Data plane segmentation using the Sidecar resource (recommended approach). The smaller the scope of an individual istio sidecar, the less data in the data plane needs to be updated and the less CPU and network load.

A rough estimate of overhead for a control plane instance that serves 1000 services and 2000 istio sidecars is 1 vCPU and 1.5 GB RAM.

Data plane

The consumption of data plane resources (istio sidecars) is affected by many factors:

- Number of connections
- The intensity of requests
- Size of requests and responses
- Protocol (HTTP/TCP)
- Number of CPU cores
- Complexity of the service mesh configuration

A rough estimate of the overhead for an istio sidecar instance is 0.5 vCPU for 1000 requests/sec and 50 MB RAM.

Istio sidecars also increase latency in network requests, about 2.5 ms per request.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Application service architecture with Istio enabled

> Compatibility between Istio versions and Kubernetes versions is defined by the compatibility table in the `istio` module documentation. Before using Istio, refer to the current versions and their status in that section.

Architecture features

- **Sidecar proxy**: Each application service Pod gets a sidecar container, a sidecar proxy, with two applications:
    - **Envoy**: Proxies application traffic. It is responsible for implementing all the Istio functionality, including routing, authentication, authorization, etc.
    - **Pilot-agent**: A part of Istio that is responsible for keeping the Envoy configuration up to date and has a built-in caching DNS server.
- **DNAT settings**:
    - DNAT of incoming and outgoing application requests in the sidecar proxy is configured in each Pod using an additional init container. Thus, traffic will be intercepted transparently for applications.
    - Since incoming traffic is redirected to the sidecar proxy, this also applies to readiness/liveness probes. Since the Kubernetes subsystem does not support Mutual TLS probes, all existing probes are redirected to a port in the sidecar proxy, which passes them to the application unchanged.
- **Ingress Controller**:
    - Each Pod of an Ingress controller also includes a sidecar proxy, which handles traffic between the controller

    and services.
    - Incoming traffic from users is handled directly by the controller.
- **Ingress resources**: These resources require minimal modification in the form of adding annotations:
    - `nginx.ingress.kubernetes.io/service-upstream: "true"`: The Ingress controller will use the service's ClusterIP as upstream instead of the Pod addresses. In this case, traffic balancing between the Pods is handled by the sidecar proxy. Use this option only if your service has a ClusterIP.
    - `nginx.ingress.kubernetes.io/upstream-vhost: "myservice.myns.svc"`: The Ingress controller's sidecar proxy makes routing decisions based on the `Host` header. If this annotation is omitted, the controller will leave a header with the site address (for example, `Host: example.com`).
- **Services**:
    - Service resources do not require modifications and continue to work without adaptation. Applications can still access service addresses like `servicename`, `servicename.myns.svc`, etc.
- **DNS queries**:
    - Internal DNS queries of Pods are transparently redirected to the sidecar proxy for processing to resolve DNS names of services from neighboring clusters.

User request lifecycle

Caching DNS server in a cluster

Standard DNS operation in Kubernetes comes with a series of issues that may cause degradation of key service performance indicators:

- By default, the Linux kernel does not cache DNS requests, so there is no local cache in Pods.
- All DNS requests from a container result in a network request to the cluster DNS. This is also true for requests to resources located on the same node.
- A Pod's DNS request is first resolved through cluster DNS zones, and only afterward sent to external DNS servers. For example, a request to `ya.com` will first be resolved through cluster zones like `cluster.local`, `svc.cluster.local`, and `<namespace>.svc.cluster.local`. Only after receiving negative responses (meaning, on the second attempt or later) it will be resolved correctly.

Any minor network delays can significantly degrade service quality due to the above-mentioned issues.

One possible solution is to install a DNS server on each node. In Deckhouse Platform, this is implemented using the `node-local-dns` module.

When using a caching DNS server, external requests (that are not already cached) will still be attempted to resolve through the internal zone chain first. Under high load (for example, with many repeated requests per second for the same records, which is common), caching is enough to significantly improve DNS resolution performance.

Caching DNS server operation principles

When the caching DNS server is deployed, the `node-local-dns` module applies the following configuration steps on each cluster node:

- Configuring an interface with the IP address of the `kube-dns` service's clusterIP.
- Starting a caching CoreDNS that listens on that address.
- Adding an iptables rule: if the socket is open, traffic is redirected to it. Otherwise, a standard Kubernetes routing via ClusterIP is used:

  ```
  -A PREROUTING -d <kube-dns IP address> -m socket --nowildcard -j NOTRACK
  ```

CoreDNS configuration aspects

Key characteristics of the CoreDNS configuration:

- All requests are cached.
- All DNS requests are forwarded to the cluster DNS ClusterIP.

Grafana dashboard

The `Kubernetes / DNS (node local)` dashboard displays:

- General charts (providing an overall view of DNS performance),
- Per-node charts (helping investigate node-specific issues identified in the general charts),

- Upstream charts (helping evaluate performance of the cluster DNS and node DNS servers specified in `/etc/resolv.conf`).

>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Storage subsystem

This subsection describes the architecture of the Storage subsystem of Deckhouse Platform (DP).

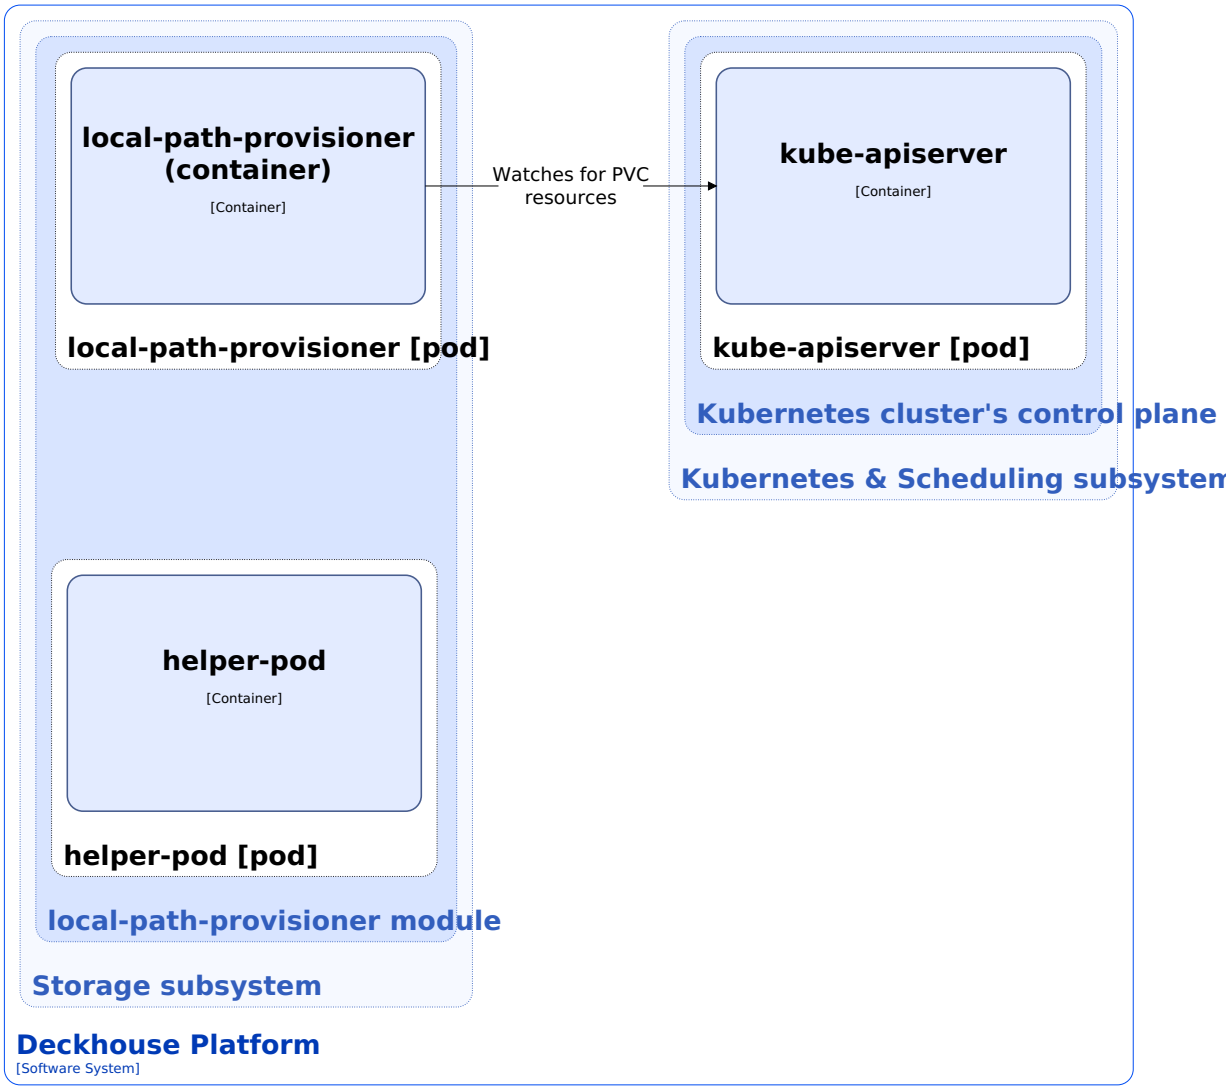
The Storage subsystem includes the following modules:

- `local-path-provisioner`: Provides the local storage on Kubernetes nodes using `HostPath` volumes and creates StorageClass resources to manage the allocation of local storage.
- `snapshot-controller`: Enables snapshot support for compatible CSI-drivers in the Kubernetes cluster.
- `sds-local-volume`: Manages the local block storage based on LVM and enables creating StorageClass resources in Kubernetes using the LocalStorageClass resource.
- `sds-node-configurator`: Manages block devices and LVM on Kubernetes cluster nodes through Kubernetes custom resources.
- `sds-replicated-volume`: Manages replicated block storage based on DRBD. LINSTOR is used as a control plane.
- `storage-volume-data-manager`: Provides secure export and import of persistent volume contents over HTTP protocol.

- Modules that provide a CSI driver implementation for integration with various types of storage (software and hardware):
  - `csi-ceph`
  - `csi-hpe`
  - `csi-huawei`
  - `csi-netapp`
  - `csi-nfs`
  - `csi-s3`
  - `csi-scsi-generic`
  - `csi-vsphere`
  - `csi-yadro-tatlin-unified`

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Local-path-provisioner module



The `local-path-provisioner` module provides the local storage on Kubernetes nodes using `HostPath` volumes and creates StorageClass resources to manage the allocation of local storage.

For more details about module, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `local-path-provisioner` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagrams:

Module components

The module consists of the following components:

1. **Local-path-provisioner**: It performs the following actions when a pod orders a disk:
   - Creates a PersistentVolume of the `HostPath` volume type.
   - Creates a local disk directory for the volume on the target node. The directory path is based on the `path` parameter of the LocalPathProvisioner custom resource, as well as the PersistentVolume and PersistentVolumeClaim names.

   It consists of a single container:

   - **local-path-provisioner**: It is an open source project.
2. **Helper-pod**: It runs an installation script (`SETUP`) on the node before creating the volume to prepare the volume directory on the node and a cleanup script (`TEARDOWN`) after deleting the volume to clear the volume directory on the node.

   It consists of a single container:

   - **helper-pod**

Module interactions

The module interacts with the following components:

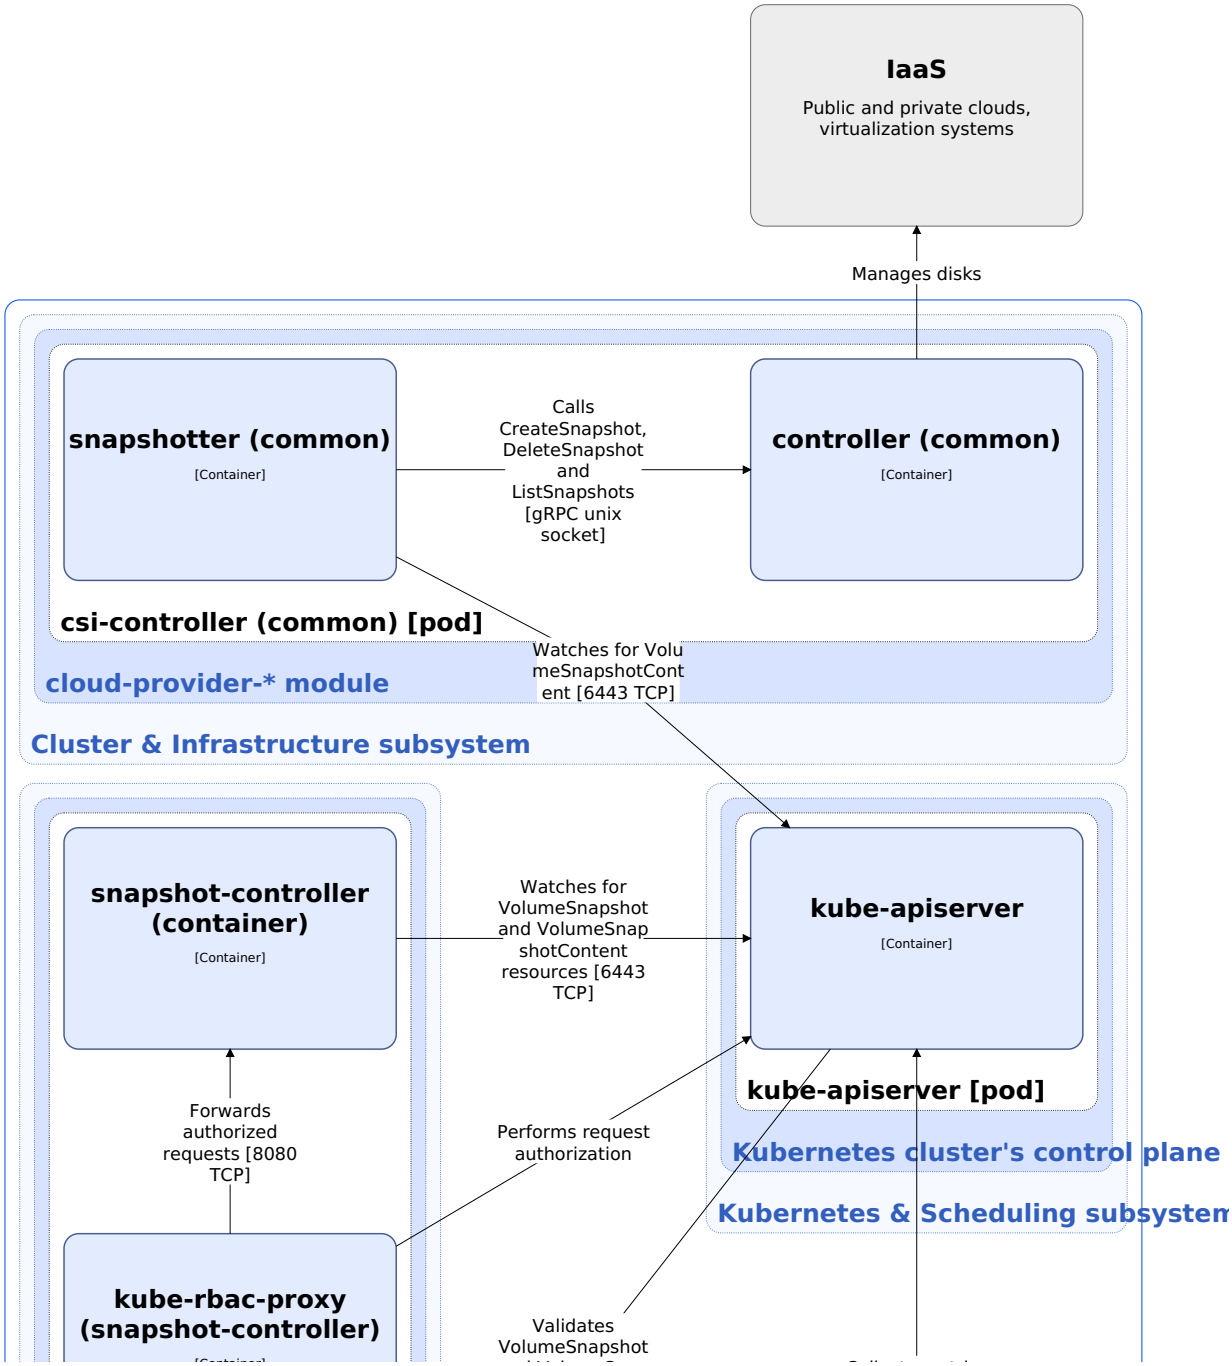
1. **Kube-apiserver**:
   - Manages PersistentVolumeClaim resources.

Additional resources

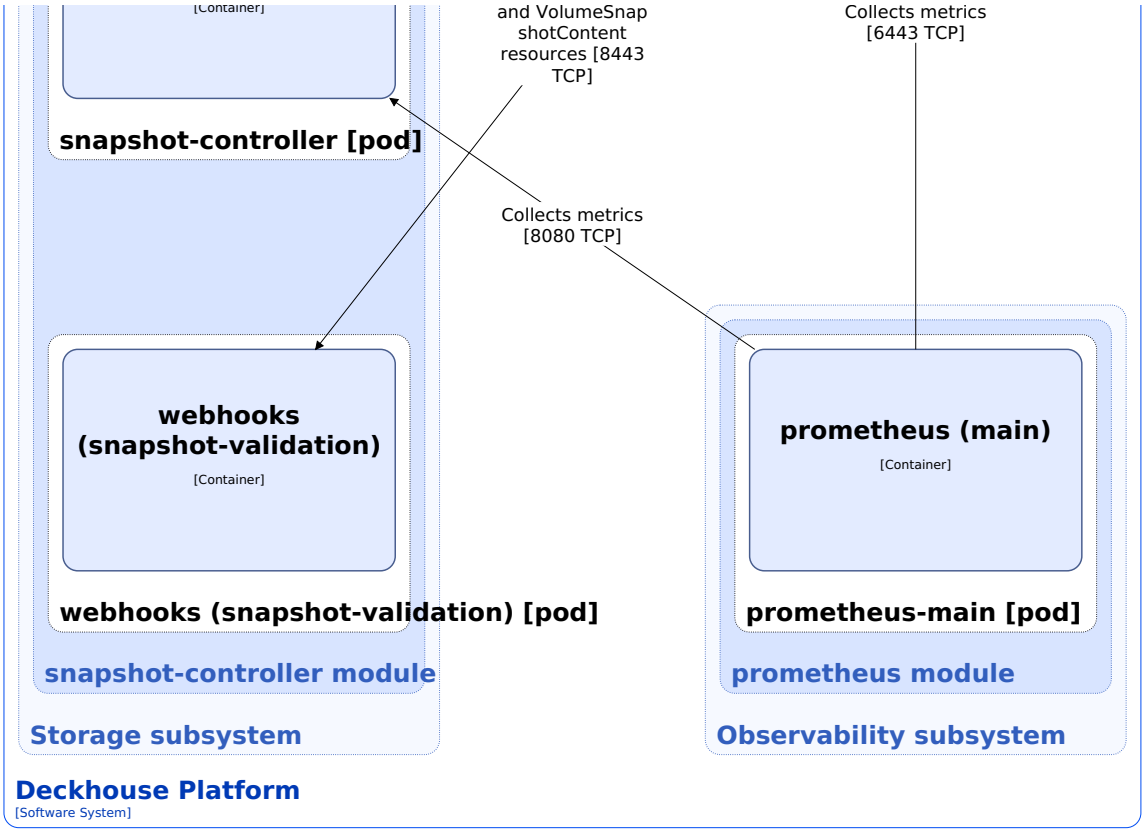
- Module `local-path-provisioner` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Snapshot-controller module



The `snapshot-controller` enables snapshot support for compatible CSI-drivers in Deckhouse Platform (DP).



For more details about the module, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `snapshot-controller` module and its interactions with other components of DP are shown in the following diagrams:

Module components

The module consists of the following components:

1. **Snapshot-controller**: Works in conjunction with the snapshotter (external-snapshotter) sidecar container of the csi-controller Pod of the `cloud-provider-*` module (as long as the provider's CSI driver supports snapshot creation).

   A single snapshot-controller is used for all installed CSI drivers. It watches for VolumeSnapshot and VolumeSnapshotContent resources. When a new VolumeSnapshot resource is created, the controller creates a VolumeSnapshotContent resource and binds them together. As a result, VolumeSnapshot points to a respective VolumeSnapshotContent, and that VolumeSnapshotContent points to the original VolumeSnapshot.

   Snapshot creation is multi-step process:

   1. Snapshot-controller creates a VolumeSnapshotContent resource.
   2. The snapshotter sidecar triggers snapshot creation through csi-controller on the corresponding node and updates the VolumeSnapshotContent status (`snapshotHandle`, `creationTime`, `restoreSize`, `readyToUse`, and `error` fields).
   3. Snapshot-controller watches for the VolumeSnapshotContent status and keeps updating the VolumeSnapshot status until the bi-directional binding is complete and the `readyToUse` field is set to `true`. If any error occurs, the `error` field is updated accordingly.

   It consists of the following containers:

   - **snapshot-controller**: It is an open-source project.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the controller metrics. It is an open-source project.

2. **Webhooks**: Component implementing a webhook server used for validating the VolumeSnapshot and VolumeSnapshotContent resources through Validating Admission Controllers. It consists of a single container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for VolumeSnapshot and VolumeSnapshotContent resources.
   - Authorizes requests for controller metrics.

The following external components interact with the module:

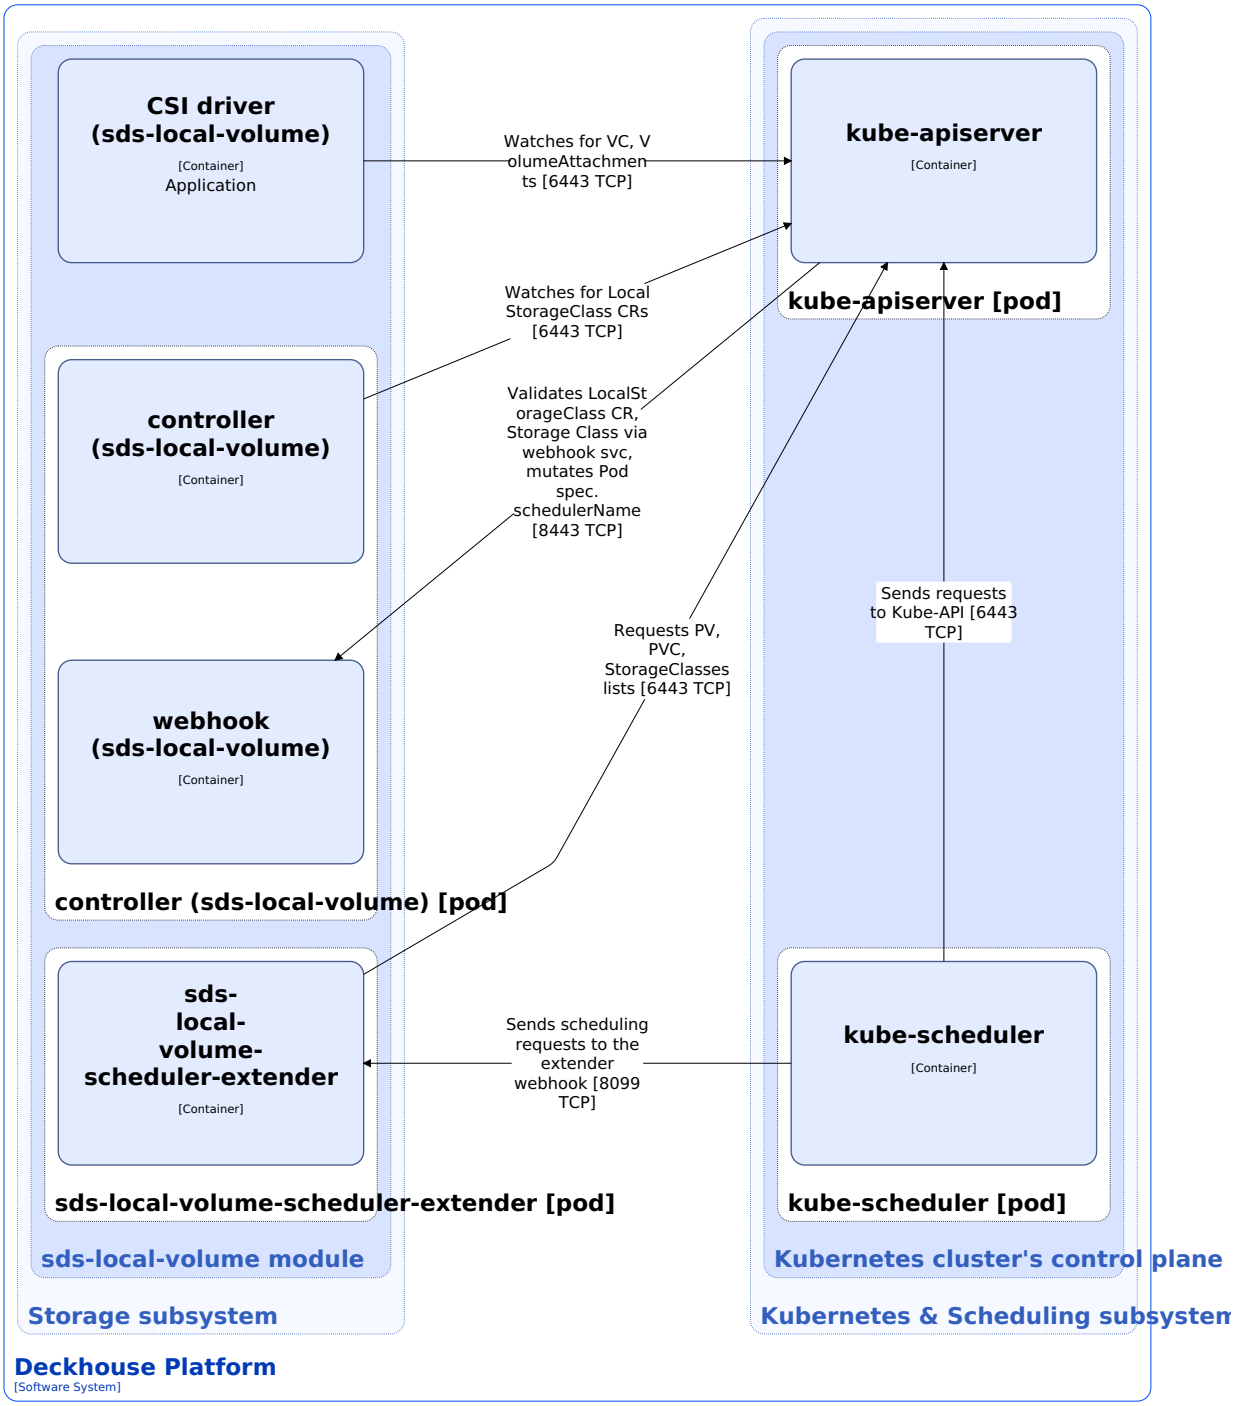
1. **Kube-apiserver**: Uses the validation webhook to verify the created VolumeSnapshot and VolumeSnapshotContent resources.
2. **Prometheus-main**: Collects metrics from the controller.

Additional resources

- Module `snapshot-controller` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Sds-local-volume module



The `sds-local-volume` module is designed to manage local block storage based on LVM. It enables creating StorageClasses in Kubernetes using the LocalStorageClass resource.

For more details about module, refer to the module documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `sds-local-volume` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagrams:

Module components

The module consists of the following components:

1. **Controller**: It reconciles LocalStorageClass custom resources. LocalStorageClass is a Kubernetes custom resource that defines the configuration for Kubernetes StorageClass. The StorageClass being created uses `local.csi.storage.deckhouse.io` provisioner. StorageClass configures LVM logical volume types, VolumeGroups settings, reclaim policy, volume binding mode, etc. These settings are used by the provisioner of CSI driver (`sds-local-volume`) when managing LVM-based local volumes.

   It consists of the following containers:

   - **controller**: Main container.
   - **webhook**: A sidecar container that implements a webhook server for validating LocalStorageClass custom resources, StorageClass resources, as well as for mutating the `spec.schedulerName` attribute of pods using volumes created by `local.csi.storage.deckhouse.io` provisioner. As a result of the mutation, `sds-local-volume` is filled in the name of the scheduler (`spec.schedulerName`) in the pod specification, so that the placement of the pod is determined not by the standard Kubernetes scheduler (kube-scheduler), but by the `sds-local-volume-scheduler-extender` component from this module.

2. **Sds-local-volume-scheduler-extender**: It consists of a single container. It is a kube-scheduler extender, which implements a scheduling logic specific for pods using local volumes. When planning, the free space on the nodes used to place local volumes on them is taken into account, as well as the size of the disk space that needs to be reserved for these volumes.

3. **CSI driver (`sds-local-volume`)**: It is an implementation of the CSI driver for `local.csi.storage.deckhouse.io`. To study the CSI driver typical architecture used in DP, refer to the CSI-driver architecture documentation section. CSI driver (`sds-local-volume`) is developed by Flant.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolume, PersistentVolumeClaim, VolumeAttachment and StorageClass resources.
   - Reconciles LocalStorageClass custom resources.
   - Creates StorageClass resources.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Validates LocalStorageClass custom resources and StorageClass resources.
   - Mutates `spec.schedulerName` attribute for pods which use volumes created by `local.csi.storage.deckhouse.io` provisioner.
2. **Kube-scheduler**: Sends scheduling requests to the `sds-local-volume-scheduler-extender` webhook for the pods with `sds-local-volume` value specified in the `spec.schedulerName` attribute.

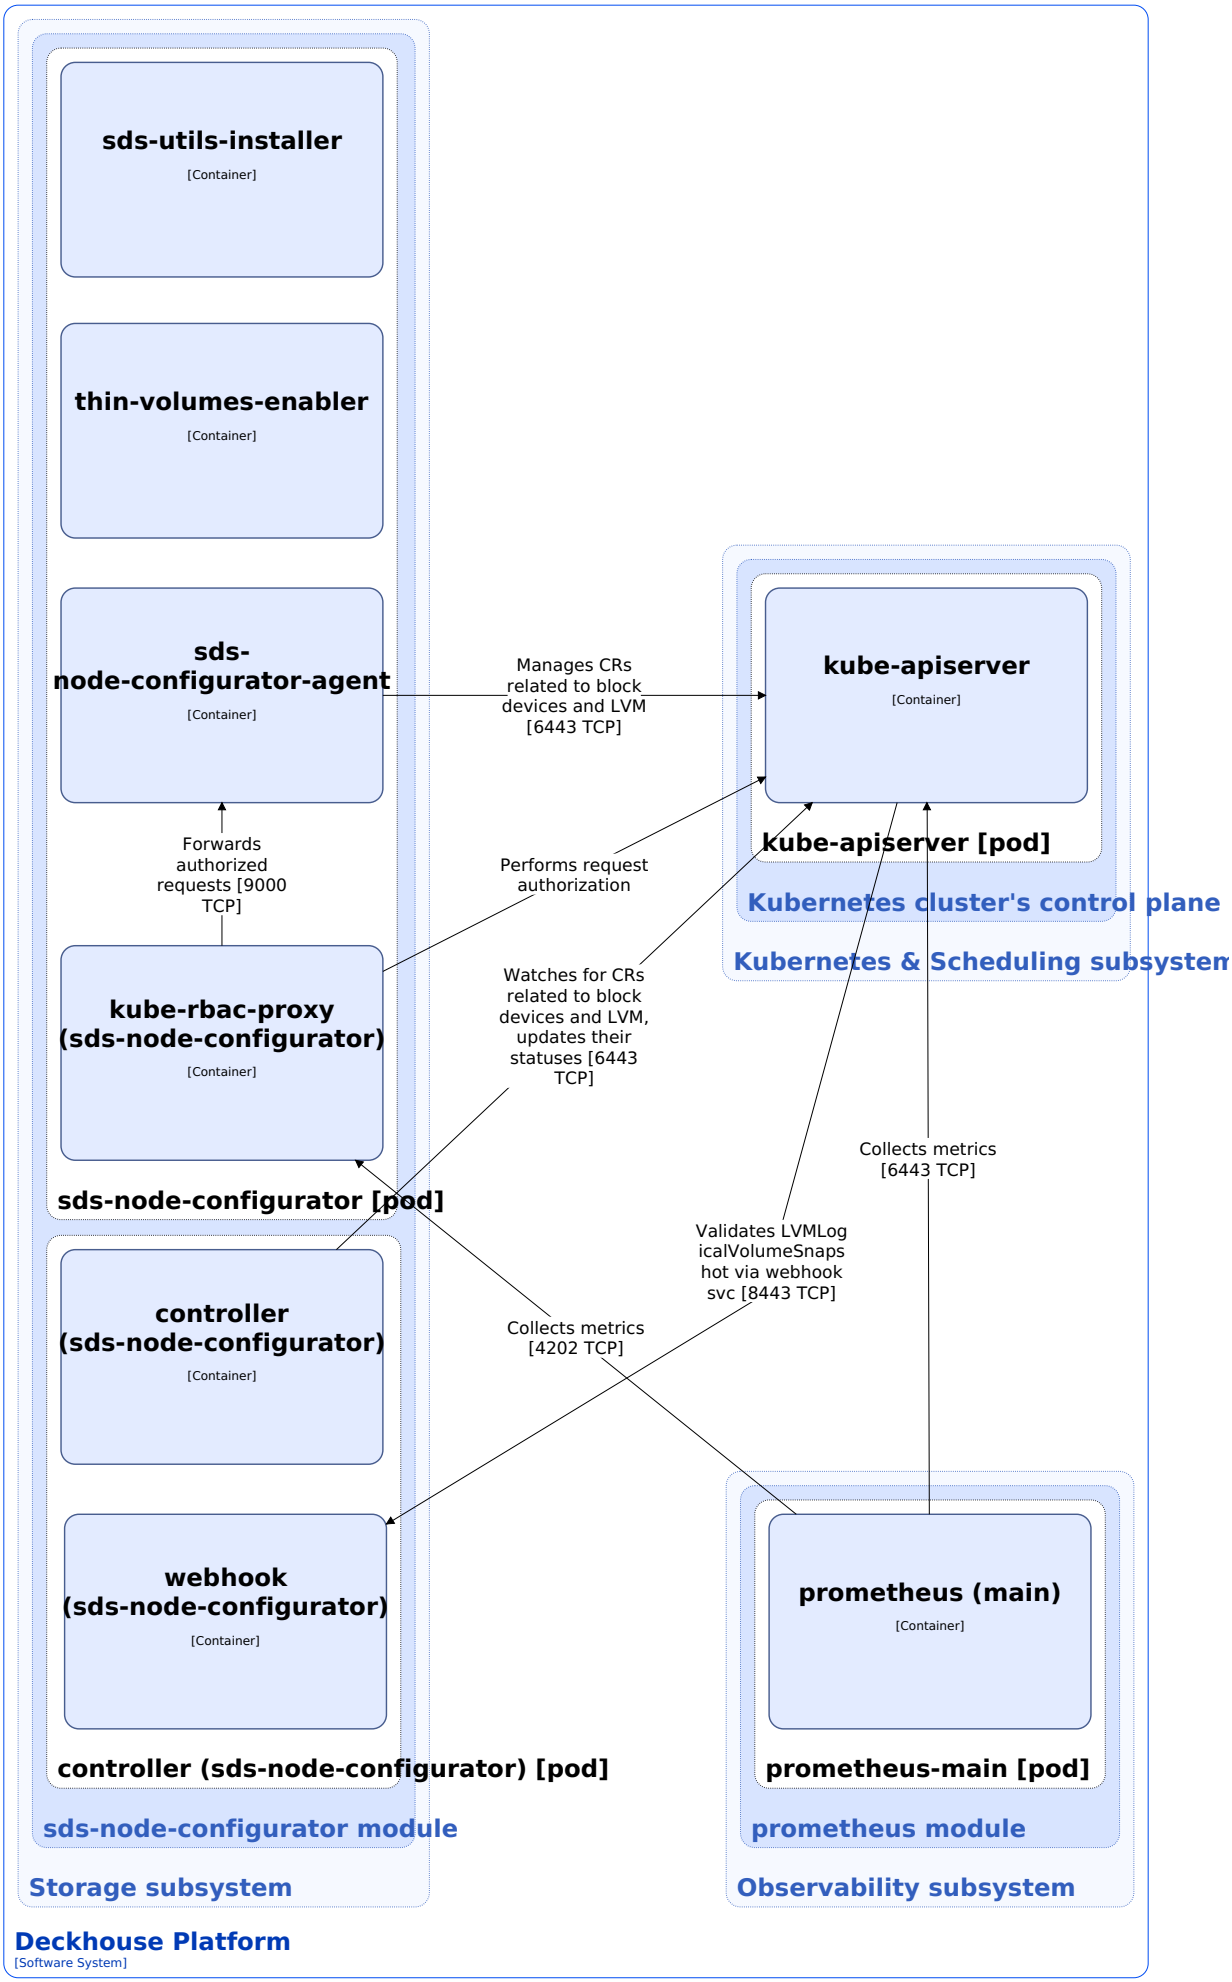
Additional resources

- Module `sds-local-volume` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Sds-node-configurator module

The `sds-node-configurator` manages block devices and LVM on Kubernetes cluster nodes through Kubernetes custom resources, performing following operations:



- Automatic discovery of block devices and creation/update/deletion of corresponding BlockDevice custom resources.
- Automatic discovery of LVM Volume Groups with `storage.deckhouse.io/enabled=true` LVM tag and thin pools on them on nodes, as well as management of corresponding LVMVolumeGroup resources. The module automatically creates a LVMVolumeGroup resource if it doesn't exist yet for the discovered LVM Volume Group.
- Scanning LVM Physical Volumes on nodes that are part of managed LVM Volume Groups. When underlying block devices are expanded, corresponding LVM Physical Volumes are automatically increased (performs pvresize).
- Creation/expansion/deletion of LVM Volume Groups on the node according to LVMVolumeGroup resource settings.

For more details about the module, refer to the module documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

Module components

The module consists of the following components:

1. **Sds-node-configurator** (DaemonSet): A controller running on cluster nodes and performing mentioned above operations with BlockDevice, LVMVolumeGroup, LVMLogicalVolume, LVMLogicalVolumeSnapshot custom resources, etc. The full list of resources managed by the module is provided in the module documentation.

   It consists of the following containers:

   - **sds-utils-installer**: Init container that installs a set of utilities necessary for managing block devices and LVM volumes.
   - **thin-volumes-enabler**: Init container that enables thin volumes.
   - **sds-node-configurator-agent**: Main container.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the controller metrics. It is an open-source project.

2. **Controller** (Deployment): A controller that monitors custom resources related to block devices and LVM. The controller works with the metadata of resources and updates their statuses.

   It consists of the following containers:

   - **controller**: Main container.
   - **webhook**: Sidecar container that implements a webhook server for LVMLogicalVolumeSnapshot custom resources validation. If used edition of DP does not support LVM logical volume snapshots functionality, LVMLogicalVolumeSnapshot custom resource does not pass validation.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Reconciles custom resources related to block devices and LVM.
   - Authorizes requests for metrics.

The following external components interact with the module:

1. **Kube-apiserver**: Validates LVMLogicalVolumeSnapshot custom resources.
2. **Prometheus-main**: Collects `sds-node-configurator` metrics.

Additional resources

- Module `sds-node-configurator` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

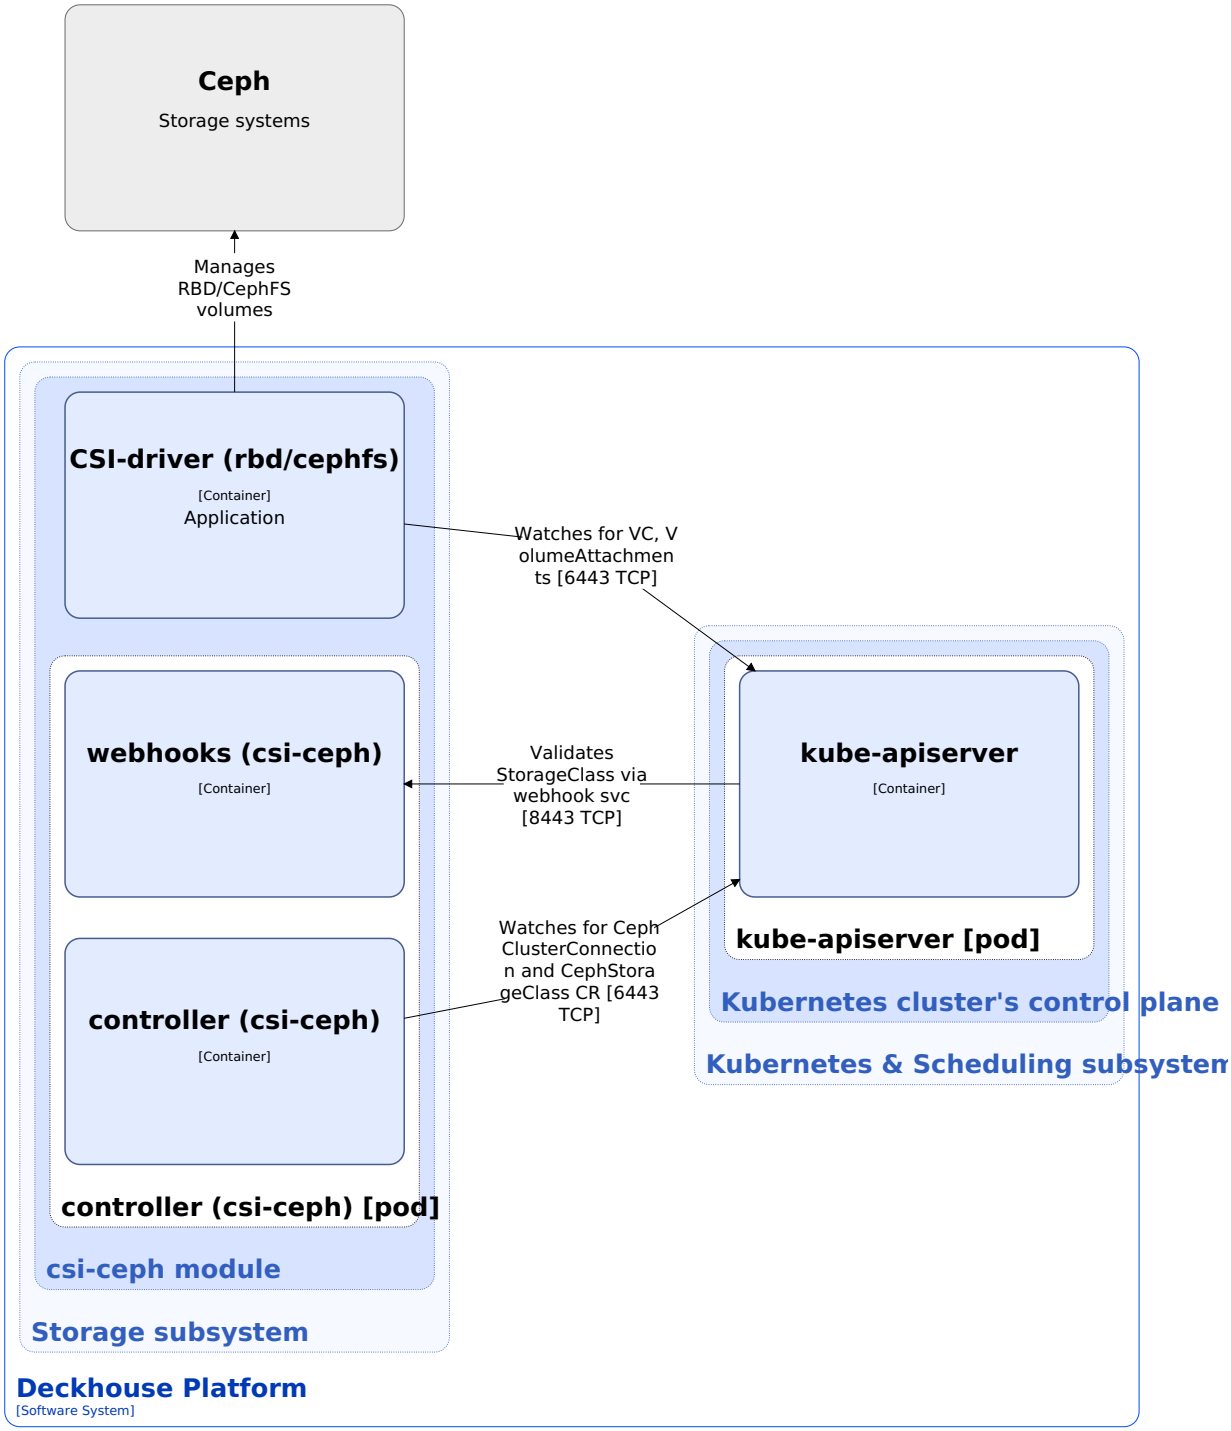
Csi-ceph module



The `csi-ceph` module is designed to integrate DP with Ceph clusters and provides storage management based on RBD (RADOS Block Device) or CephFS. It allows creating StorageClasses in Kubernetes using the CephStorageClass resource.

For more details about the module, refer to the module documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-ceph` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the following custom resources:

   - CephClusterConnection: Ceph cluster connection parameters.
   - CephStorageClass: Defines the configuration for the Kubernetes StorageClass that will be created.

   CephStorageClass specifies the storage class type (`CephFS` or `RBD`), reclaim policy, Ceph cluster connection parameters, and additional parameters specific to each storage class type. Depending on the storage class type, these parameters are used by the provisioner of either the `rbd.csi.ceph.com` or `cephfs.csi.ceph.com` CSI driver when managing volumes.

   The CephMetadataBackup custom resource is used in migration and recovery workflows implemented by module hooks, rather than by the main runtime controller.

   It consists of the following containers:

   - **controller**: Main container.
   - **webhooks**: A sidecar container that implements a webhook server for StorageClass resources validation.

2. **CSI driver (rbd/cephfs)**: An implementation of the CSI driver for the `rbd.csi.ceph.com` or `cephfs.csi.ceph.com` provisioner. The CSI driver is selected by setting the storage class type in the

CephStorageClass custom resource.

The `csi-cephfs` CSI driver follows the standard CSI driver architecture used in DP.

The `csi-rbd` CSI driver uses an architecture that differs from the standard CSI driver architecture.

Module interactions

The module interacts with the following components:

- **Kube-apiserver**:
  - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
  - Reconciles CephClusterConnection and CephStorageClass custom resources.
  - Creates StorageClass resources.

The following external components interact with the module:

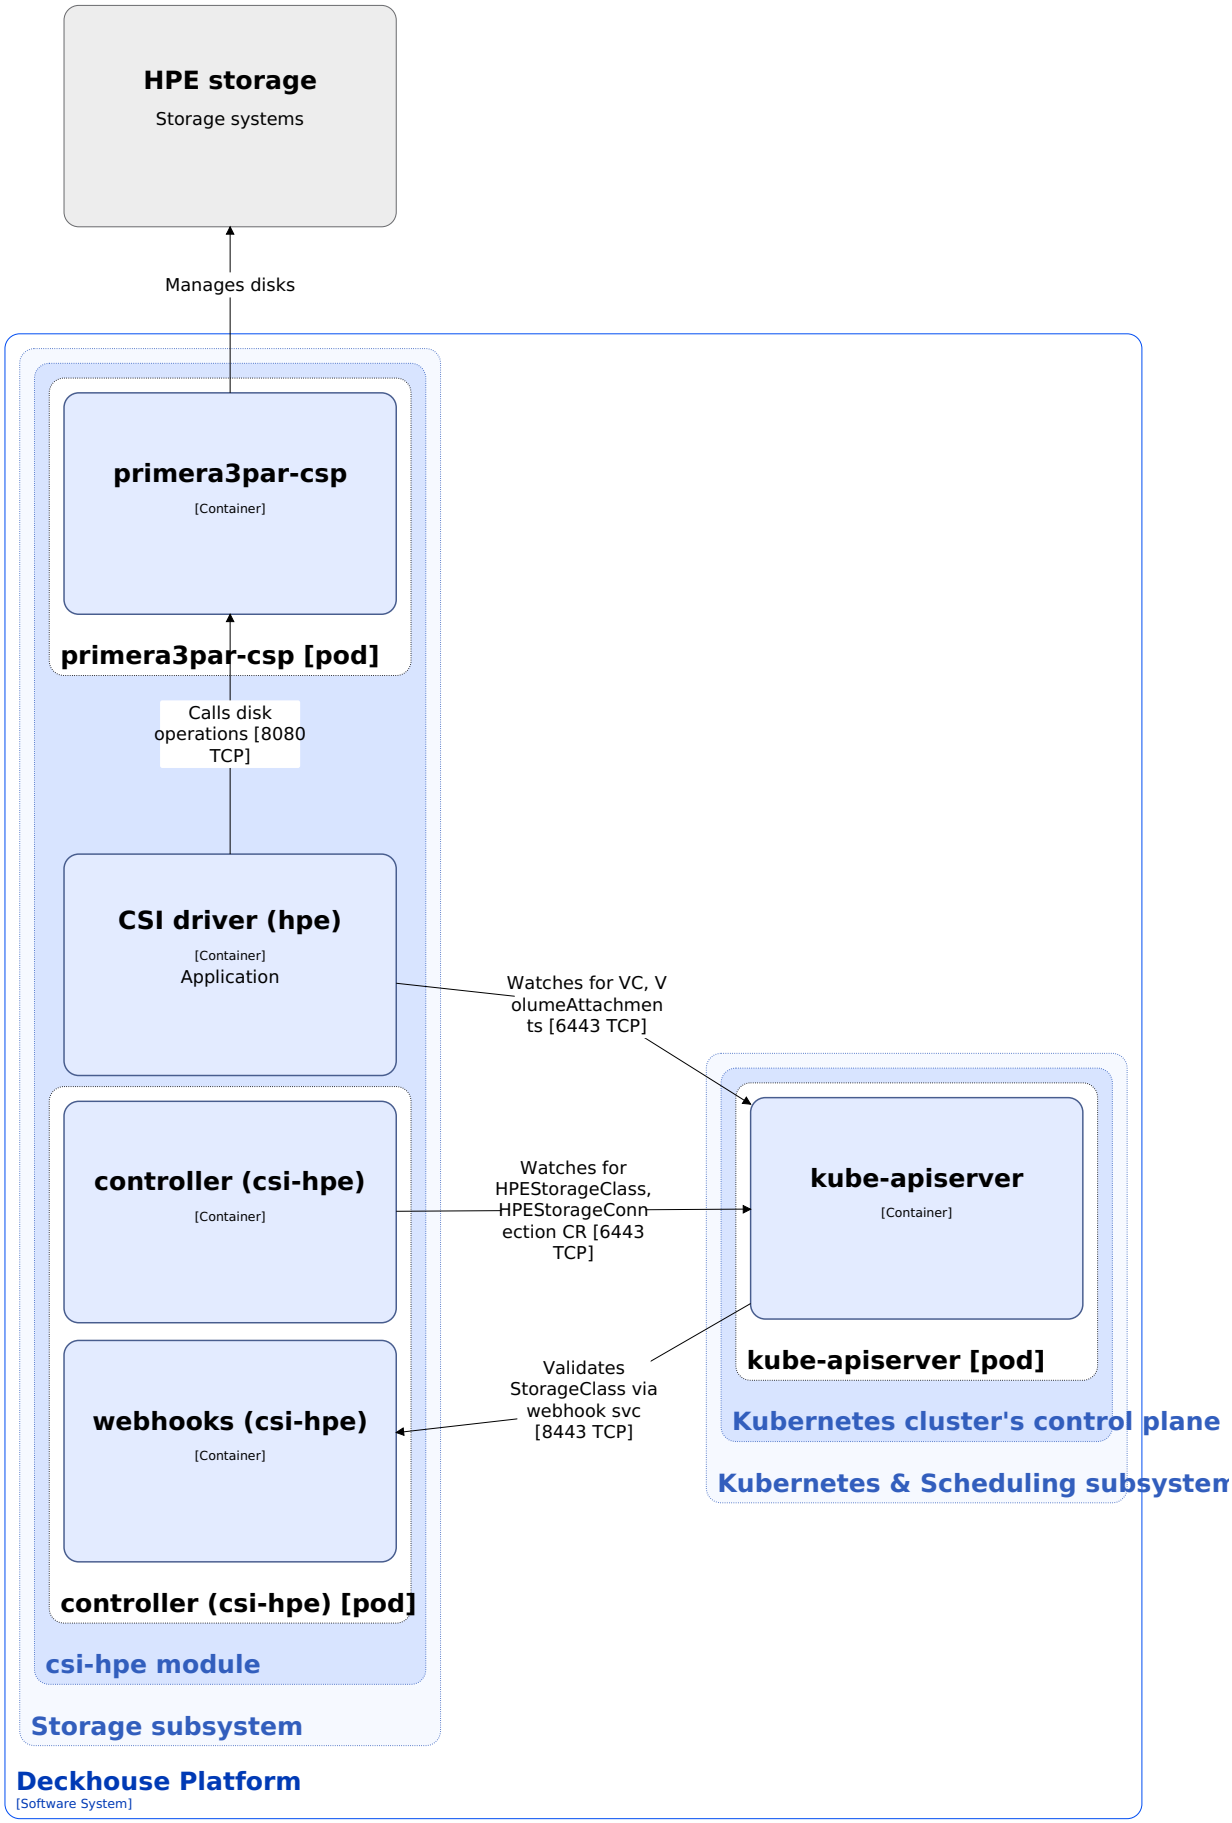
- **Kube-apiserver**: Validates StorageClass resources.

Additional resources

- Module `csi-ceph` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-hpe module



The `csi-hpe` module is designed to manage volumes using HPE storage systems. It enables creating StorageClass resources in Kubernetes using the HPEStorageClass custom resource.

For more details about the module, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-hpe` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the following custom resources:
   - HPEStorageConnection: Parameters for connecting to HPE storage systems.

    - HPEStorageClass: Defines configuration for Kubernetes StorageClass.

  HPEStorageClass defines the connection protocol, resource pool name, filesystem type, and reclaim policy.

  The controller also synchronizes the `storage.deckhouse.io/csi-hpe-node` label on cluster nodes according to the `spec.settings.nodeSelector` value in the ModuleConfig custom resource.

  It consists of the following containers:

    - **controller**: Main container.
    - **webhooks**: Sidecar container implementing a webhook server for StorageClass validation.

2. **CSI driver (hpe)**: CSI driver implementation for the `csi.hpe.com` provisioner. To study the typical CSI driver architecture used in DP, refer to the CSI driver documentation page.
3. **Primera3par-csp**: A service container provider (Container Storage Provider, CSP) responsible for integrating the CSI driver with HPE Primera and 3PAR storage systems. It handles communication between Kubernetes and the storage arrays, manages session handling, and path replication.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
    - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
    - Reconciles HPEStorageConnection and HPEStorageClass custom resources.
    - Creates and updates VolumeSnapshotClass, Secret, and StorageClass resources.
2. **HPE storage system**: Creates, deletes, and manages volumes, and provides multipath data access.

The following external components interact with the module:

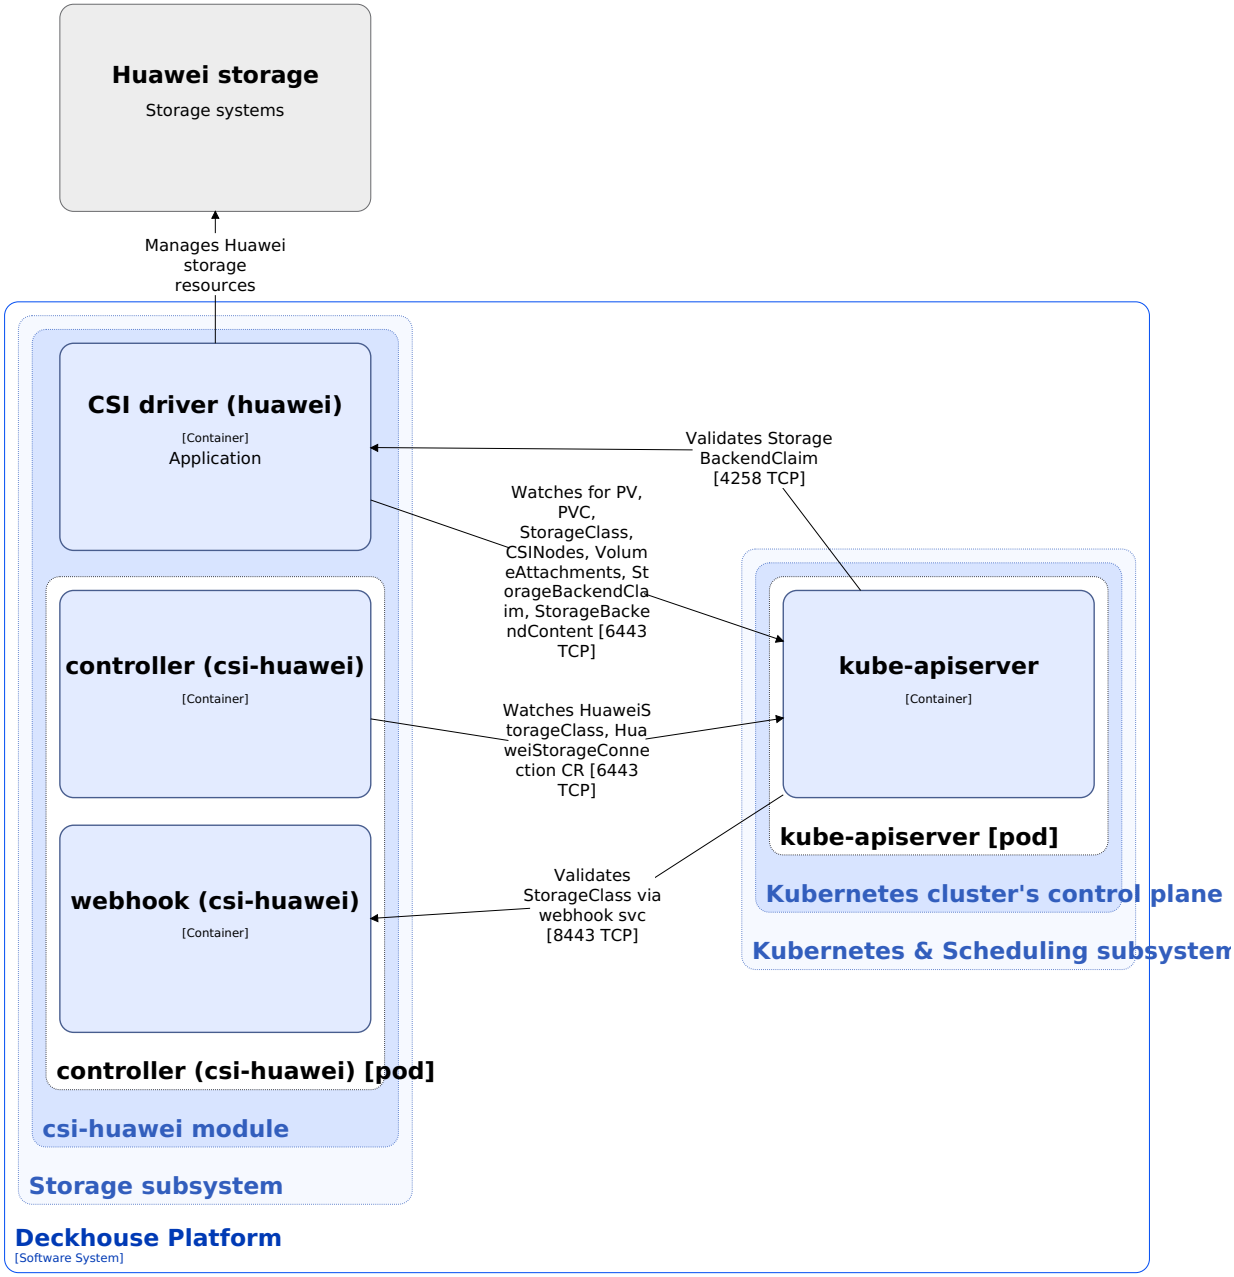
1. **Kube-apiserver**: Validates StorageClass resources.

Additional resources

- Module `csi-hpe` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-huawei module



The `csi-huawei` module is designed to manage volumes using Huawei storage systems. It enables creating StorageClass resources in Kubernetes using the HuaweiStorageClass custom resource.

For more details about the module, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-huawei` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the following custom resources:
   - HuaweiStorageConnection: Parameters for connecting to Huawei storage systems.
   - HuaweiStorageClass: Defines configuration for Kubernetes StorageClass.

   HuaweiStorageClass defines the resource pool name, filesystem type, and reclaim policy.

   It consists of the following containers:

   - **controller**: Main container.
   - **webhooks**: Sidecar container implementing a webhook server for StorageClass validation.
2. **CSI driver (huawei)**: CSI driver implementation for the `csi.huawei.com` provisioner. To study the architecture of the `csi-huawei` CSI driver, refer to the corresponding documentation page.

   The `csi-huawei` CSI driver reconciles the following custom resources:

   - StorageBackendClaim: A request to connect to Huawei storage.
   - StorageBackendContent: Description of the actual connection to Huawei storage.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

    - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
    - Reconciles HuaweiStorageConnection, HuaweiStorageClass, StorageBackendClaim, and StorageBackendContent custom resources.
    - Creates StorageClass resources.

2. **Huawei storage system**: Creates and deletes volumes, and attaches/detaches volumes to/from nodes.

The following external components interact with the module:

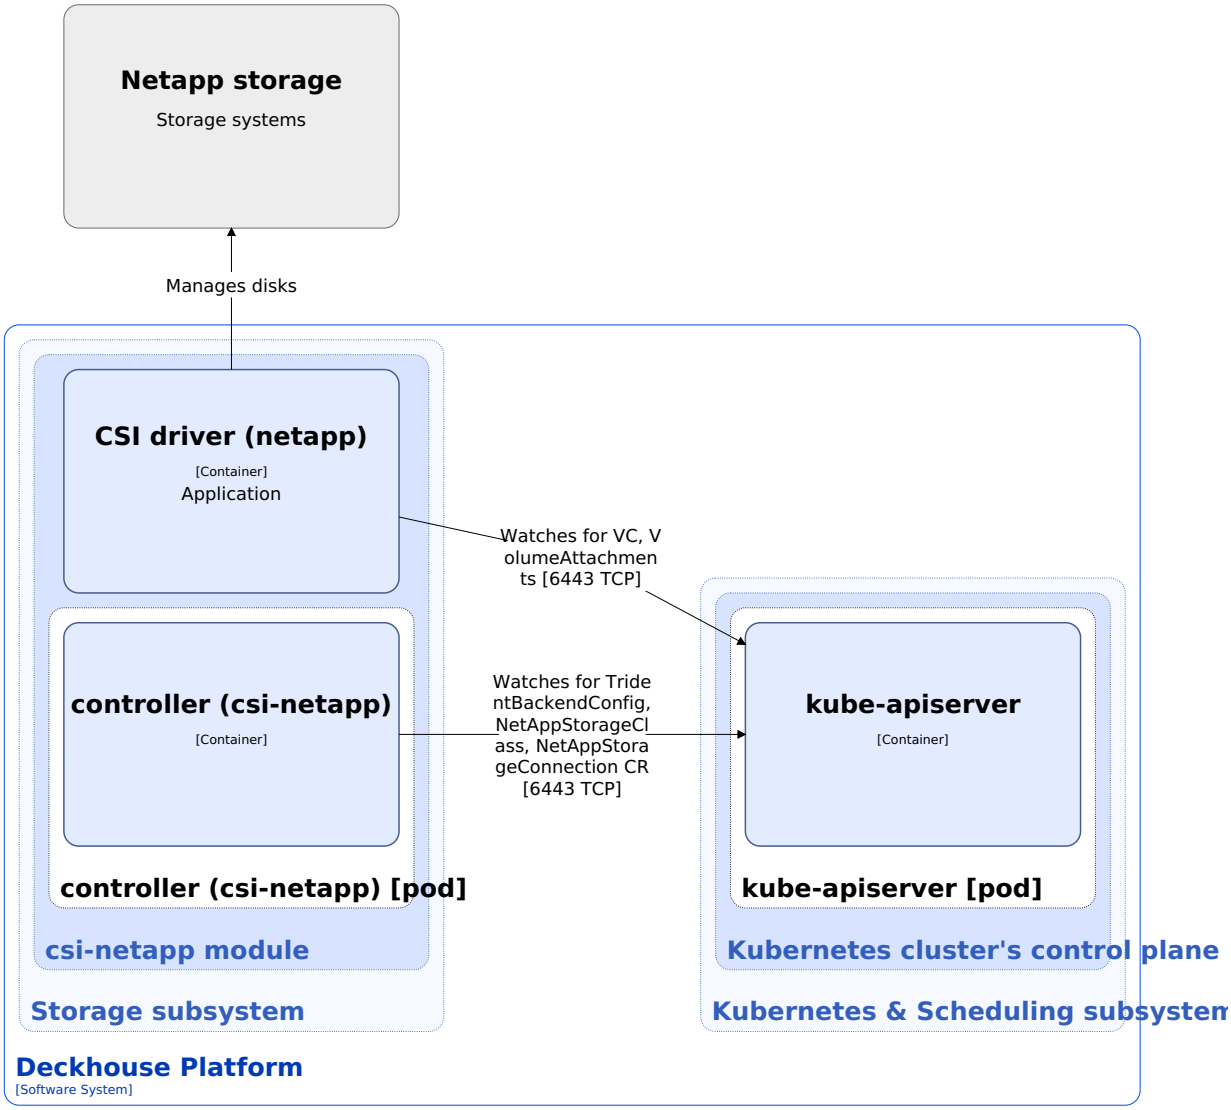
1. **Kube-apiserver**: Validates StorageBackendClaim custom resources and standard StorageClass resources.

Additional resources

- Module `csi-huawei` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-netapp module



The `csi-netapp` module is designed to manage volumes using NetApp storage systems. It enables creating StorageClass resources in Kubernetes using the NetappStorageClass custom resource.

For more details about the module, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-netapp` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the following custom resources:
   - NetappStorageConnection: Parameters for connecting to NetApp storage systems.
   - NetappStorageClass: Defines configuration for creating Kubernetes StorageClass that uses the `csi.trident.netapp.io` provisioner.

   The controller also synchronizes the `storage.deckhouse.io/csi-netapp-node` label on cluster nodes according to the `spec.settings.nodeSelector` value in the ModuleConfig custom resource.

   It consists of a single container, **controller**.
2. **CSI driver (netapp)**: CSI driver implementation for the `csi.trident.netapp.io` provisioner. To study the typical CSI driver architecture used in DP, refer to the CSI driver documentation page.

Module interactions

The module interacts with the following components:

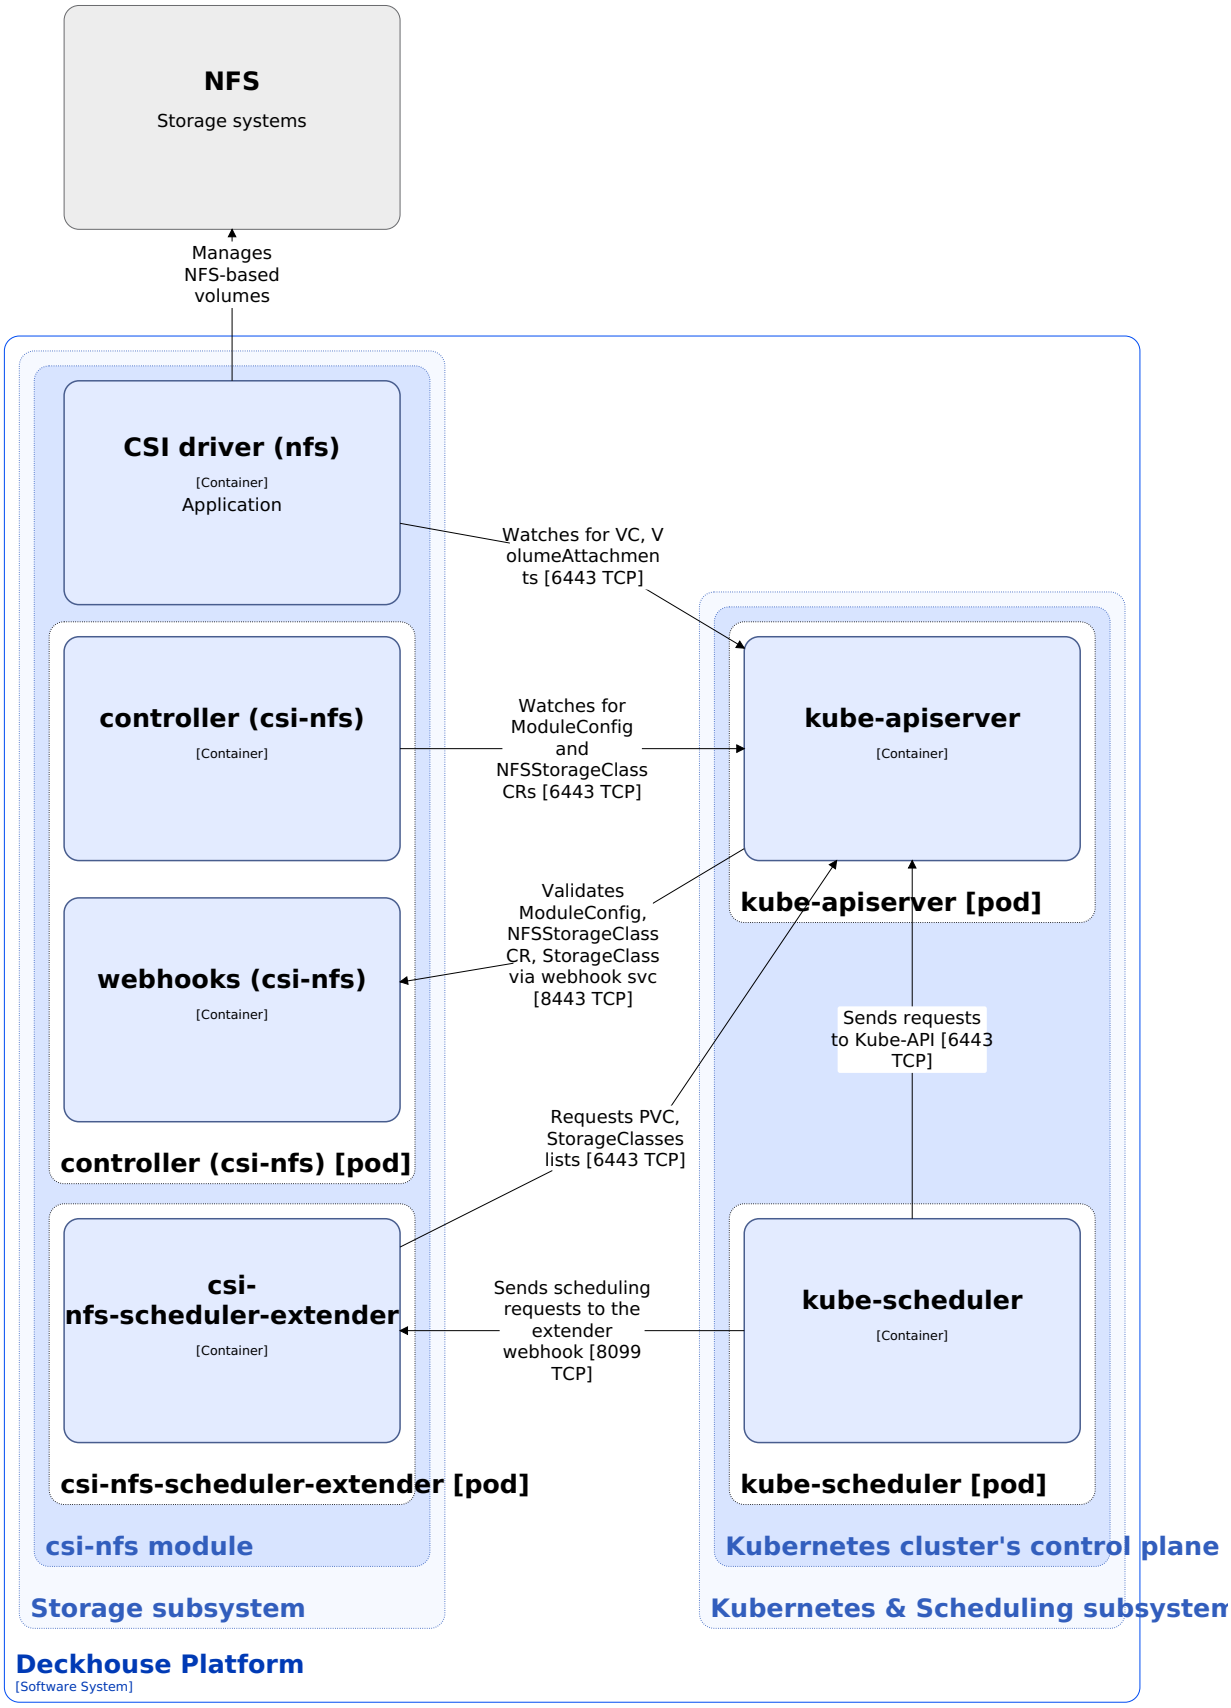
1. **Kube-apiserver**:
   - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
   - Reconciles TridentBackendConfig, NetappStorageConnection, and NetappStorageClass custom resources.
   - Creates VolumeSnapshotClass, Secret, and StorageClass resources.
2. **NetApp storage system**: Creates, deletes, and manages volumes, and attaches/detaches volumes to/from nodes.

Additional resources

- Module `csi-netapp` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-nfs module



The `csi-nfs` module is designed to manage NFS-based volumes. It enables creating StorageClasses in Kubernetes using the NFSStorageClass resource.

For more details about the module, refer to the module documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-nfs` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagrams:

Module components

The module consists of the following components:

1. **Controller**: It reconciles NFSStorageClass custom resources. NFSStorageClass defines the configuration for the created Kubernetes StorageClass, which uses the `nfs.csi.k8s.io` provisioner.

   The created StorageClass configures the NFS server connection settings, a reclaim policy, the volume binding mode, etc. These settings are used by the provisioner of the `csi-nfs` CSI driver when managing NFS-based volumes.

   Also the controller sets the `storage.deckhouse.io/csi-nfs-node` label on the cluster nodes according to the

`spec.workloadNodes.nodeSelector` parameter value of the NFSStorageClass custom resource.

It consists of the following containers:

- **controller**: Main container.
- **webhooks**: A sidecar container that implements a webhook server for validating ModuleConfig and NFSStorageClass custom resources, as well as StorageClass resources.

2. **Csi-nfs-scheduler-extender**: It consists of a single container. It is a kube-scheduler extender, which implements a scheduling logic specific for pods using NFS-based volumes. When scheduling pods, it relies on the node selectors set in the NFSStorageClass custom resource.

   The **csi-nfs-scheduler-extender** may be absent if node selectors are not set in the NFSStorageClass custom resource.

3. **CSI driver (`csi-nfs`)**: It is an implementation of the CSI driver for `nfs.csi.k8s.io` (NFS CSI driver). To study the `csi-nfs` CSI driver architecture, refer to the CSI driver documentation page.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches for PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
   - Reconciles NFSStorageClass custom resources.
   - Creates StorageClass resources.

The following external components interact with the module:

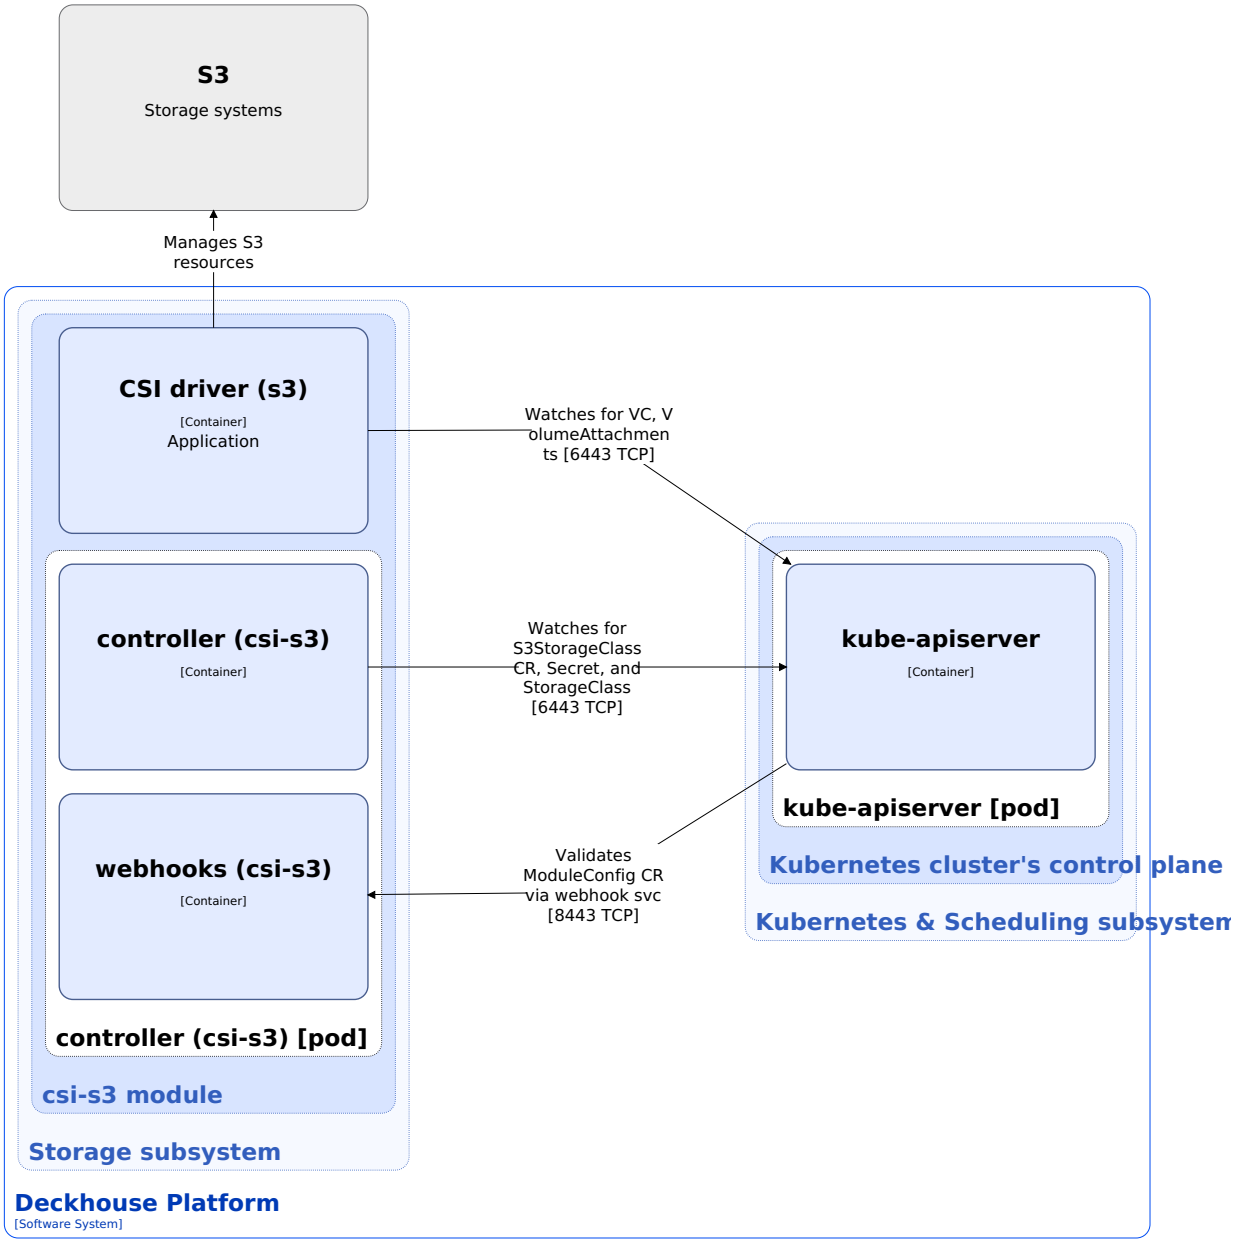
1. **Kube-apiserver**: Validates ModuleConfig and NFSStorageClass custom resources, as well as StorageClass resources.
2. **Kube-scheduler**: Sends scheduling requests to the `csi-nfs-scheduler-extender` webhook for the pods using NFS-based volumes.

Additional resources

- Module `csi-nfs` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-s3 module



The `csi-s3` module is designed to manage volumes based on S3 storage. The module uses geeseFS, an S3-backed FUSE filesystem. The module enables creating StorageClass resources in Kubernetes using the S3StorageClass custom resource.

For more details about the module, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-s3` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the S3StorageClass custom resource. The S3StorageClass resource defines configuration for a Kubernetes StorageClass that uses the `ru.yandex.s3.csi` provisioner.

   It consists of the following containers:

   - **controller**: Main container.
   - **webhooks**: Sidecar container implementing a webhook server for ModuleConfig custom resource validation.

2. **CSI driver (s3)**: CSI driver implementation for the `ru.yandex.s3.csi` provisioner. To study the architecture of the `csi-s3` CSI driver, refer to the CSI driver documentation page.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, Secret, and StorageClass resources.
   - Reconciles S3StorageClass and ModuleConfig custom resources.
   - Creates StorageClass and Secret resources.

2. **S3 storage**: Creates and deletes volumes, and attaches/detaches volumes to/from nodes.

The following external components interact with the module:

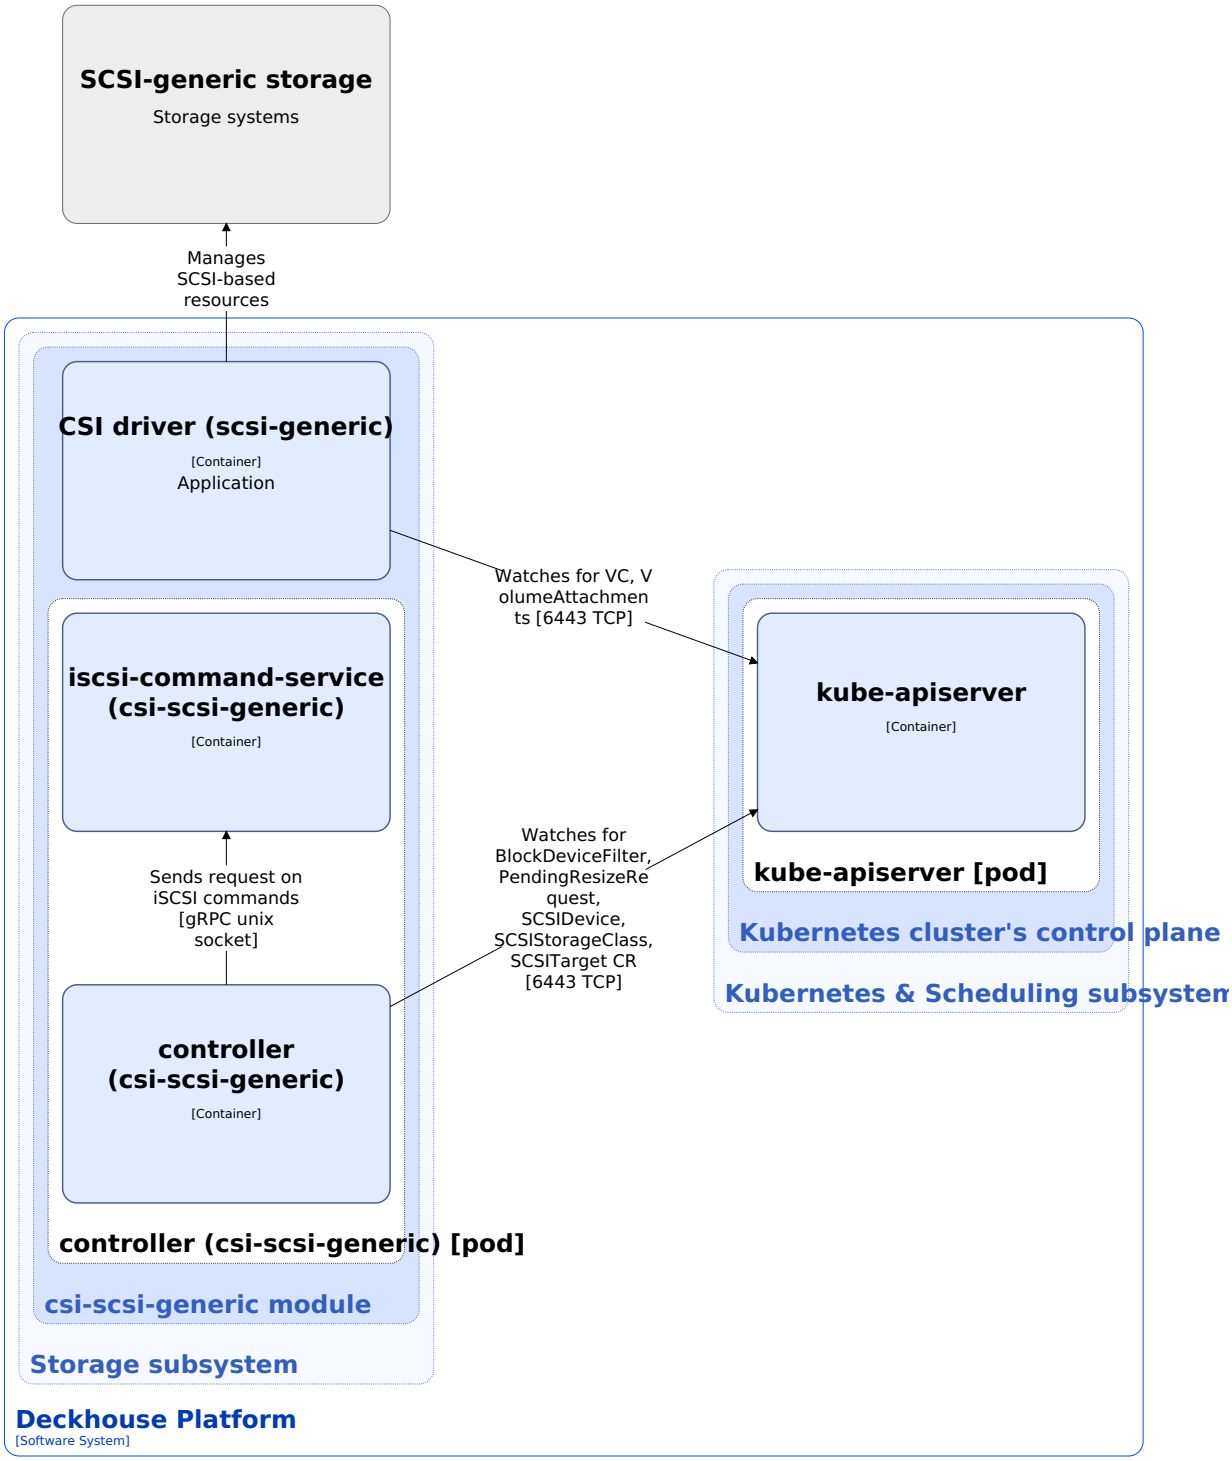
1. **Kube-apiserver**: Validates ModuleConfig custom resources.

Additional resources

- Module `csi-s3` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-scsi-generic module



The `csi-scsi-generic` module is designed to manage volumes on storage systems connected over SCSI. It enables creating StorageClass resources in Kubernetes using the SCSIStorageClass resource and supports both iSCSI and Fibre Channel (FC) technologies.

For more details about the module, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-scsi-generic` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the following custom resources:
   - SCSITarget: Describes a storage connection endpoint (iSCSI/FC).
   - SCSIDevice: Describes a discovered SCSI device.
   - PendingResizeRequest: Represents a request for deferred PVC expansion when the requested size is larger than the current device size.
   - SCSIStorageClass: Defines configuration for Kubernetes StorageClass.
   - BlockDeviceFilter: Specifies filters for selecting physical SCSI devices that can be used to create volumes in the system. Provides flexible management of the available device pool by setting rules based on device attributes and including/excluding specific devices.

   SCSIStorageClass defines the device selector (`scsiDeviceSelector`), reclaim policy, and volume cleanup parameters.

   It consists of the following containers:

   - **controller**: Main container.
   - **iscsi-command-service**: Sidecar container implementing SCSI device discovery.

2. **CSI driver (`csi-scsi-generic`)**: CSI driver implementation for the `scsi-generic.csi.storage.deckhouse.io` provisioner. To study the architecture of the `csi-scsi-generic` CSI driver, refer to the CSI driver documentation page.

Module interactions

The module interacts with the following components:

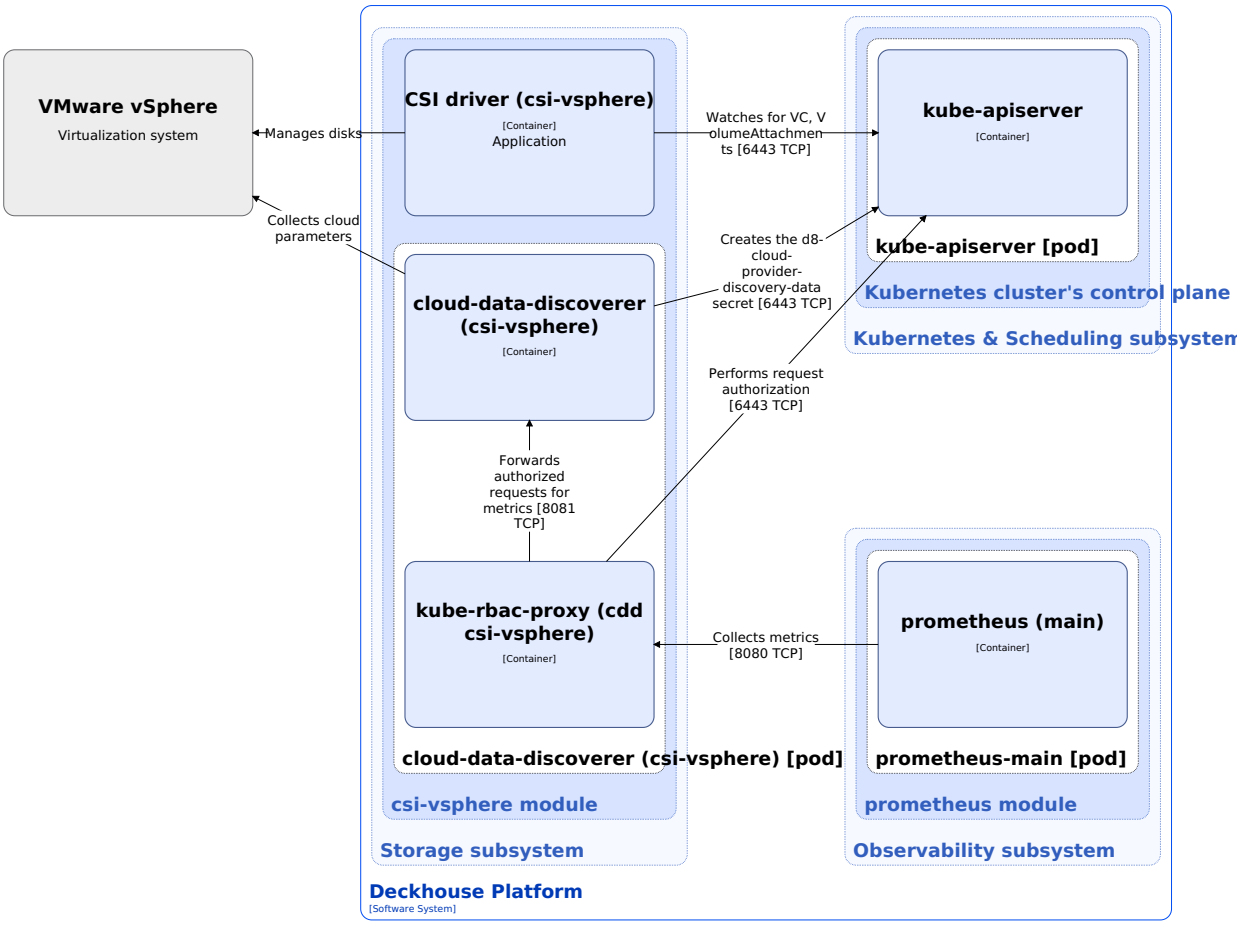
1. **Kube-apiserver**:
   - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
   - Reconciles BlockDeviceFilter, SCSITarget, SCSIDevice, PendingResizeRequest, and SCSIStorageClass custom resources.
   - Creates StorageClass resources.
2. **SCSI-connected storage systems**: Coordinates the usage of available SCSI devices, including their binding and cleanup, as well as node attachment.

Additional resources

- Module `csi-scsi-generic` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-vsphere module



The `csi-vsphere` module provides Container Storage Interface (CSI) support for VMware vSphere environments, enabling dynamic provisioning and management of persistent storage volumes in Kubernetes clusters running on vSphere infrastructure.

For more details about the module configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-vsphere` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Cloud-data-discoverer**: It is responsible for collecting data from the VMware vSphere API and providing it as a `kube-system/d8-cloud-provider-discovery-data` Secret. This secret contains the parameters of a specific cloud used CSI driver for volume management.

   It consists of the following containers:

   - **cloud-data-discoverer**: Main container.
   - **kube-rbac-proxy**: Sidecar container providing an RBAC-based authorization proxy for secure access to the cloud-data-discoverer metrics.

2. **CSI driver (vsphere)**: It is an implementation of the CSI driver for VMware vSphere. To study the `csi-vsphere` CSI driver architecture, refer to the corresponding documentation section.

   CSI driver (vsphere) does not support snapshots. For this reason, the `csi-controller` Pod does not include the snapshotter (external-snapshotter) sidecar container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches for PersistentVolumeClaim and VolumeAttachment custom resources.
   - Creates the `kube-system/d8-cloud-provider-discovery-data` Secret.
   - Creates StorageClass resources for each discovered datastore.
   - Authorizes the requests for metrics.

2. **VMware vSphere**:

   - Collects cloud parameters.
   - Manages disks.

The following external components interact with the module:

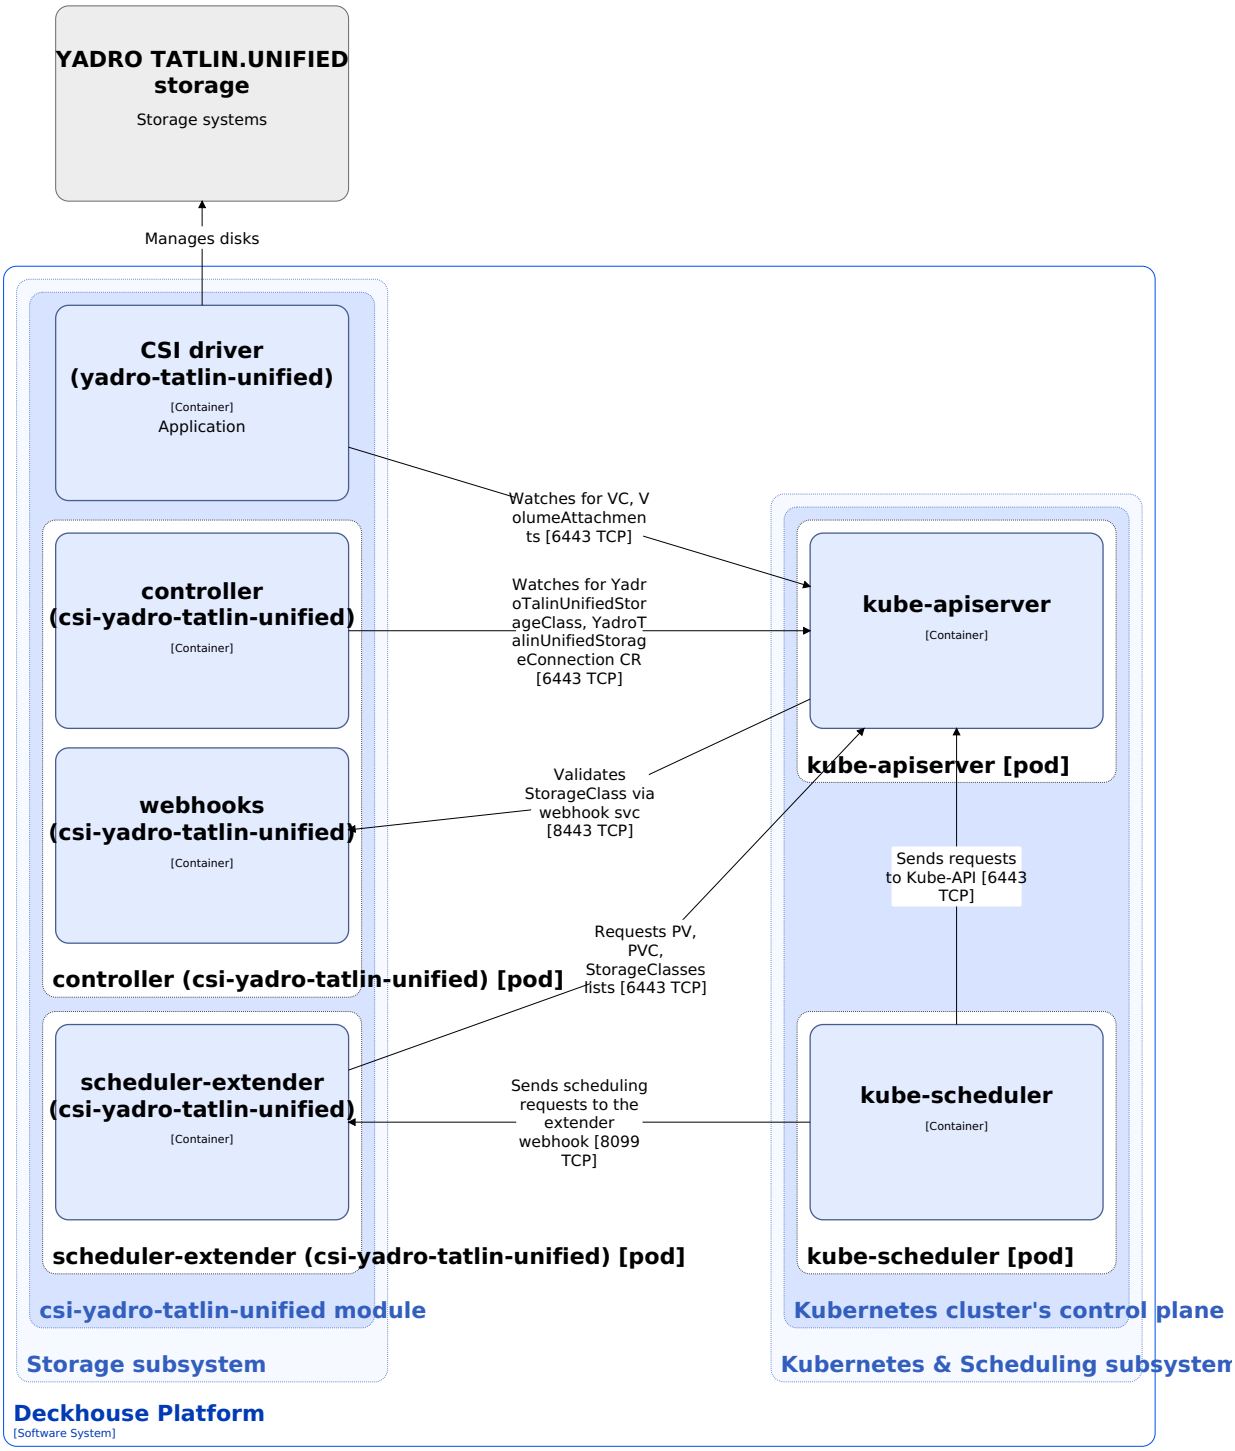
- **Prometheus-main**: Collects cloud-data-discoverer metrics.

Additional resources

- Module `csi-vsphere` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Csi-yadro-tatlin-unified module



The `csi-yadro-tatlin-unified` module is designed to manage volumes using TATLIN.UNIFIED storage systems. It enables creating StorageClass resources in Kubernetes using the YadroTatlinUnifiedStorageClass custom resource.

For more details about the module, refer to the module documentation.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-yadro-tatlin-unified` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Controller**: A controller that reconciles the following custom resources:

   - YadroTatlinUnifiedStorageConnection: Parameters for connecting to TATLIN.UNIFIED storage systems.
   - YadroTatlinUnifiedStorageClass: Defines configuration for creating Kubernetes StorageClass that uses the `csi-tatlinunified.yadro.com` provisioner.

   YadroTatlinUnifiedStorageClass defines connection parameters, as well as resource pool name, filesystem type, and reclaim policy.

   It consists of the following containers:

   - **controller**: Main container.
   - **webhook**: Sidecar container implementing a webhook server for StorageClass resource validation.

2. **CSI driver (yadro-tatlin-unified)**: CSI driver implementation for the `csi-tatlinunified.yadro.com` provisioner. To study the typical CSI driver architecture used in DP, refer to the CSI driver documentation page.

3. **Scheduler-extender**: A single-container component that acts as an extender for kube-scheduler. It implements scheduling logic specific to pods using volumes from TATLIN.UNIFIED storage systems. During scheduling, node

selectors defined in the YadroTatlinUnifiedStorageConnection custom resource under the `controlPlane` and `dataPlane` parameters are taken into account.

The component may be absent if node selectors are not set in the YadroTatlinUnifiedStorageConnection custom resource.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, and StorageClass resources.
   - Reconciles YadroTatlinUnifiedStorageConnection and YadroTatlinUnifiedStorageClass custom resources.
   - Creates StorageClass resources.
2. **YADRO TATLIN.UNIFIED storage system**: Creates and deletes volumes, and attaches/detaches volumes to/from nodes.

The following external components interact with the module:

1. **Kube-apiserver**: Validates standard StorageClass resources.

Additional resources

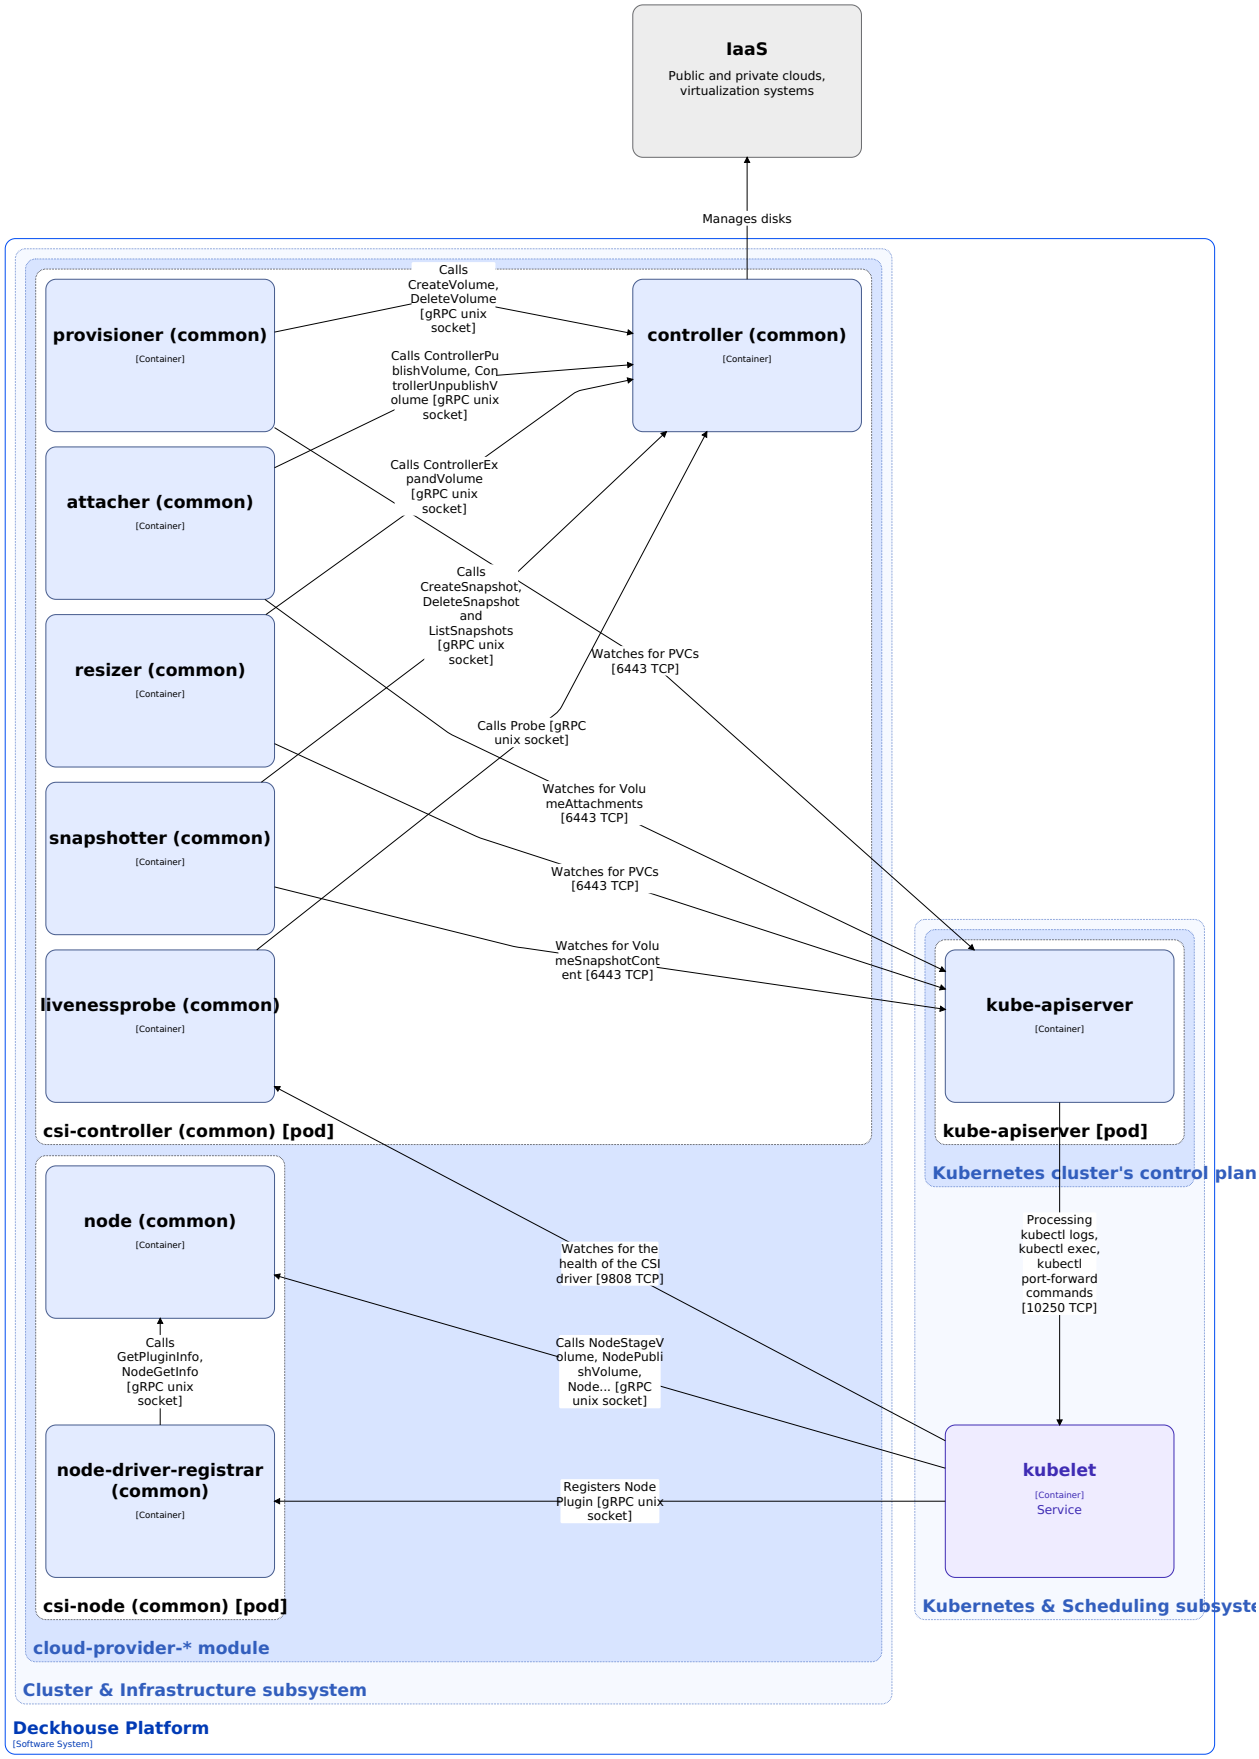
Standard CSI driver

A CSI driver (plugin) is used to manage persistent storage volumes in Deckhouse Platform (DP).

Container Storage Interface (CSI) is a standard interface that unifies access to storage systems and simplifies integration of different storage systems into clusters.



The CSI driver is included in DP modules named `cloud-provider-*` and `csi-*`. Although each supported cloud provider or storage system uses its own implementation of the CSI specification, the architecture of the CSI driver is the same across all implementations. Implementations may differ in the set of supported capabilities and components.

The following is a description of the reference CSI driver architecture used in DP. It includes all possible components and implements the full functionality used by DP modules.

Driver architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The reference CSI driver architecture at Level 2 of the C4 model and its interactions with other DP components are shown in the following diagram:

Driver components

The CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, attaching and detaching volumes from nodes, and managing snapshots. For example, in AWS this component calls the EC2 API to create EBS volumes.

   It consists of the following containers:

   - **controller**: Main container implementing CSI driver functionality (capabilities) through the gRPC services

Identity Service and Controller Service according to the CSI specification.

- **controller sidecar containers**: Kubernetes community-maintained external controllers.

  These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI driver functions in the controller container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

  External controllers communicate with the controller container over gRPC via Unix sockets.

  Csi-controller includes the following external controllers:

  - **provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`. It also uses `ValidateVolumeCapabilities` to verify compatibility.
  - **attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node and attaches or detaches volumes using the RPC methods `ControllerPublishVolume` and `ControllerUnpublishVolume`.
  - **resizer** (external-resizer): Watches updates to PersistentVolumeClaim resources and expands volumes using the `ControllerExpandVolume` RPC method when a user requests additional storage for a PVC, and the driver supports the `EXPAND_VOLUME` capability.
  - **snapshotter** (external-snapshotter): Works together with the `snapshot-controller` module, watches VolumeSnapshotContent resources, and manages volume snapshots using the RPC methods `CreateSnapshot`, `DeleteSnapshot`, and `ListSnapshots` (if supported by the driver).
  - **livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.

2. **Csi-node** (DaemonSet): Node Plugin running on all cluster nodes and responsible for local volume mount and unmount operations.

   ⚠ The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the node container occurs over gRPC via a Unix socket.

i Some sidecar containers from the external controller list (for example, snapshotter) may be absent in the Deployment of specific `cloud-provider-*` or `csi-*` modules if the corresponding functionality is not supported by the CSI driver implementation.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**: Monitors PersistentVolumeClaim, VolumeAttachment, and VolumeSnapshotContent resources.
2. **Cloud infrastructure** (or a virtualization system): Creates and deletes volumes, attaches and detaches volumes from nodes, and manages snapshots.

The following external components interact with the driver:

1. Kubelet:
   - Checks the CSI driver livenessProbe.
   - Registers the Node Plugin.
   - Calls the RPC methods `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, `NodeUnpublishVolume`, and `NodeExpandVolume` in Node Plugin.

   Kubelet communicates with Node Plugin via gRPC over a Unix socket.

Ceph RBD CSI driver

The `csi-rbd` CSI driver is an implementation of the Container Storage Interface (CSI) standard to manage Ceph RBD (RADOS Block Device) volumes in Deckhouse Platform (DP).

Driver architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-rbd` CSI driver and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Driver components

The `csi-rbd` CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, attaching and detaching volumes from nodes, and managing snapshots.

   It consists of the following containers:

   - **controller**: Main container that performs background tasks for managing Kubernetes resources related to Ceph.
   - **rbdplugin**: Sidecar container exposes the CSI endpoint over a Unix socket, implements Identity Service and Controller Service according to the CSI specification. It interacts with the Ceph cluster for RBD volumes.
   - **controller sidecar containers**: Kubernetes community-maintained external controllers.

     These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI RPC methods exposed by the rbdplugin container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

     External controllers communicate with the rbdplugin container over gRPC via Unix sockets.

     Csi-controller includes the following external controllers:

     - **Provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`. It also uses `ValidateVolumeCapabilities` to verify compatibility.
     - **Attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node and attaches or detaches volumes using the RPC methods `ControllerPublishVolume` and `ControllerUnpublishVolume`.
     - **Resizer** (external-resizer): Watches updates to PersistentVolumeClaim resources and expands volumes using the `ControllerExpandVolume` RPC method when a user requests additional storage for a PVC, and the driver supports the `EXPAND_VOLUME` capability.
     - **Snapshotter** (external-snapshotter): Works together with the `snapshot-controller` module, watches VolumeSnapshotContent resources, and manages volume snapshots using the RPC methods `CreateSnapshot`, `DeleteSnapshot`, and `ListSnapshots` (if supported by the driver).
     - **Livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.

2. **Csi-node** (DaemonSet): Node Plugin running on all cluster nodes and responsible for local volume mount and unmount operations.

   > ⚠ The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the **node** container occurs over gRPC via a Unix socket.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**: Monitors PersistentVolumeClaim, VolumeAttachment, and VolumeSnapshotContent resources.
2. **Ceph cluster**: Creates and deletes volumes, attaches and detaches volumes from nodes, and manages snapshots.

The following external components interact with the driver:

- Kubelet:
  - Checks the CSI driver livenessProbe.
  - Registers the Node Plugin.
  - Calls the RPC methods `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, `NodeUnpublishVolume`, and `NodeExpandVolume` in Node Plugin.

  Kubelet communicates with Node Plugin via gRPC over a Unix socket.

Additional resources

- Module `snapshot-controller` documentation

Huawei CSI driver

The `csi-huawei` CSI driver is the implementation of the Container Storage Interface (CSI) standard to manage volumes on Huawei storage systems in Deckhouse Platform (DP).

Driver architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-huawei` CSI driver and its interactions with other components of DP are shown in the following diagram:

Driver components

The `csi-huawei` CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, attaching and detaching volumes from nodes, and managing snapshots.

   It consists of the following containers:

   - **controller**: Main container implementing CSI driver functionality (capabilities) through the gRPC services Identity Service and Controller Service according to the CSI specification.
   - **controller sidecar containers**: Kubernetes community-maintained external controllers.

     These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI driver functions in the controller container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

     External controllers communicate with the controller container over gRPC via Unix sockets.

     The csi-controller includes the following external controllers:

     - **Provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`. It also uses `ValidateVolumeCapabilities` to verify compatibility.
     - **Attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node and attaches or detaches volumes using the RPC methods `ControllerPublishVolume` and `ControllerUnpublishVolume`.
     - **Resizer** (external-resizer): Watches updates to PersistentVolumeClaim resources and expands volumes using the `ControllerExpandVolume` RPC method when a user requests additional storage for a PVC, and the driver supports the `EXPAND_VOLUME` capability.
     - **Snapshotter** (external-snapshotter): Works together with the `snapshot-controller` module, watches VolumeSnapshotContent resources, and manages volume snapshots using the RPC methods `CreateSnapshot`, `DeleteSnapshot`, and `ListSnapshots`.
     - **Livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.
   - **storage-backend-controller**: An additional controller that reconciles the following custom resources:
     - StorageBackendClaim: A request to connect to Huawei storage.
     - StorageBackendContent: Description of the actual connection to Huawei storage.
   - **storage-backend-sidecar**: Sidecar container that provides integration with Huawei storage via `AddStorageBackend`, `UpdateStorageBackend`, `RemoveStorageBackend`, and `GetBackendStats` RPC calls.
2. **Csi-node** (DaemonSet): Node Plugin running on all cluster nodes and responsible for local volume mount and unmount operations.

   > ⚠ The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the node container occurs over gRPC via a Unix socket.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**:
   - Watches PersistentVolumeClaim and VolumeAttachment resources.
   - Reconciles StorageBackendClaim and StorageBackendContent custom resources.
2. **Huawei storage system**: Creates and deletes volumes, and attaches/detaches volumes to/from nodes.

The following external components interact with the driver:

1. **Kube-apiserver**: Validates StorageBackendClaim custom resources.
2. Kubelet:
   - Checks CSI driver livenessProbe.
   - Registers the Node Plugin.
   - Calls `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, and `NodeUnpublishVolume` RPCs in the

Node Plugin.

Kubelet interacts with the Node Plugin over gRPC via a Unix socket.

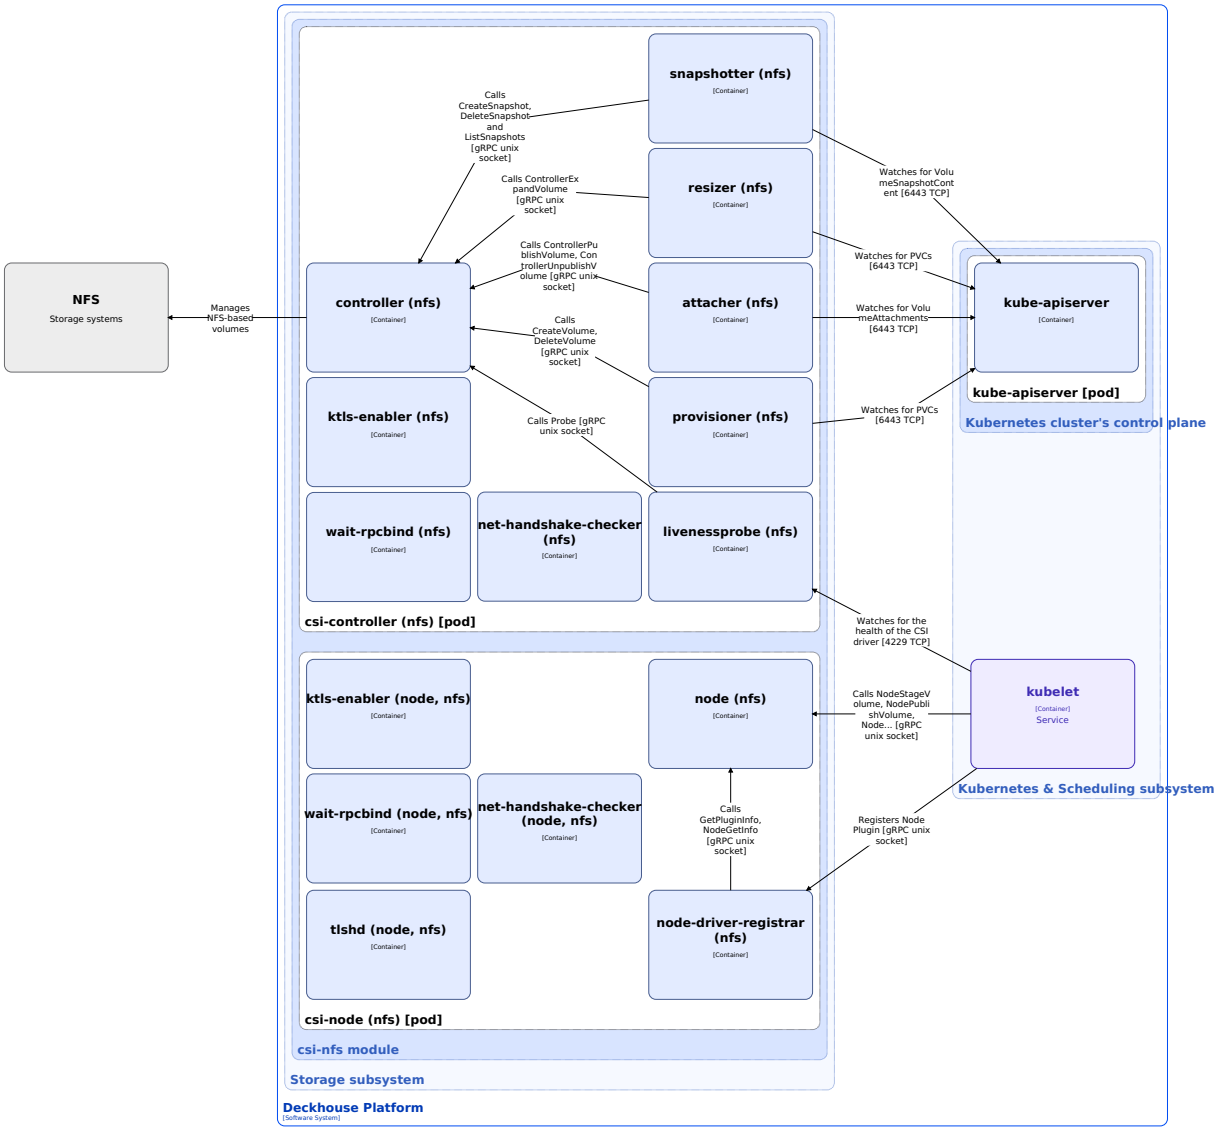
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.



NFS CSI driver

The CSI driver `csi-nfs` is the implementation of the Container Storage Interface (CSI) standard to manage NFS-based volumes in Deckhouse Platform (DP).

Driver architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-nfs` CSI driver and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Driver components

The `csi-nfs` CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, attaching and detaching volumes from nodes, and managing snapshots.

   It consists of the following containers:

   - **wait-rpcbind**: Init-container. It waits for when the Unix socket of the `rpcbind` service is ready and accepts connections.
   - **ktls-enabler**: Init-container. It loads and checks Linux kernel modules on the node for RPC-with-TLS support.
   - **net-handshake-checker**: Init-container. It runs `tlshd` one time to check kernel TLS handshake support.
   - **controller**: Main container implementing CSI driver functionality (capabilities) through the gRPC services Identity Service and Controller Service according to the CSI specification.
   - **controller sidecar containers**: Kubernetes community-maintained external controllers.

     These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI driver functions in the controller container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

     External controllers communicate with the controller container over gRPC via Unix sockets.

     Csi-controller includes the following external controllers:

     - **Provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`. It also uses `ValidateVolumeCapabilities` to verify compatibility.
     - **Attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node and attaches or detaches volumes using the RPC methods `ControllerPublishVolume` and `ControllerUnpublishVolume`.
     - **Resizer** (external-resizer): Watches updates to PersistentVolumeClaim resources and expands volumes using the `ControllerExpandVolume` RPC method when a user requests additional storage for a PVC, and the driver supports the `EXPAND_VOLUME` capability.
     - **Snapshotter** (external-snapshotter): Works together with the `snapshot-controller` module, watches VolumeSnapshotContent resources, and manages volume snapshots using the RPC methods `CreateSnapshot`, `DeleteSnapshot`, and `ListSnapshots` (if supported by the driver).
     - **Livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.

2. **Csi-node** (DaemonSet): Node Plugin running on cluster nodes labeled with `storage.deckhouse.io/csi-nfs-node` and responsible for local volume mount and unmount operations.

   > ⚠ The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **wait-rpcbind**: Init-container. It waits for when the Unix socket of the `rpcbind` service is ready and accepts connections.
   - **ktls-enabler**: Init-container. It loads and checks Linux kernel modules on the node for RPC-with-TLS support.
   - **net-handshake-checker**: Init-container. It runs `tlshd` one time to check kernel TLS handshake support.
   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **tlshd**: Sidecar container that provides an RPC-with-TLS connection.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the node container occurs over gRPC via a Unix socket.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**: Monitors PersistentVolumeClaim, VolumeAttachment, and VolumeSnapshotContent resources.
2. **NFS storage**:
   - Attaches and detaches NFS-based volumes from nodes.
   - Manages snapshots.

The following external components interact with the driver:

- Kubelet:
  - Checks the CSI driver livenessProbe.
  - Registers the Node Plugin.
  - Calls the RPC methods `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, `NodeUnpublishVolume`, and `NodeExpandVolume` in Node Plugin.

Kubelet communicates with Node Plugin via gRPC over a Unix socket.

S3 CSI driver

The `csi-s3` CSI driver is the implementation of the Container Storage Interface (CSI) standard to manage S3-based volumes in Deckhouse Platform (DP).

Driver architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-s3` CSI driver and its interactions with other components of DP are shown in the following diagram:

Driver components

The `csi-s3` CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, and attaching and detaching volumes from nodes.

   It consists of the following containers:

   - **controller**: Main container implementing CSI driver functionality (capabilities) through the gRPC services Identity Service and Controller Service according to the CSI specification.
   - **controller sidecar containers**: Kubernetes community-maintained external controllers.

     These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI driver functions in the controller container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

     External controllers interact with the controller container over gRPC via Unix sockets.

     The csi-controller includes the following external controllers:

     - **Provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`. It also uses `ValidateVolumeCapabilities` to verify compatibility.
     - **Attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node and attaches or detaches volumes using the RPC methods `ControllerPublishVolume` and `ControllerUnpublishVolume`.
     - **Livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.

2. **Csi-node** (DaemonSet): Node Plugin running on all cluster nodes and responsible for local volume mount and unmount operations.

   > ⚠ The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the node container occurs over gRPC via a Unix socket.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**: Watches PersistentVolumeClaim and VolumeAttachment resources.
2. **S3 storage**: Creates and deletes volumes, and attaches/detaches volumes to/from nodes.

The following external components interact with the driver:

1. Kubelet:
   - Checks CSI driver livenessProbe.
   - Registers the Node Plugin.
   - Calls `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, and `NodeUnpublishVolume` RPCs in the Node Plugin.

   Kubelet interacts with the Node Plugin over gRPC via a Unix socket.

SCSI Generic CSI driver

The `csi-scsi-generic` CSI driver is the implementation of the Container Storage Interface (CSI) standard to manage volumes on SCSI-connected storage systems in Deckhouse Platform (DP). The CSI driver supports both iSCSI and Fibre Channel (FC) connection technologies.

Driver architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-scsi-generic` CSI driver and its interactions with other components of DP are shown in the following diagram:

Driver components

The `csi-scsi-generic` CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, and attaching and detaching volumes from nodes.

   It consists of the following containers:

   - **scsi-modules-loader**: Init container that loads the Linux kernel module required for iSCSI (`iscsi_tcp`).
   - **controller**: Main container implementing CSI driver functionality (capabilities) through the gRPC services Identity Service and Controller Service according to the CSI specification.
   - **controller sidecar containers**: Kubernetes community-maintained external controllers.

     These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI driver functions in the controller container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

     External controllers interact with the controller container over gRPC via Unix sockets.

     The csi-controller includes the following external controllers:

- **Provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`.
- **Attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node.
- **Resizer** (external-resizer): Watches updates to PersistentVolumeClaim resources and expands volumes using the `ControllerExpandVolume` RPC method when a user requests additional storage for a PVC, and the driver supports the `EXPAND_VOLUME` capability. The controller doesn't expand the Logical Unit Number (LUN) size in the storage system, but updates information in the cluster metadata.
- **Livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.

2. **Csi-node** (DaemonSet): Node Plugin running on all cluster nodes and responsible for local volume mount and unmount operations.

   ⚠ The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **scsi-modules-loader**: Init container that loads the kernel module required for iSCSI (`iscsi_tcp`).
   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the node container occurs over gRPC via a Unix socket.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**: Watches PersistentVolume, PersistentVolumeClaim, VolumeAttachment, PendingResizeRequest, SCSIDevice, and SCSITarget resources.
2. **SCSI-connected storage systems**: Coordinates the usage of already available SCSI devices, including their binding/cleanup and node attachment.

The following external components interact with the driver:

1. Kubelet:
   - Checks CSI driver livenessProbe.
   - Registers the Node Plugin.
   - Calls `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, and `NodeUnpublishVolume` RPCs in the Node Plugin.

   Kubelet interacts with the Node Plugin over gRPC via a Unix socket.

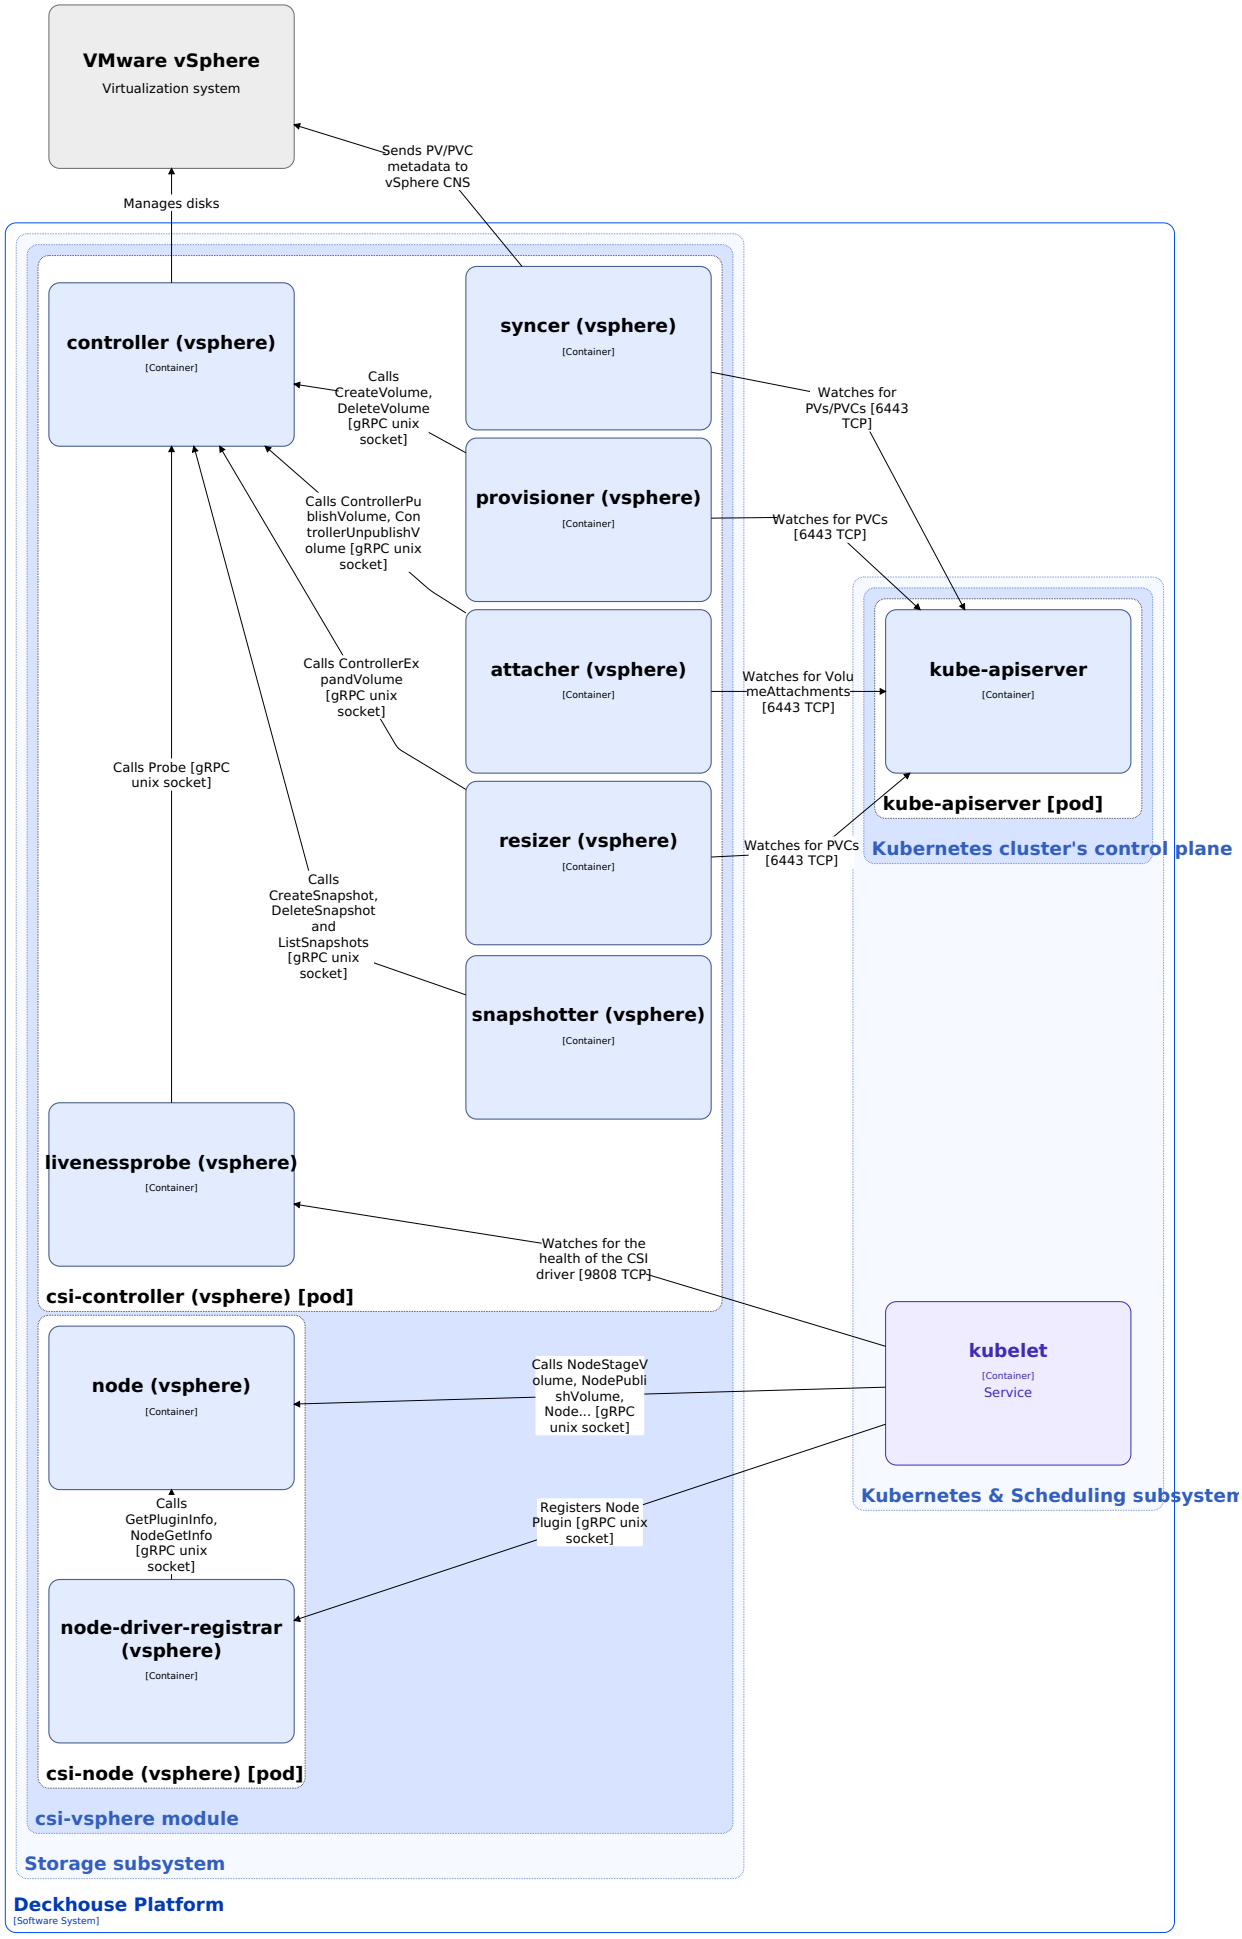
ℹ **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

VMware vSphere CSI driver

A CSI driver (plugin) is used to manage persistent storage volumes in Deckhouse Platform (DP).

Container Storage Interface (CSI) is a standard interface that unifies access to storage systems and simplifies integration of different storage systems into clusters.



The `cloud-provider-vsphere` module uses `csi-vsphere` (based on vSphere CSI Driver). It differs from the drivers used in other DP modules by the presence of a syncer component specific to VMware vSphere.

Driver architecture

ℹ The following simplifications are made in the diagram:

- The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
- Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `csi-vsphere` CSI driver and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Driver components

The CSI driver consists of the following components:

1. **Csi-controller** (Deployment): Controller Plugin responsible for global volume operations such as creating and deleting volumes, attaching and detaching volumes from nodes, and managing snapshots.

   It consists of the following containers:

   - **controller**: Main container implementing CSI driver functionality (capabilities) through the gRPC services Identity Service and Controller Service according to the CSI specification.
   - **controller sidecar containers**: Kubernetes community-maintained external controllers.

     These controllers are required because the persistent volume controller running in kube-controller-manager (a component of the DP control plane) does not provide an interface for direct interaction with CSI drivers. External controllers monitor PersistentVolumeClaim resources and call the corresponding CSI driver functions in the controller container. They also perform auxiliary tasks such as retrieving plugin information and capabilities or checking driver health (liveness probe).

     External controllers communicate with the controller container over gRPC via Unix sockets.

     Csi-controller includes the following external controllers:

     - **Provisioner** (external-provisioner): Watches PersistentVolumeClaim resources and calls the RPC methods `CreateVolume` or `DeleteVolume`. It also uses `ValidateVolumeCapabilities` to verify compatibility.
     - **Attacher** (external-attacher): Monitors VolumeAttachment resources after a pod is scheduled to a node and attaches or detaches volumes using the RPC methods `ControllerPublishVolume` and `ControllerUnpublishVolume`.
     - **Resizer** (external-resizer): Watches updates to PersistentVolumeClaim resources and expands volumes using the `ControllerExpandVolume` RPC method when a user requests additional storage for a PVC, and the driver supports the `EXPAND_VOLUME` capability.
     - **Snapshotter** (external-snapshotter): Works together with the `snapshot-controller` module, watches VolumeSnapshotContent resources, and manages volume snapshots using the RPC methods `CreateSnapshot`, `DeleteSnapshot`, and `ListSnapshots` (if supported by the driver).
     - **Livenessprobe**: Monitors the health of the CSI driver through the `Probe` RPC from the Identity Service and exposes the HTTP endpoint `/healthz`, which is checked by kubelet. If *livenessProbe* fails, kubelet restarts the csi-controller pod.
     - **Syncer**: VMware vSphere specific controller, it is responsible for pushing the PersistentVolumes, PersistentVolumeClaims, and pod metadata to Cloud Native Storage (CNS). CNS is a control plane managing various volume types in the VMware vSphere storage system.

2. **Csi-node** (DaemonSet): Node Plugin running on all cluster nodes and responsible for local volume mount and unmount operations.

   > **Warning.** The plugin has privileged access to the filesystem of each node. On Linux, this requires the `CAP_SYS_ADMIN` capability. This is necessary to perform mount operations and interact with block devices.

   It consists of the following containers:

   - **node**: Main container implementing CSI driver functionality through the gRPC services Identity Service and Node Service according to the CSI specification.
   - **node-driver-registrar**: Sidecar container that registers the Node Plugin with kubelet. It calls the RPC methods `GetPluginInfo` and `NodeGetInfo` in the node container to retrieve plugin and node information. Communication with the node container occurs over gRPC via a Unix socket.

Driver interactions

The driver interacts with the following components:

1. **Kube-apiserver**: Monitors PersistentVolumeClaim, VolumeAttachment, and VolumeSnapshotContent resources.
2. **VMware vSphere**:
   - Creates and deletes volumes.
   - Attaches and detaches volumes from nodes.
   - Manages snapshots.
   - Synchronizes PersistentVolumes, PersistentVolumeClaims, and pod metadata with the Cloud Native Storage (CNS).

The following external components interact with the driver:

1. Kubelet:
   - Checks the CSI driver livenessProbe.
   - Registers the Node Plugin.
   - Calls the RPC methods `NodeStageVolume`, `NodeUnstageVolume`, `NodePublishVolume`, `NodeUnpublishVolume`, and `NodeExpandVolume` in Node Plugin.

   Kubelet communicates with Node Plugin via gRPC over a Unix socket.

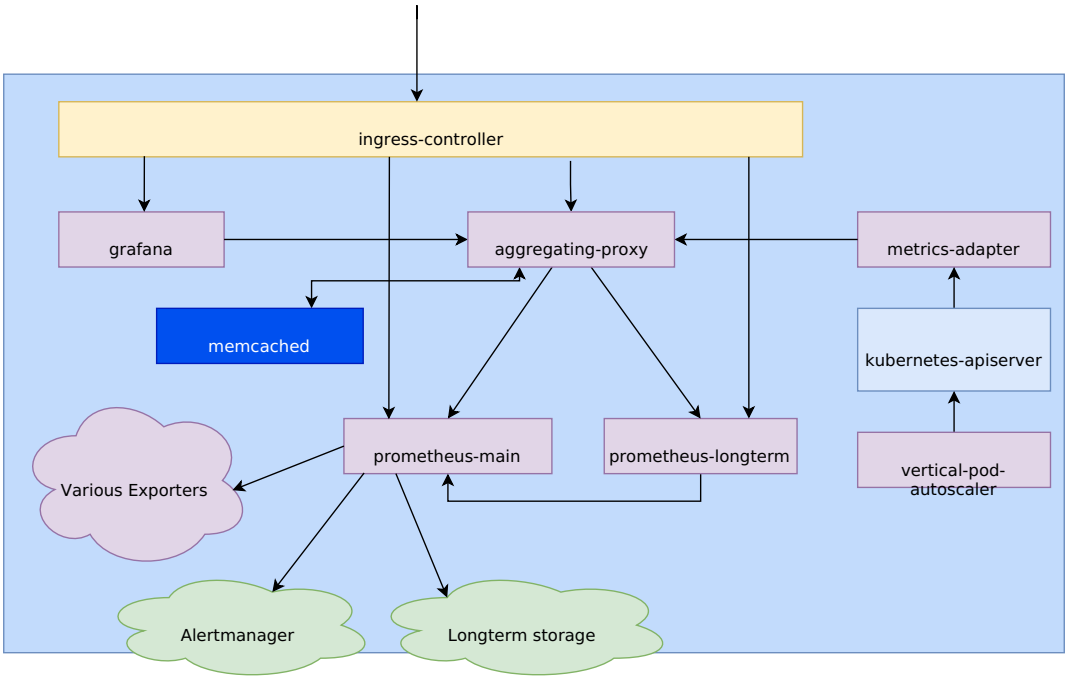
Observability subsystem

This section describes the architecture of the Observability subsystem of Deckhouse Platform (DP).



The Observability subsystem includes the following modules:

- `prometheus`: Deploys a monitoring stack with predefined settings for DP and applications, simplifying the initial configuration.
- `operator-prometheus`: Installs Prometheus Operator, which automates the deployment and management of Prometheus instances.
- `prometheus-metrics-adapter`: Allows HPA and VPA autoscalers to use monitoring metrics when making scaling decisions.
- `log-shipper`: Simplifies log collection setup in Kubernetes clusters.
- `loki`: Deploys a short-term log storage system in the cluster based on Grafana Loki.
- `observability`: Extends the functionality of the `prometheus` module and the Deckhouse web UI, providing additional capabilities for flexible management of metrics, dashboards, and alerts, as well as access control mechanisms for them.
- `extended-monitoring`: Enhances cluster monitoring by deploying additional Prometheus exporters that help detect potential issues before they affect service operation.
- `monitoring-custom`: Simplifies monitoring configuration for user applications by requiring only a specific label to be set for the target application.
- `monitoring-kubernetes`: Provides transparent and timely monitoring of all cluster nodes and key infrastructure components.
- `upmeter`: Checks platform availability and cluster component health in real time and displays the results on dedicated dashboards.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

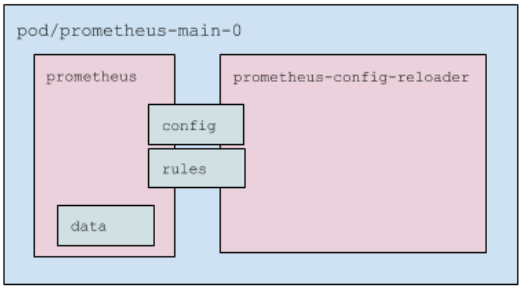
Architecture of monitoring in the Deckhouse Platform

Composition and interaction scheme of monitoring components

Components installed by DP

Component	Description
prometheus-operator	DP module responsible for running Prometheus in the cluster.
prometheus-main	Main Prometheus that performs scraping every 30 seconds (can be changed using the `scrapeInterval` parameter). It processes all rules, sends alerts and is the main data source.
prometheus-longterm	Additional Prometheus storing sparse data samples from the main prometheus-main
aggregating-proxy	Aggregating and caching proxy that combines main and longterm into one source. Helps avoid data gaps when one of the Prometheus instances is unavailable.
memcached	In-memory data caching service.
grafana	UI for displaying metrics in dashboard format.
metrics-adapter	Component providing Kubernetes API for accessing metrics. Required for proper VPA operation.
Various exporters	Set of ready-made Prometheus exporters for all necessary metrics: `kube-state-metrics`, `node-exporter`, `oomkill-exporter`, `image-availability-exporter`.
upmeter	Module for assessing DP component availability.
trickster	Caching proxy that reduces load on Prometheus. Will be deprecated soon.

Prometheus



Prometheus collects metrics and executes rules:

- For each *target* (monitoring target) with a given period `scrape_interval`, Prometheus makes an HTTP request to this *target*, receives metrics in its own format in response and saves them to its database.
- Each `evaluation_interval` processes rules (*rules*), based on which:
  - sends alerts;
  - or saves new metrics (result of rule execution) to its database.

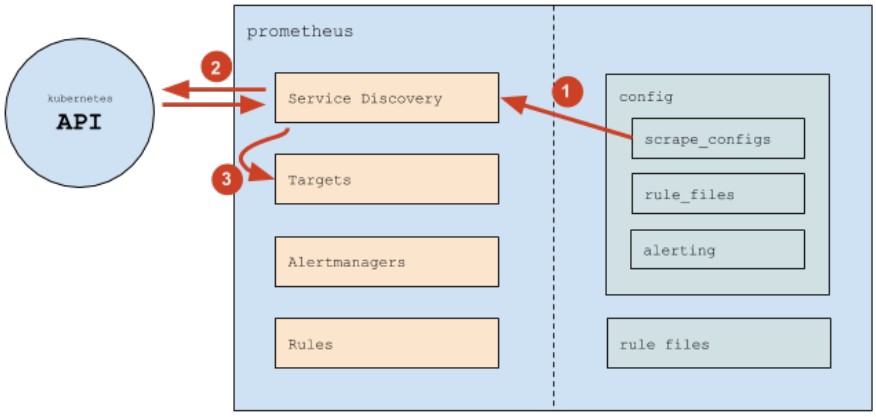
Prometheus is installed by the `prometheus-operator` module of DP, which performs the following functions:

- Defines the following custom resources:
  - `Prometheus`: Defines the installation (cluster) of *Prometheus*.
  - `ServiceMonitor`: Defines how to collect metrics from services.
  - `Alertmanager`: Defines the cluster of *Alertmanagers*.
  - `PrometheusRule`: Defines the list of *Prometheus rules*.
- Monitors these resources, and also:
  - Generates `StatefulSet` with *Prometheus* itself.
  - Creates secrets with configuration files necessary for Prometheus operation (`prometheus.yaml` — Prometheus configuration, and `configmaps.json` — configuration for `prometheus-config-reloader`).
  - Monitors `ServiceMonitor` and `PrometheusRule` resources and updates *Prometheus* configuration files by making changes to secrets based on them.

What's in the Prometheus pod?

- Two containers:
  - `prometheus`: Prometheus itself;
  - `prometheus-config-reloader`: Wrapper that:
    - Monitors changes to `prometheus.yaml` and, if necessary, calls configuration reload to Prometheus (via special HTTP request, see more details below).
    - Monitors PrometheusRules (see more details below) and downloads them and restarts Prometheus as needed.
- Pod uses three volumes:
  - config: Mounted secret (two files: `prometheus.yaml` and `configmaps.json`). Connected to both containers.
  - rules: `emptyDir` that is filled by `prometheus-config-reloader` and read by `prometheus`. Connected to both containers, but in `prometheus` in read-only mode.
  - data: Prometheus data. Mounted only in `prometheus`.

How is Prometheus configured?



- The Prometheus server has *config* and *rule files* (files with rules);
- The `config` has the following sections:
  - `scrape_configs`: Settings for finding *targets* (monitoring targets, see more details in the next section).
  - `rule_files`: List of directories where *rules* that need to be loaded are located:

    ```
    rule_files:
    - /etc/prometheus/rules/rules-0/*
    - /etc/prometheus/rules/rules-1/*
    ```

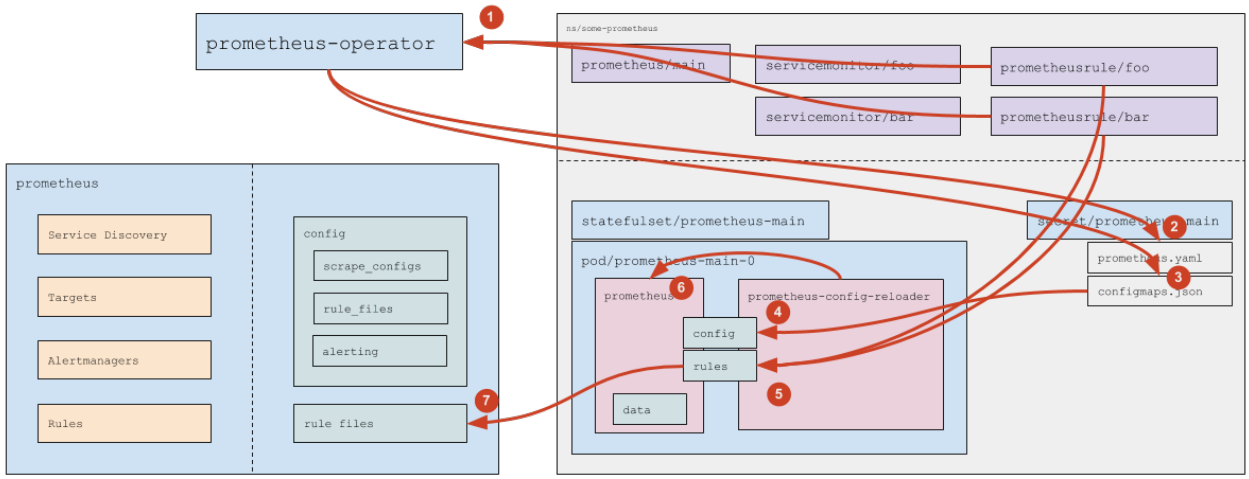
  - `alerting`: Settings for finding *Alert Managers* to send alerts to. This section is very similar to `scrape_configs`, only the result of its work is a list of *endpoints* to which Prometheus will send alerts.

Where does Prometheus get the list of *targets*?

- In general, Prometheus works as follows:

  - **(1)** Prometheus reads the `scrape_configs` section of the config, according to which it configures its internal Service Discovery mechanism.
  - **(2)** The Service Discovery mechanism interacts with the Kubernetes API (mainly — gets endpoints).
  - **(3)** Based on what happens in Kubernetes, the Service Discovery mechanism updates Targets (list of *targets*).
- In `scrape_configs` a list of *scrape jobs* (internal Prometheus concept) is specified, each of which is defined as follows:

```
scrape_configs:
  # General settings
- job_name: d8-monitoring/custom/0   # just the name of the scrape job, shown in the Service
Discovery section
  scrape_interval: 30s               # how often to collect data
  scrape_timeout: 10s                # request timeout
  metrics_path: /metrics              # path to request
  scheme: http                       # http or https
  # Service discovery settings
  kubernetes_sd_configs:              # means that targets are obtained from Kubernetes
  - api_server: null                 # means to use the API server address from environment
variables (which are in every Pod)
    role: endpoints                  # take targets from endpoints
    namespaces:
      names:                        # search for endpoints only in these namespaces
      - foo
      - baz
  # "Filtering" settings (which endpoints to take and which not) and "relabeling" (which
labels to add or remove, on all received metrics)
  relabel_configs:
  # Filter by the value of the prometheus_custom_target label (obtained from the service
associated with the endpoint)
  - source_labels: [__meta_kubernetes_service_label_prometheus_custom_target]
    regex: .+                       # any NON-empty label matches
    action: keep
  # Filter by port name
  - source_labels: [__meta_kubernetes_endpointslice_port_name]
    regex: http-metrics              # matches only if the port is called http-metrics
    action: keep
  # Add job label, use the value of the prometheus_custom_target label of the service, to
which we add the prefix "custom-"
  #
  # The job label is a Prometheus service label:
  #    * it determines the name of the group in which the target will be shown on the targets
page
  #    * and of course it will be on each metric obtained from these targets, so you can
easily filter in rules and dashboards
  - source_labels: [__meta_kubernetes_service_label_prometheus_custom_target]
    regex: (.*)
    target_label: job
    replacement: custom-$1
    action: replace
  # Add namespace label
  - source_labels: [__meta_kubernetes_namespace]
    regex: (.*)
    target_label: namespace
    replacement: $1
    action: replace
  # Add service label
  - source_labels: [__meta_kubernetes_service_name]
    regex: (.*)
    target_label: service
    replacement: $1
    action: replace
  # Add instance label (which will contain the Pod name)
  - source_labels: [__meta_kubernetes_pod_name]
    regex: (.*)
    target_label: instance
    replacement: $1
    action: replace
```



- Thus, Prometheus itself tracks:
  - Addition and removal of Pods (when Pods are added/removed, Kubernetes changes endpoints, and Prometheus sees this and adds/removes *targets*).
  - Addition and removal of services (more precisely endpoints) in specified namespaces.
- Config changes are required in the following cases:
  - Need to add a new scrape config (usually — a new type of services that need to be monitored).
  - Need to change the list of namespaces.

How are Service Monitors processed?

1. Prometheus Operator reads (and also monitors addition/removal/changes) Service Monitors (which specific Service Monitors — specified in the `prometheus` resource itself, see more details in official documentation).
2. For each Service Monitor, if it does NOT specify a specific list of namespaces (specified `any: true`), Prometheus Operator calculates (by accessing the Kubernetes API) a list of namespaces where there are Services (matching the labels specified in the Service Monitor).
3. Based on the read `servicemonitor` resources (see official documentation) and based on the calculated namespaces, Prometheus Operator generates part of the config (the `scrape_configs` section) and saves the config to the corresponding Secret.
4. Using standard Kubernetes means, data from the secret comes to the Pod (the `prometheus.yaml` file is updated).
5. The `prometheus-config-reloader` notices the file change and sends an HTTP request to Prometheus to reload.
6. Prometheus re-reads the config and sees changes in scrape_configs, which it processes according to its own logic (see more details above).

How are custom resources with *rules* processed?

1. Prometheus Operator monitors PrometheusRules (matching the `ruleSelector` specified in the `prometheus` resource).
2. If a new PrometheusRule appears (or an existing one is deleted) — Prometheus Operator updates `prometheus.yaml` (and then the logic exactly corresponding to Service Monitor processing, which is described above, is triggered).
3. Both in case of adding/removing PrometheusRule and when changing the content of PrometheusRule, Prometheus Operator updates the ConfigMap `prometheus-main-rulefiles-0`.
4. Using standard Kubernetes means, data from ConfigMap comes to the Pod
5. The `prometheus-config-reloader` notices the file change and:
   - Downloads changed ConfigMaps to the rules directory (this is `emptyDir`).
   - Sends an HTTP request to Prometheus to reload.
6. Prometheus re-reads the config and sees the changed *rules*.

Architecture of DP component availability assessment (upmeter)

Availability assessment in DP is performed by the upmeter module.

Composition of the upmeter module:

- **agent**: Works on master nodes and performs availability probes, sends results to the server.
- **upmeter**: Collects results and maintains an API server for their extraction.

- **front**:
  - **status**: Shows availability level for the last 10 minutes (requires authorization, but it can be disabled);
  - **webui**: Shows a dashboard with statistics on probes and availability groups (requires authorization).
- **smoke-mini**: Maintains continuous *smoke testing* using StatefulSet.

The module sends about 100 metric readings every 5 minutes. This value depends on the number of enabled Deckhouse Platform modules.

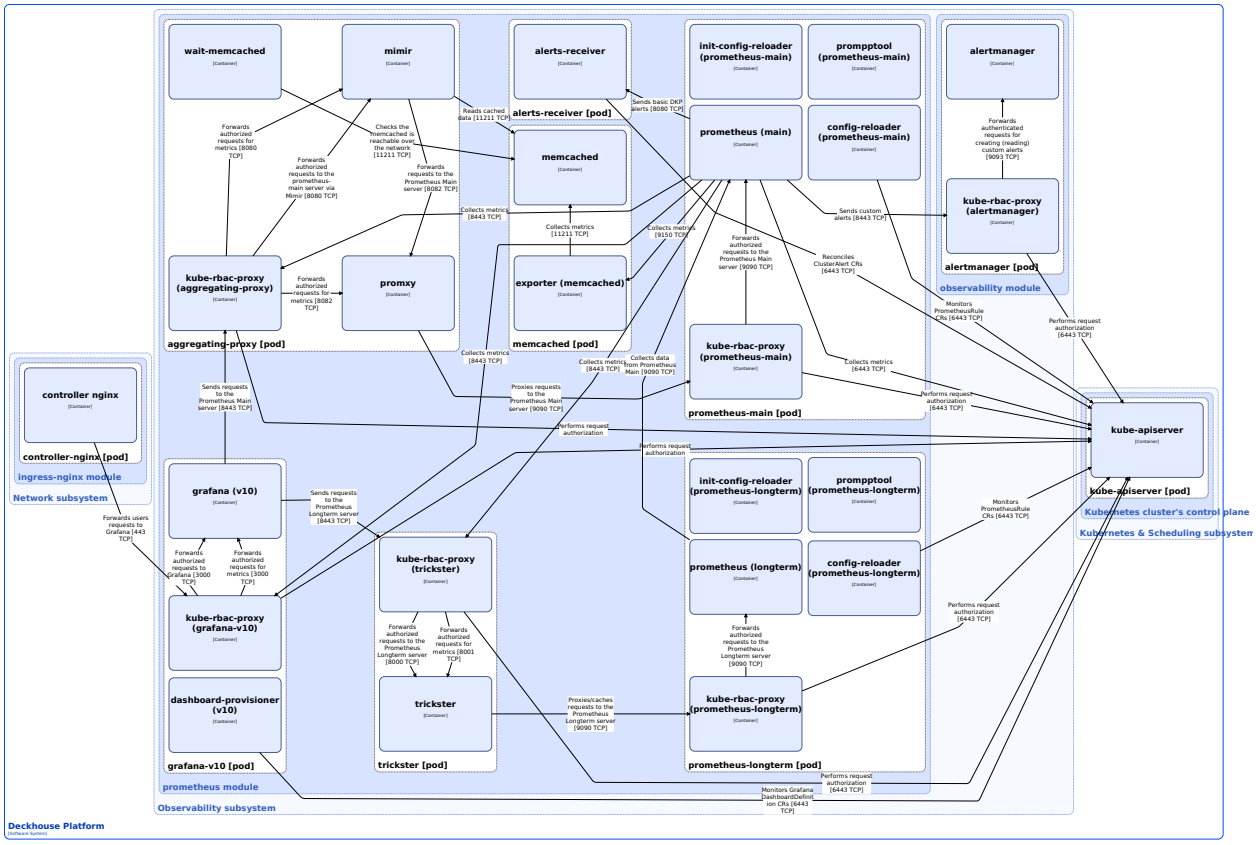
Prometheus module



The `prometheus` module deploys a monitoring stack with predefined settings for Deckhouse Platform (DP) and provides the collection, storage, and processing of cluster and application metrics.

For more details about the module, refer to the module documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `prometheus` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Prometheus-main** (StatefulSet): Main Prometheus instance. Prometheus is a monitoring and notification system using a time series database (TSDB). It collects and analyzes application and server performance metrics in real

time. Prometheus-main collects metrics from configured monitoring objects every 30 seconds. You can use the `scrapeInterval` parameter to change this value.

Prometheus-main can use the original (“vanilla”) Prometheus or Deckhouse Prom++, a high-performance open-source fork of Prometheus designed to reduce memory consumption while maintaining full compatibility with the original project. The module uses Deckhouse Prom++ by default. It is possible to switch from Deckhouse Prom++ to the original Prometheus. In this case, migration of write-ahead log (WAL) data will be required, since Deckhouse Prom++ uses its own WAL log format. Migration is performed automatically using the prompptool init container.

Prometheus-main is the main data source. It collects metrics, processes configured rules, and sends alerts according to set configuration. The Prometheus Operator creates the Prometheus instance and its configuration based on following custom resources:

- Prometheus: Describes a Prometheus installation (cluster).
- ServiceMonitor: Defines metrics collection settings from a set of services.
- PrometheusRule: Contains a set of Prometheus rules.

Prometheus Operator watches Prometheus resources and, for each one, generates:

- StatefulSet with Prometheus itself.
- Secret containing `prometheus.yaml` (the main configuration file) and `configmaps.json` (the configuration file for the config-reloader container, described below). The `prometheus-main` Secret is mounted in prometheus-main Pod and is used by the config-reloader container.

Prometheus Operator also watches ServiceMonitor and PrometheusRule resources and, based on them, updates the configuration (`prometheus.yaml` and `configmaps.json`) in the described above Secret.

For more details about the working of Prometheus Operator, refer to the `operator-prometheus` module documentation section.

For more details about the prometheus-main operation, refer to the section describing the architecture of the monitoring in DP.

Prometheus-main consists of the following containers:

- **init-config-reloader**: Init container that performs a single run of config-reloader to load the Prometheus configuration.
- **prompptool**: Init container that performs automatic WAL data migration in case of switching from Deckhouse Prom++ to the original Prometheus and vice versa.
- **config-reloader**: Sidecar container that monitors changes in the `prometheus.yaml` configuration file and, if needed, triggers a Prometheus configuration reload (via a special HTTP request to the `/-/reload` endpoint). Config-reloader is a utility from the Prometheus Operator open-source project.
- **prometheus**: Main container.
- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the Prometheus server. It is an open-source project.

2. **Prometheus-longterm** (StatefulSet): An additional Prometheus instance that scrapes the data of the primary Prometheus instance (`prometheus-main`). This allows users to view and analyze historical trends over a long period of time. Prometheus-longterm receives data due to a configured federation mechanism with the primary Prometheus instance.

   The original Prometheus or Deckhouse Prom++ can be used in prometheus-longterm too. Prometheus-longterm has the same set of containers as in prometheus-main, as well as operation principles.

3. **Grafana-v10**: Optional Grafana component that provides a web interface for visualizing monitoring data. Grafana displays dashboards supplied with DP modules. Grafana could work in High Availability mode, does not store state, and is configured with custom resources. Grafana is enabled by default, but it can be disabled using the `settings.grafana.enabled` parameter.

   > **i** Grafana-v10 will be disabled in the future DP releases. To view the monitoring dashboards, use the Deckhouse web UI.

   It consists of the following containers:

   - **dashboard-provisioner**: Sidecar container that watches GrafanaDashboardDefinition custom resources and when a new resource appears, it adds to the Grafana folder the dashboards described there.
   - **grafana**: Main container. It is an open-source project.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to the Grafana server and its metrics (described above).

4. **Aggregating-proxy**: Component that performs metrics caching, data collection from several Prometheus instances (if they are in High Availability mode), data deduplication, and query calculation.

   It consists of the following containers:

   - **wait-memcached**: Init container that waits the memcached component to be available over the network. Aggregating-proxy uses memcached to cache metrics in RAM.
   - **mimir**: Sidecar container that works with the memcached component to optimize queries and cache data. If there is no data in the cache, mimir forwards the request to the prometheus-main component via promxy, that is another sidecar container. It is an open-source project.
   - **promxy**: Sidecar container that proxies requests to the prometheus-main component and provides a single endpoint to access data of multiple Prometheus instances. It is an open-source project.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to the mimir containers (queries to the Prometheus server and container metrics) and promxy (queries to container metrics). It’s described above in detail.

5. **Memcached** (StatefulSet): Component used by aggregating-proxy for caching Prometheus metrics. Memcached is a software that implements a service for caching data in RAM to speed up Prometheus metrics query execution.

   It consists of the following containers:

   - **memcached**: Main container. It is an open-source project.
   - **exporter**: Sidecar container that exports memcached container metrics. Exporter collects memcached container metrics via a network connection, as well as from the memcached process's PID file. It is an open-source project.

6. **Trickster**: Caching proxy server that reduces the load on Prometheus. It is used for caching and proxying prometheus-longterm requests. In the future DP releases, it's expected to become deprecated and will no longer be supported.

   It consists of the following containers:

   - **trickster**: Main container. It is an open-source project.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to the proxy server and its metrics (described above).

   > **i** In the future DP releases, alerts-receiver will be removed from the `prometheus` module. The Alertmanager component of the `observability` module will be used to receive all alerts.

7. **Alerts-receiver**: A server compatible with Alertmanager API. Alerts-receiver receives basic alerts from prometheus-main, creates the ClusterAlert custom resources based on them, updates their statuses and deletes them if the alert is no longer active. The ClusterAlert custom resources are used to inform DP users on active alerts and are displayed in the Deckhouse web UI. Alerts-receiver is developed by Flant. It consists of one container.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Watches the PrometheusRule and GrafanaDashboardDefinition custom resources.
   - Manages the ClusterAlert custom resources.
   - Authorizes requests for metrics of module components.
2. **Alertmanager**: Sends custom alerts.

The Prometheus instance, which is part of the module, collects metrics from all DP components:

- Components of modules
- Components of cluster control plane
- Exporters that collect metrics of cluster hardware resources utilization
- Exporters that collect Kubernetes resources metrics
- User applications (additional configuration is required)

To prevent complicating the diagram with a large number of relations, Prometheus interactions related to the collection of metrics from DP components are omitted.

The following external components interact with the module:

1. **Ingress-controller** (shown on the diagram as "controller nginx"): Forwards users requests to Grafana.

Fault tolerance and High Availability (HA) monitoring mode

The `prometheus` module provides built-in fault tolerance for all its key components. All monitoring services (Prometheus servers, storage systems, proxies, and other important components) are deployed in multiple copies by default. This ensures that in the event of a failure of a separate instance, the service will continue to work without loss of data and availability.

Prometheus, the main component of metric collection, runs in at least two copies (if there are enough nodes in the cluster). All Prometheus instances use the same configuration and receive the same data. To ensure seamless operation in case of failure of one of the copies, a special component, the aggregating-proxy, is used to access Prometheus. It allows you to combine metrics from several Prometheus instances and always return the most complete and up-to-date data, even if one of the copies is temporarily unavailable.

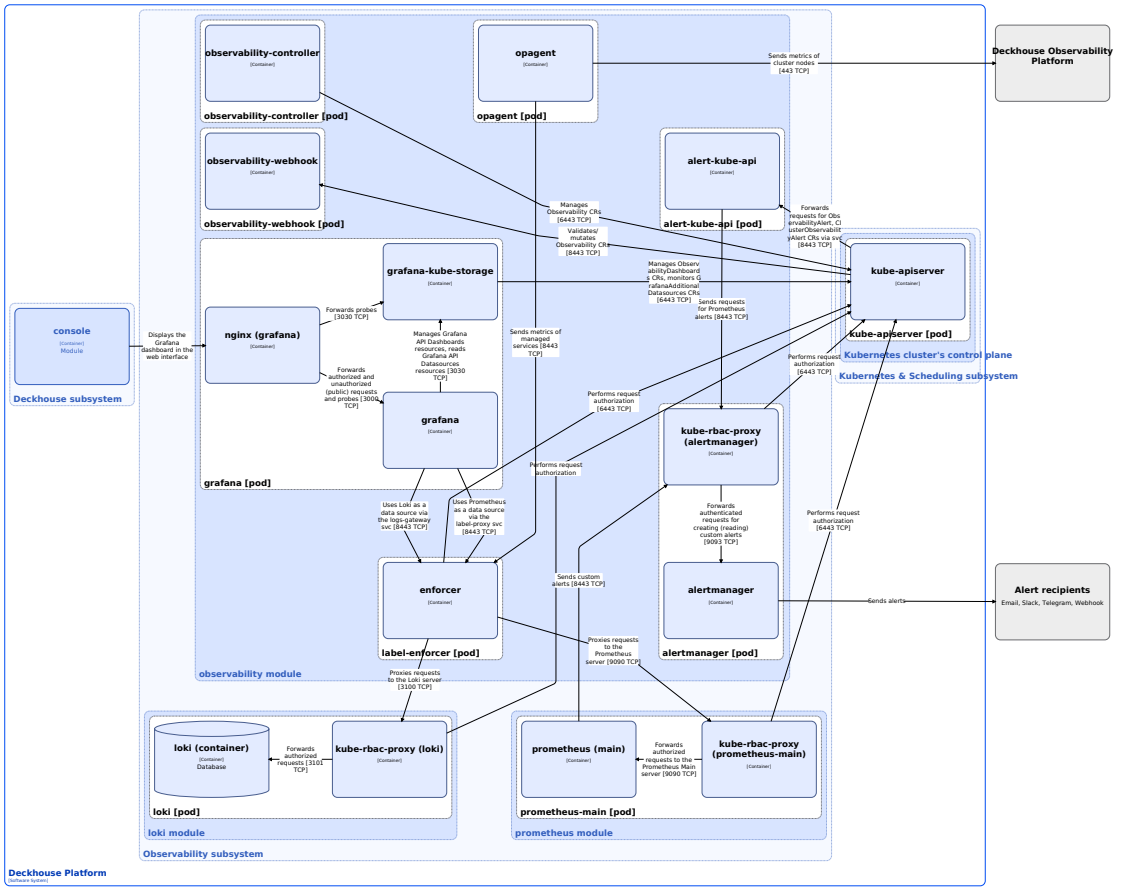
> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Observability module

The `observability` module extends the functionality of the `prometheus` module and the Deckhouse web UI, providing additional capabilities for flexible management of metrics, dashboards, and alerts, as well as access control mechanisms for them.

Module capabilities:



- **Dashboard management**: Allows users to add their own dashboards in Grafana format.
- **Alerting and recording rule group management**: Allows creating and configuring custom alerting and recording rule groups.
- **Notification configuration**: Allows configuring notification channels (Telegram, Slack, email, and webhooks), notification policies, and disabling notifications when needed.
- **Alert management**: Provides information about active alerts and stores the history of resolved alerts.
- **Standard data sources provisioning**.
- **Custom data sources support**: The module allows you to add custom data sources in addition to the provided set of standard data sources.

For more details about the module, refer to the module documentation.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `observability` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Observability-controller**: Consists of a single **observability-controller** container and manages the lifecycle of most of the module's custom resources, such as ObservabilityMetricsRulesGroup, ObservabilityNotificationChannels, ObservabilityNotificationSilence, and others. For complete list of resources managed by the module, refer to the "Custom resources" section in the module documentation.

2. **Observability-webhook**: Consists of a single **observability-webhook** container that implements a webhook server, which is used to validate and mutate Kubernetes API resources through the Validating/Mutating Admission Controllers mechanisms.

3. **Alert-kube-api**: Consists of a single **alert-kube-api** container and implements Kubernetes Extension API Server that extends Kubernetes API with ObservabilityAlert и ClusterObservabilityAlert custom resources. Alert-kube-api

allows you to request alerts as custom resources using the Alertmanager component as a backend and caches them in memory for quick access.

4. **Alertmanager**: Receives alerts from prometheus-main component of the `prometheus` module, processes and sends them to the end recipients. DP supports sending alerts through the following delivery channels:

   - `Email`
   - `Telegram`
   - `Slack`
   - `Webhook`

   It consists of the following containers:

   - **alertmanager**: Main container. A fork of the original Alertmanager made by Flant that supports multitenancy, which allows dividing alerts by system (cluster) and project ones. The delivery of alerts (policies, channels, silencers) is also multitenant, allowing individual configuration of channels and delivery policies in different projects.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the Alertmanager API endpoint. It is an open-source project.

5. **Grafana**: A component that provides a web interface for visualizing monitoring data. A fork of Grafana made by Flant is used in the module. The modified Grafana has advanced features, such as separate access to metrics and dashboards according to multitenancy. Grafana dashboards of the `observability` module are integrated into the Deckhouse web UI (monitoring system management from one window).

   It consists of the following containers:

   - **grafana**: Main container.
   - **grafana-kube-storage**: Sidecar container that implements a backend for grafana container and providing management of Dashboard resources and reading Datasource resources of the Grafana component API. These resources allow you to view and manage dashboards within namespaces (projects), as well as to connect custom data sources.
   - **nginx**: Sidecar container that is an NGINX proxy server, which is used to publish static files. It is an open-source project.

6. **Label-enforcer**: A component that authorizes and proxies user requests to metrics (prometheus-main via the label-proxy service) and logs (loki via the logs-gateway service) sources, specified in the Datasource resources of grafana component API. Label-enforcer verifies RBAC access to monitoring data based on user rights, retrieves a list of available namespaces, and enriches requests with labels to filter requested data within user namespaces. For more information about metrics access control, refer to the module documentation. Label-enforcer handles both metrics read and write requests.

   It consists of a single container named **enforcer**.

7. **Opagent** (DaemonSet): An agent designed to collect metrics from both the operating system and the application software installed on the servers. OpAgent is developed by Flant for the Deckhouse Observability Platform (DOP) based on Okagent (Okmeter agent), that is also a part of the Okmeter monitoring system.

   In the `observability` module, opAgent connects to managed services, such as `managed-postgres`, `managed-memcached`, `managed-kafka`, and others (the list of supported managed services is constantly expanding), collects metrics from them, and sends them to prometheus-main component of the `prometheus` module. If the `observability-platform` module is enabled, opAgent collects metrics from the cluster nodes and sends them to DOP.

   OpAgent sends the collected data using the Prometheus Remote Write protocol:

   - Metrics from managed services: To Prometheus via label-enforcer.
   - Metrics from cluster nodes: To DOP.

   It consists of a single container named **opagent**.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Authorizes requests for monitoring data.
   - Manages module custom resources.
2. **Prometheus**: Uses it as a data source and destination.
3. **Loki**: Uses it as a data source.
4. **Alerts receivers**: Sends alerts.
5. DOP: Uses it as a data destination (metrics from cluster nodes).

The following external components interact with the module:

1. **Kube-apiserver**:
   - Validates and mutates module custom resources (with validating and mutating webhooks).
   - Forwards to alert-kube-api requests for ObservabilityAlert and ClusterObservabilityAlert custom resources.
2. **Prometheus-main**: Sends alerts to alertmanager.
3. **Deckhouse web UI**: Uses Grafana for visualizing monitoring data.

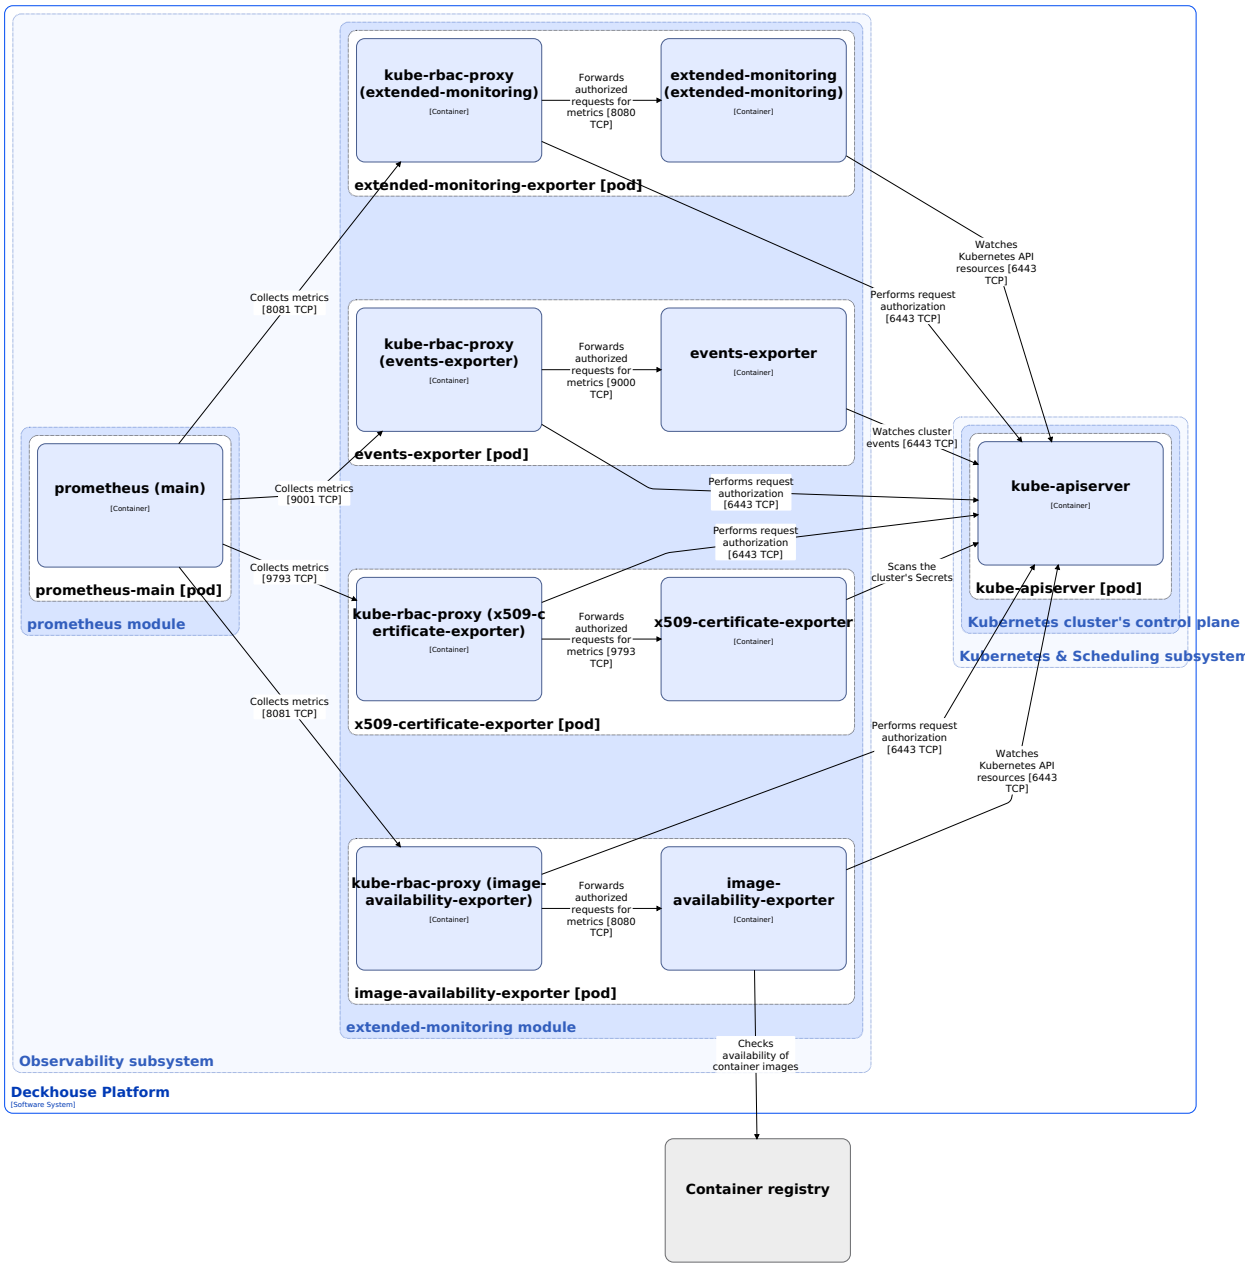
- Module `managed-memcached` documentation
- Module `managed-postgres` documentation
- Module `observability` documentation
- Module `prometheus` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Extended-monitoring module

The `extended-monitoring` module extends cluster monitoring capabilities with additional Prometheus exporters, which allow you to identify potential problems before they affect the operation of services.

Module features:



- Advanced metrics collection.
- Container image monitoring.
- Cluster events collection.
- Certificate control.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `extended-monitoring` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagrams.

Module components

The module consists of the following components:

1. **Extended-monitoring-exporter**: Prometheus exporter that collects and expounds metrics for free space and inodes on nodes, as well as for objects with a label `extended-monitoring.deckhouse.io/enabled =""` in the namespace. For more details about configuration of extended-monitoring metrics, refer to the corresponding documentation section. The module also contains Prometheus rules, based on which the Prometheus generates alerts. This allows you to detect and diagnose incidents faster.

   It consists of the following containers:

   - **extended-monitoring-exporter**: Main container. This exporter is developed by Flant.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC, providing secure access to exporter metrics. It is an open source project.

2. **Image-availability-exporter**: Prometheus exporter that monitors container images of pods running in cluster. Image-availability-exporter adds metrics about unavailability of container images to registry for all types of workload (Deployments, StatefulSets, DaemonSets, CronJobs). The module also contains appropriate Prometheus rules, based on which the Prometheus generates alerts. This helps to find out in advance about possible problems with launching or updating pods.

   It consists of the following containers:

   - **image-availability-exporter**: Main container. This exporter is developed by Flant.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to exporter metrics (described above).

3. **Events-exporter**: Prometheus exporter that collects Kubernetes events and displays them as metrics, which allow you to track the dynamics of changes and respond faster to incidents.

   It consists of the following containers:

    - **events-exporter**: Main container. This exporter is developed by Flant.
    - **kube-rbac-proxy**: Sidecar container providing authorized access to exporter metrics (described above).

4. **X509-certificate-exporter**: Prometheus exporter that provides certificate control:

    - Scans the cluster's Secrets and generates metrics about the expiration of x509 certificates.
    - The module also contains appropriate Prometheus rules, based on which the Prometheus generates alerts. This allows you not to miss critical moments and update certificates on time, avoiding application downtime due to expired certificates.

    It consists of the following containers:

    - **x509-certificate-exporter**: Main container. It is an open source project;
    - **kube-rbac-proxy**: Sidecar container providing authorized access to exporter metrics (described above).

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

    - Watches Kubernetes API resources.
    - Watches cluster events (Events resources).
    - Scans the cluster's Secrets.
    - Authorizes requests for metrics.

2. **Container registry**: Checks availability of container images.

The following external components interact with the module:

1. **Prometheus-main**: Collects metrics from module exporters.

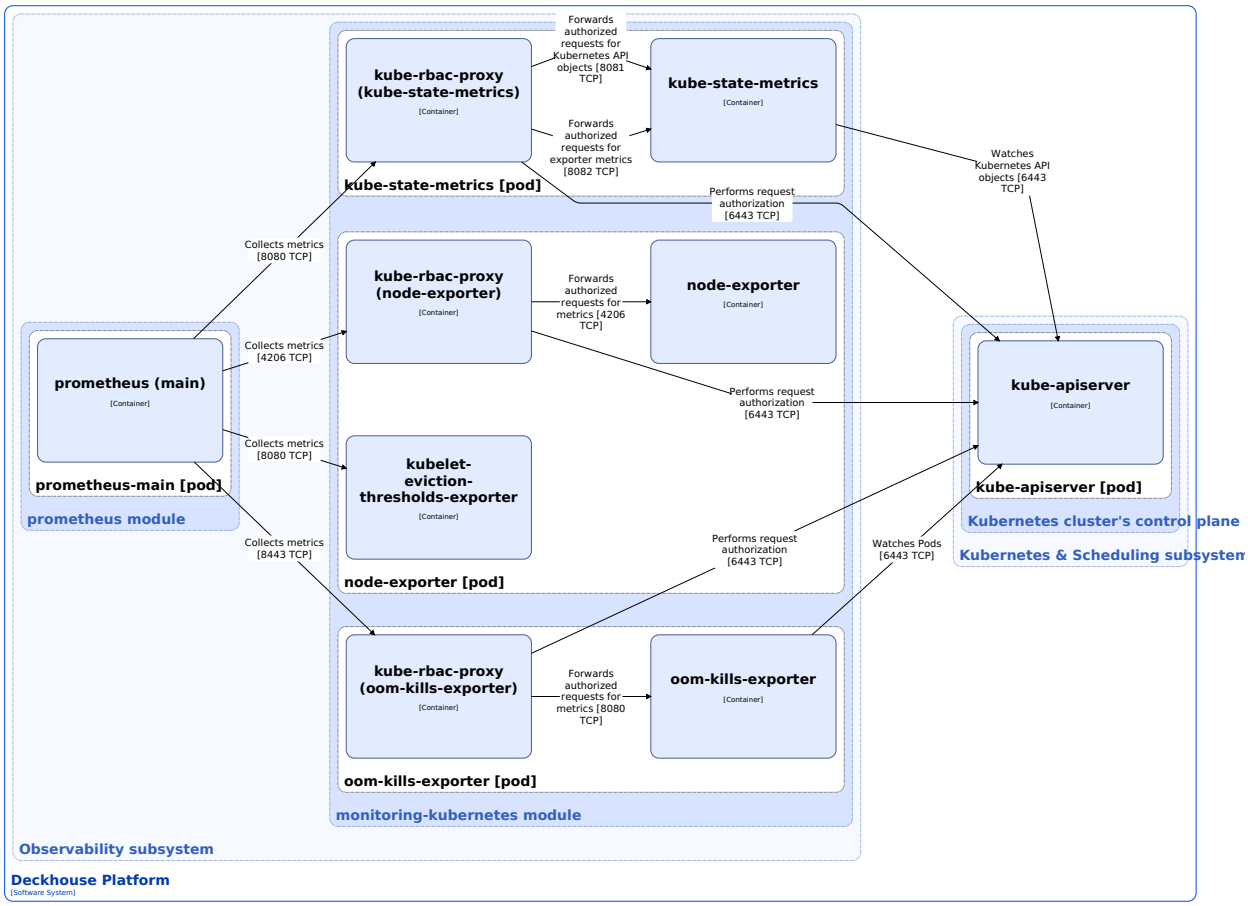
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Monitoring-kubernetes module



The `monitoring-kubernetes` module provides transparent and timely monitoring of the status of all cluster nodes and key infrastructure components.

For more details about module features and configuration, refer to the corresponding documentation section.

Module architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `monitoring-kubernetes` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Module components

The module consists of the following components:

1. **Kube-state-metrics** (Deployment): Prometheus exporter that collects and provides metrics about the state of objects in a Kubernetes cluster. It connects to the Kubernetes API server, analyzes the current status of resources (Pods, Services, Deployments, Nodes, and others), and generates metrics based on this.

   It consists of the following containers:

   - **kube-state-metrics**: Main container. It is an open-source project.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the exporter metrics. It is an open-source project.

2. **Node-exporter** (DaemonSet): Prometheus exporter that runs on each cluster node and collects metrics from these nodes. It collects data about the operating system and hardware.

   It consists of the following containers:

   - **node-exporter**: Main container. It is an open-source project;
   - **kubelet-eviction-thresholds-exporter**: Sidecar container that collects metrics on the availability of file descriptors, sockets, free space and inodes on each node, compares them as a percentage with Eviction thresholds, stated in the kubelet configuration file, and exports the resulting values as metrics. This exporter is developed by Flant.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to the exporter metrics (described above).

3. **Oom-kills-exporter** (DaemonSet): Prometheus exporter that runs on each cluster node, monitors OOM-kill (Out-Of-Memory kill) events occurring with containers running on these nodes, and exports a counter of such events as a metric. Oom-kills-exporter also watches pods to synchronize labels containing container IDs that are added to the metrics.

   It consists of the following containers:

   - **oom-kills-exporter**: Main container. This exporter is developed by Flant.
   - **kube-rbac-proxy**: Sidecar container providing authorized access to the exporter metrics (described above).

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Watches Kubernetes API objects;
   - Authorizes requests for metrics.

The following external components interact with the module:

1. **Prometheus-main**: Collects metrics from module exporters.

Additional resources

- Module `monitoring-kubernetes` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

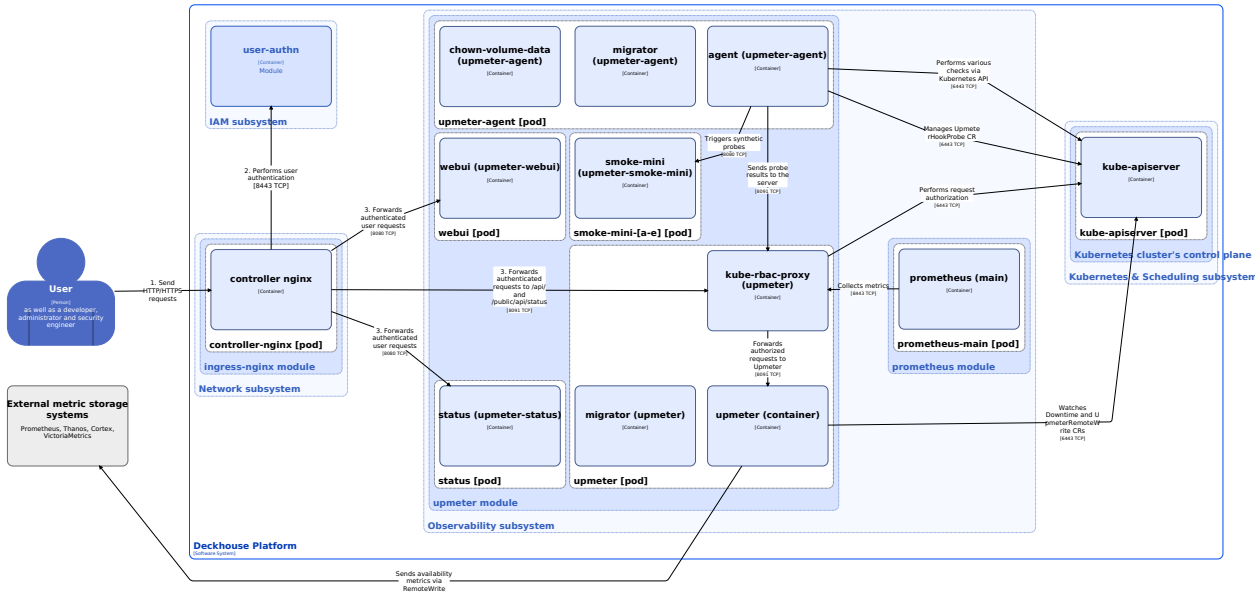
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Upmeter module



The `upmeter` module continuously checks Deckhouse Platform (DP) availability and cluster component health. Probe results are displayed on dashboards.

To learn more about module settings and usage examples, see the `upmeter` configuration page.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica per Pod is shown in the diagram.

The level-2 C4 architecture of the `upmeter` module and its interactions with other DP components are shown below.

Numbers in the diagram show the user request flow to the status and webui components. Steps 1, 2, and 3 handle requests through Ingress NGINX Controller with mandatory user authentication in the platform-wide auth system provided by the `user-authn` module. For details, see the `user-authn` architecture section.

Module components

The module includes the following components:

1. **Upmeter** (StatefulSet) is a controller that:
   - Watches the custom resource Downtime and calculates DP component availability excluding downtime intervals defined in this resource.
   - Stores DP component availability metrics in a local SQLite database.
   - Receives and processes DP component probe data.
   - Handles API requests for platform availability data.
   - Watches the custom resource UpmeterRemoteWrite and sends probe results to the endpoint defined in that resource by using the Prometheus Remote Write protocol.

   It includes the following containers:

   - **upmeter**: Main container.
   - **migrator**: Init container that applies SQL migrations to the component SQLite database.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC for secure access to the upmeter API.

2. **Upmeter-agent** (DaemonSet) runs on master nodes and regularly executes the following probe groups:

   - Control-plane: API server availability and controller health checks.
   - Deckhouse: DP cluster health and `deckhouse` module controller checks.
   - Extensions: Checks that every extension has at least one `Ready` Pod.
   - Load-balancing: Checks availability of network load balancing services.
   - Monitoring-and-autoscaling: Checks that the Observability subsystem is healthy and gathers metrics from system components.
   - Nginx: Checks that every Ingress NGINX Controller has at least one `Ready` Pod.
   - Nodegroups: Checks the number of `desired` nodes in each NodeGroup.
   - Synthetic: Checks network connectivity between cluster nodes with HTTP requests to smoke-mini-[a-e].

   The control-plane group includes the following probes:

   - Apiserver: Upmeter-agent checks Kubernetes API availability.
   - Basic-functionality: Upmeter-agent checks basic Kubernetes API behavior through the ConfigMap lifecycle.
   - Namespace: Upmeter-agent creates the `upmeter-probe-namespace` namespace and removes it after validation.
   - Scheduler: Upmeter-agent creates a Pod named `upmeter-probe-scheduler`, verifies that it is scheduled to any cluster node, and removes it.
   - Controller-manager: Upmeter-agent creates a StatefulSet named `upmeter-probe-controller-manager` with an intentionally missing container in the Pod spec, verifies that the target Pod is created and reaches the expected state, and then removes the StatefulSet.
   - Cert-manager: Upmeter-agent creates a self-signed Certificate named `upmeter-probe-cert-manager`, verifies that cert-manager created the related Secret, and then removes the Certificate and Secret.

   The following flow is used to check the deckhouse controller:

   - Upmeter-agent creates or updates the custom resource UpmeterHookProbe.
   - The deckhouse controller watches this resource and runs a hook to update it.
   - Upmeter-agent also watches UpmeterHookProbe and validates changes.

   You can disable probes or probe groups by using the `.spec.settings.disabledProbes` parameter.

   Upmeter-agent sends collected probe results to upmeter with an HTTP request `POST /downtime`.

   It includes the following containers:

   - **agent**: Main container.
   - **chown-volume-data**: Init container that sets required permissions for the `/var/lib/upmeter/agent` directory on a cluster node.
   - **migrator**: Init container that applies SQL migrations to the component SQLite database.

3. **Smoke-mini-[a-e]** (StatefulSet) is used for synthetic connectivity checks. It includes a single **smoke-mini** container. When upmeter-agent sends a request, smoke-mini-[a-e] instances send requests to each other and to the cluster DNS service, then return probe results.

   When the `upmeter` module is installed, the deckhouse controller from the `deckhouse` module registers a hook that distributes StatefulSet instances across different cluster nodes when possible. After that, it rebalances one StatefulSet every minute to another node.

4. **Status** (Deployment) includes a single **status** container and serves a web page with the current availability status of all DP components.

5. **Webui** (Deployment) includes a single **webui** container and serves a dashboard with per-component availability history.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:

   - Manages custom resources UpmeterRemoteWrite and UpmeterHookProbe.
   - Processes the Downtime custom resources.
   - Authorizes requests to upmeter.
   - Creates, validates, and deletes standard resources: Pod, StatefulSet, Namespace, and Secret, and the custom resource Certificate.

2. **External metric storage systems**: Sends probe results with the Prometheus Remote Write protocol.

The following external components interact with the module:

1. **Prometheus-main**: Uses monitoring rules and metrics related to the upmeter module.
2. **Controller nginx**: Forwards external user requests to the module web interface.

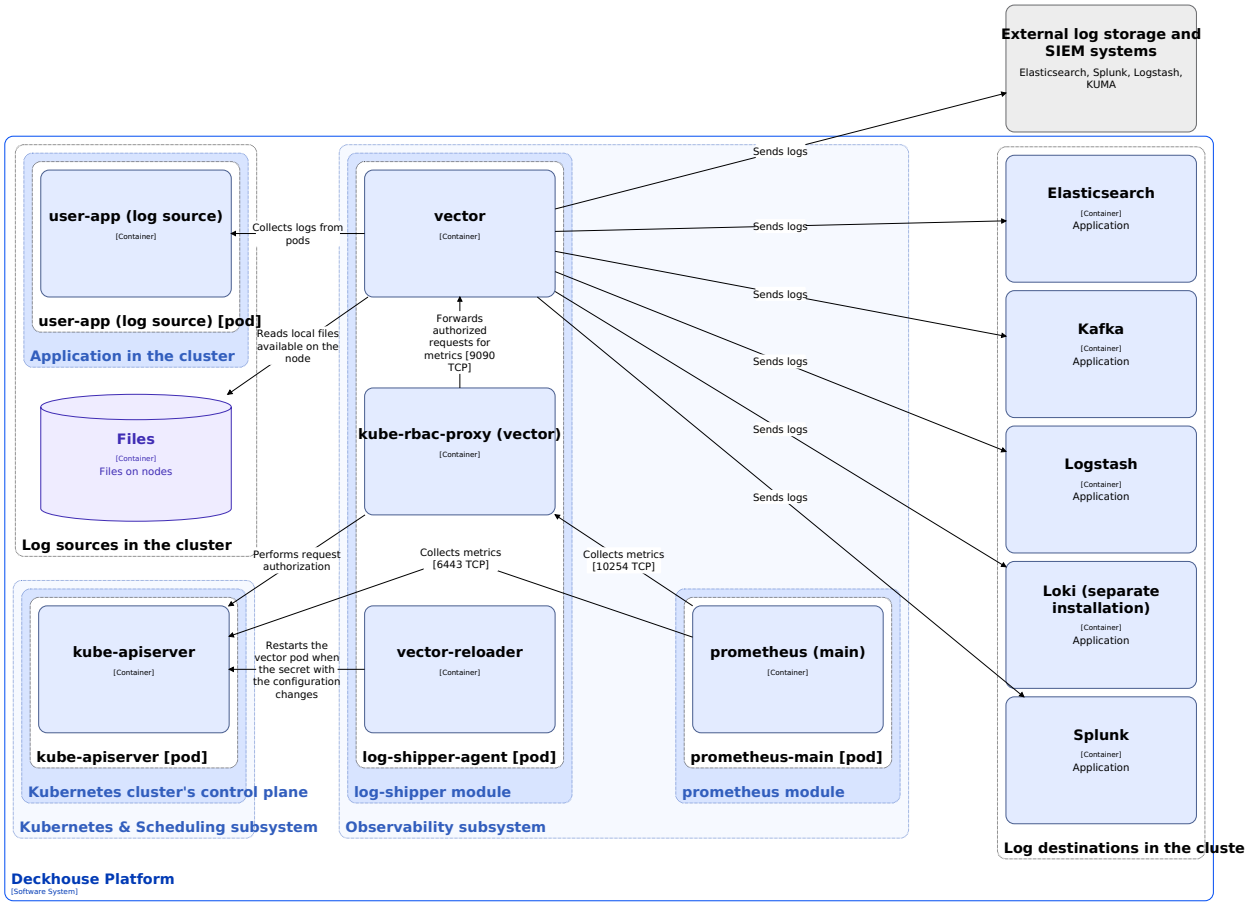
Logging modules

Log-shipper module

The `log-shipper` module simplifies log collection configuration in Kubernetes clusters. It allows collecting logs both from applications running in the cluster and from the cluster nodes, and then forwarding them to any log storage system — either internal or external (for example, Loki, Elasticsearch, and others).



> **i** Deckhouse Platform (DP) provides integration with log storage systems. The storage systems themselves must be deployed and configured by the user.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `log-shipper` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of a single component:

- **log-shipper-agent** (DaemonSet): Separate instance of log-shipper-agent runs on each cluster node and includes the following containers:
  - **vector**: Logging agent based on Datadog Vector.

    It is configured using the custom resources ClusterLogDestination, ClusterLoggingConfig, and PodLoggingConfig.
  - **vector-reloader**: Sidecar container running Reloader. It monitors changes to the configuration Secret. When changes are detected, it validates the updated configuration and restarts vector to apply the updates.

- **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to agent metrics.

Module interactions

The module interacts with the following components:

1. **Log sources in the cluster**:
   - Applications running in the cluster — the module collects logs from pods.
   - Files — the module reads local files on cluster nodes.
2. **Log destinations**:
   - Internal log storage systems.
   - External log storage systems and SIEM platforms.

   Both internal and external destinations may include Elasticsearch, Kafka, Logstash, Loki, and Splunk.
3. **Kube-apiserver**:
   - Authorizes requests for metrics.
   - Monitors changes to the Secret containing the vector configuration.

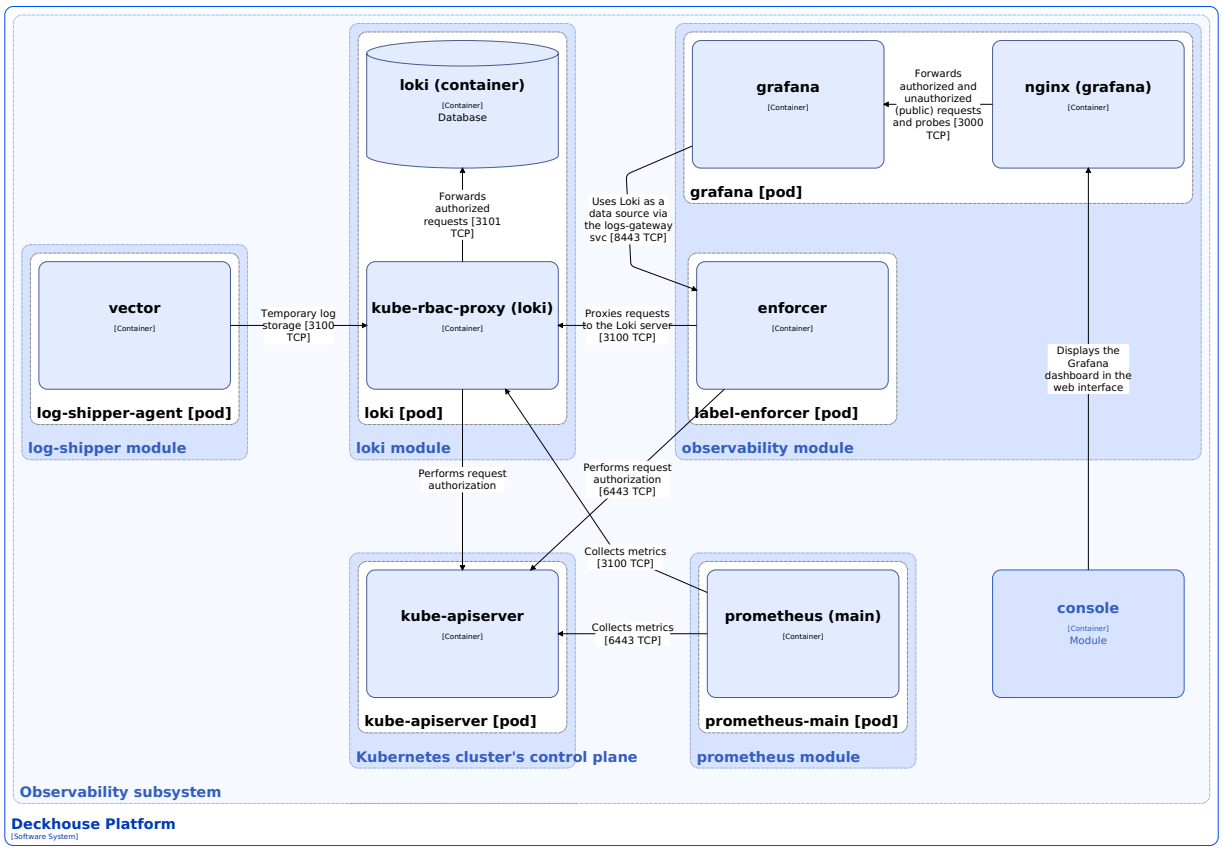
The following external components interact with the module:

1. **Prometheus-main** — collects metrics from log-shipper-agent.

Loki module

In Kubernetes, system logs stored on nodes are retained only for a limited time and may be lost during node restarts or updates. The `loki` module deploys an internal short-term log storage system in the cluster based on Grafana Loki.

Module capabilities:



- System logs are automatically sent to Loki without additional configuration.
- Logs can be accessed through Grafana and the Deckhouse web UI (the `console` module).

> ⚠ The short-term log storage based on Grafana Loki does not support high availability (HA) mode. For long-term storage of important logs, use external storage systems supported by the `log-shipper` module.

For more details about module configuration and usage examples, refer to the corresponding documentation section.

Module architecture

The Level 2 C4 architecture of the `loki` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of a single component:

- **loki**: *StatefulSet* with a single replica **loki-0**, which includes the following containers:
  - **loki**: Container running Grafana Loki.
  - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to loki and its metrics.

Module interactions

The following external components interact with the module:

- **vector**: Sends logs from system components to loki.
- **console** (the Grafana instance embedded in the web UI): Uses loki as a data source for log visualization and analysis.
- **prometheus-main**: Collects loki metrics.

Additional resources

Managed Services subsystem

This subsection describes the architecture of the Managed Services subsystem of Deckhouse Platform (DP). Managed Services subsystem automates the deployment, scaling, backup, and updating of managed services in DP.

The Managed Services subsystem includes the following modules:

- `managed-cassandra`: Manages Cassandra instances.
- `managed-clickhouse`: Manages ClickHouse instances.
- `managed-hive-metastore`: Manages Hive Metastore instances.
- `managed-kafka`: Manages Kafka instances.
- `managed-memcached`: Manages Memcached instances.
- `managed-opensearch`: Manages OpenSearch instances.
- `managed-postgres`: Manages PostgreSQL clusters.
- `managed-starrocks`: Manages StarRocks instances.
- `managed-trino`: Manages Trino instances.
- `managed-valkey`: Manages Valkey instances.

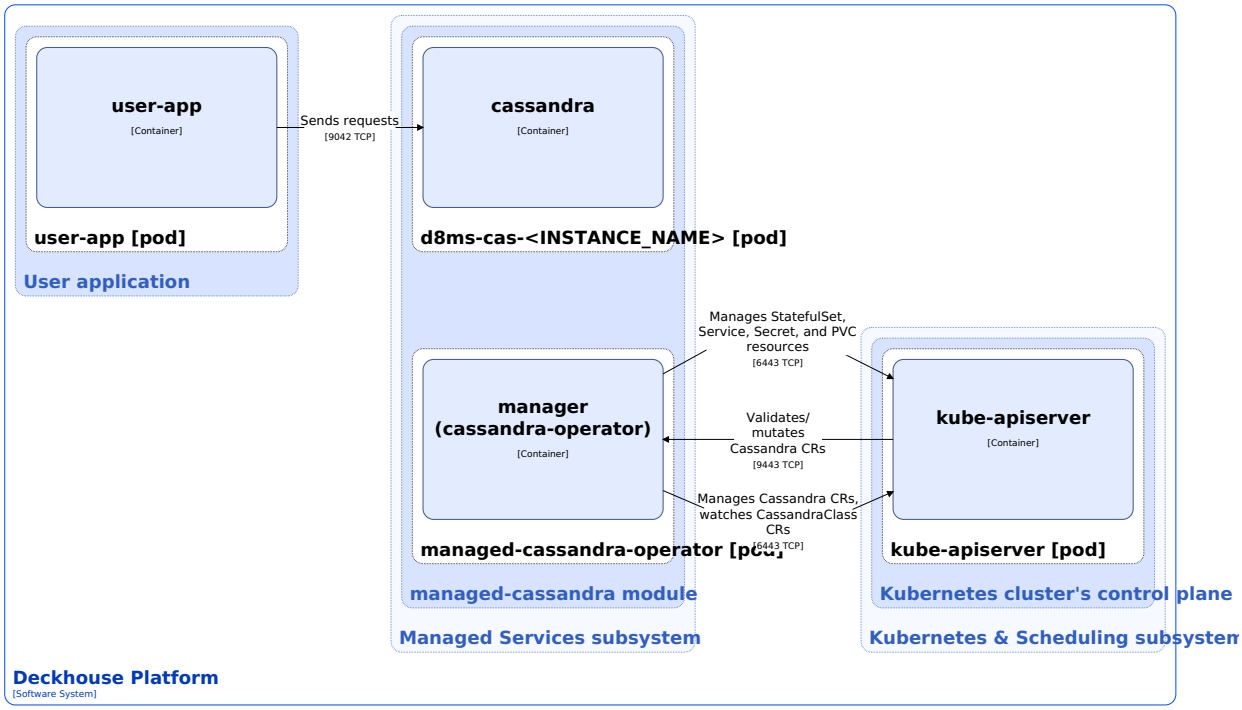
> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-cassandra module

The `managed-cassandra` module manages instances of the distributed, Open Source NoSQL database system Apache Cassandra in Deckhouse Platform (DP). It provides:



- **Automatic Deployment**: Creates a Cassandra instance using a simple YAML configuration.
- **Standalone**: Supports deployment of a standalone instance.
- **Configuration Management**: Separate CassandraClass resource for templating service creation and flexible validation of user parameters.
- **Status**: Displays the current status of the deployed Cassandra instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> **i** The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-cassandra` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-cassandra-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - Reconciles Cassandra custom resources in all user namespaces. The Cassandra and CassandraClass custom resources define the settings of the Cassandra instance.
   - Creates and manages StatefulSet, Service, Secret, and PersistentVolumeClaim resources related to the Cassandra instance.
   - Validates and mutates Cassandra custom resources using the Validating/Mutating Admission Controllers mechanism.
2. **D8ms-cas-<INSTANCE_NAME>** (StatefulSet): A component consisting of a single **cassandra** container that starts and runs the Cassandra instance. It is created by the managed-cassandra-operator component for each Cassandra custom resource.

Module interactions

The module interacts with the **kube-apiserver** component:

- Manages Cassandra custom resources.
- Watches CassandraClass custom resources.
- Manages StatefulSet, Service, Secret, and PersistentVolumeClaim resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Cassandra custom resources.
2. **User applications**: Send requests to the Cassandra instance.

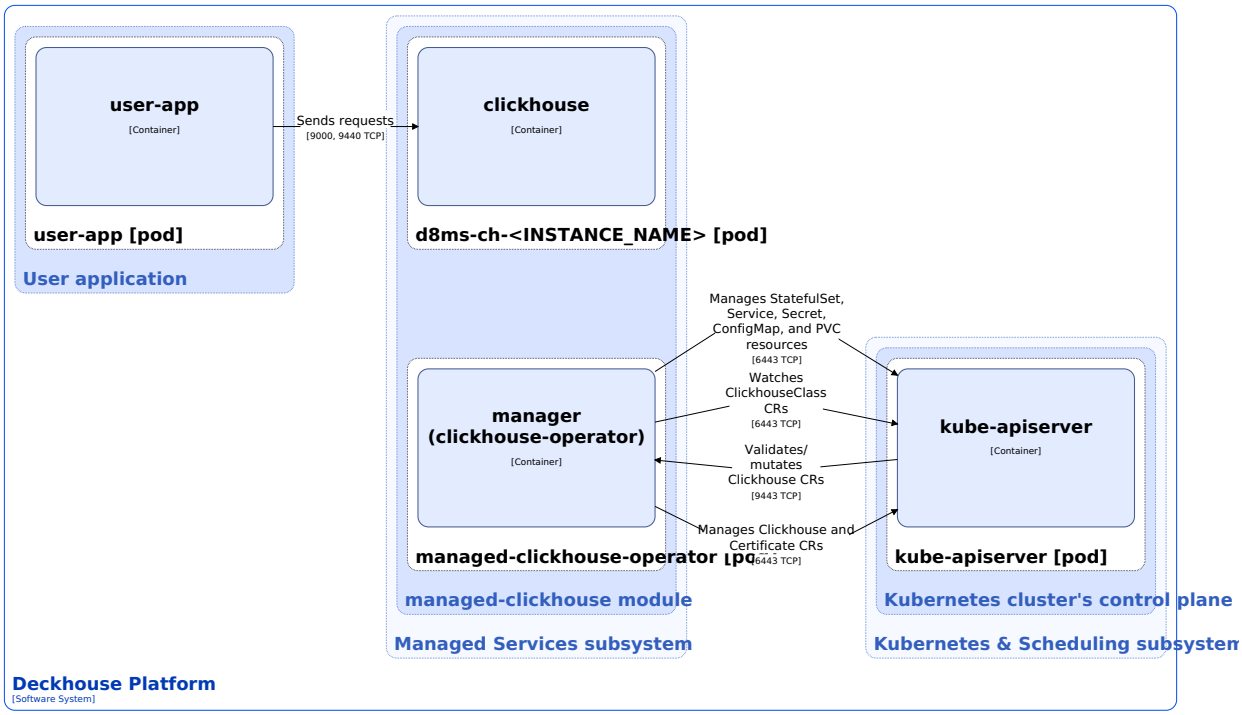
Additional resources

- Module `managed-cassandra` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-clickhouse module

The `managed-clickhouse` module manages instances of ClickHouse in Deckhouse Platform (DP). ClickHouse is a high-performance Open Source columnar DBMS designed for online analytical processing (OLAP) of large volumes of data in real time. The module provides:



- **Automatic Deployment**: Creates a ClickHouse instance using a simple YAML configuration.
- **Standalone**: Supports deployment of a standalone instance.
- **Configuration Management**: Separate ClickhouseClass resource for templating service creation and flexible validation of user parameters.
- **Status**: Displays the current status of the deployed ClickHouse instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-clickhouse` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-clickhouse-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - Reconciles Clickhouse custom resources in all user namespaces. The Clickhouse and ClickhouseClass custom resources define the settings of the ClickHouse instance.
   - Creates and manages the Certificate custom resource and StatefulSet, Secret, Service, ConfigMap, and PersistentVolumeClaim resources related to the ClickHouse instance.
   - Validates and mutates Clickhouse custom resources using the Validating/Mutating Admission Controllers mechanism.
2. **D8ms-ch-<INSTANCE_NAME>** (StatefulSet): A component consisting of a single **clickhouse** container that starts

and runs the ClickHouse instance. It is created by the managed-clickhouse-operator component for each Clickhouse custom resource.

Module interactions

The module interacts with the **kube-apiserver** component:

- Manages Clickhouse and Certificate custom resources.
- Watches ClickhouseClass custom resources.
- Manages StatefulSet, Secret, Service, ConfigMap, and PersistentVolumeClaim resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Clickhouse custom resources.
2. **User applications**: Send requests to the ClickHouse instance.

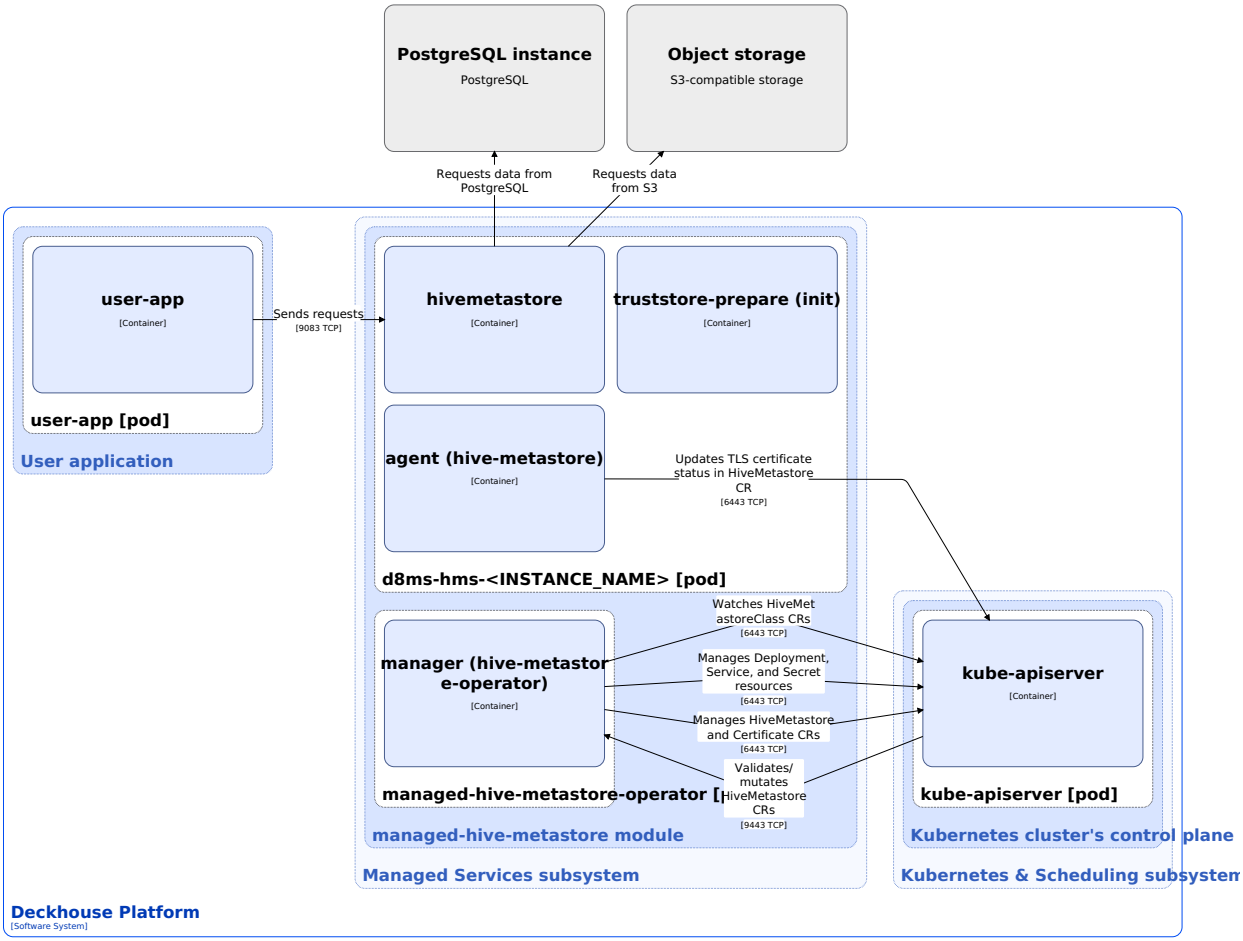
Additional resources

- Module `managed-clickhouse` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-hive-metastore module

The `managed-hive-metastore` module manages instances of Hive Metastore (HMS) in Deckhouse Platform (DP). HMS is the centralized metadata store in the big data ecosystem. The module provides:



- **Automatic Deployment**: Creates an HMS instance using a simple YAML configuration.
- **Standalone**: Supports deployment of a standalone instance.
- **Configuration Management**: Separate HiveMetastoreClass resource for templating service creation and flexible validation of user parameters.
- **Status**: Displays the current status of the deployed HMS instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-hive-metastore` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-hive-metastore-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - Reconciles HiveMetastore custom resources in all user namespaces. The HiveMetastore and HiveMetastoreClass custom resources define the settings of the HMS instance.
   - Creates and manages the Certificate custom resource and Deployment, Service, and Secret resources related to the HMS instance.
   - Validates and mutates HiveMetastore custom resources using the Validating/Mutating Admission Controllers mechanism.
2. **D8ms-hms-<INSTANCE_NAME>** (Deployment): A component that starts and runs the HMS instance.

   It consists of the following containers:
   - **truststore-prepare**: Init container that prepares the truststore.
   - **agent**: Sidecar container that monitors and updates the TLS certificate status.
   - **hivemetastore**: Main container.

Module interactions

The module interacts with the following components:

1. **PostgreSQL instance**: Processes metadata on the database server.
2. **Object storage**: Processes data in the object storage.
3. **Kube-apiserver**:
   - Manages HiveMetastore and Certificate custom resources.
   - Watches HiveMetastoreClass custom resources.
   - Manages Deployment, Service, and Secret resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates HiveMetastore custom resources.
2. **User applications**: Send requests to the HMS instance.

Additional resources

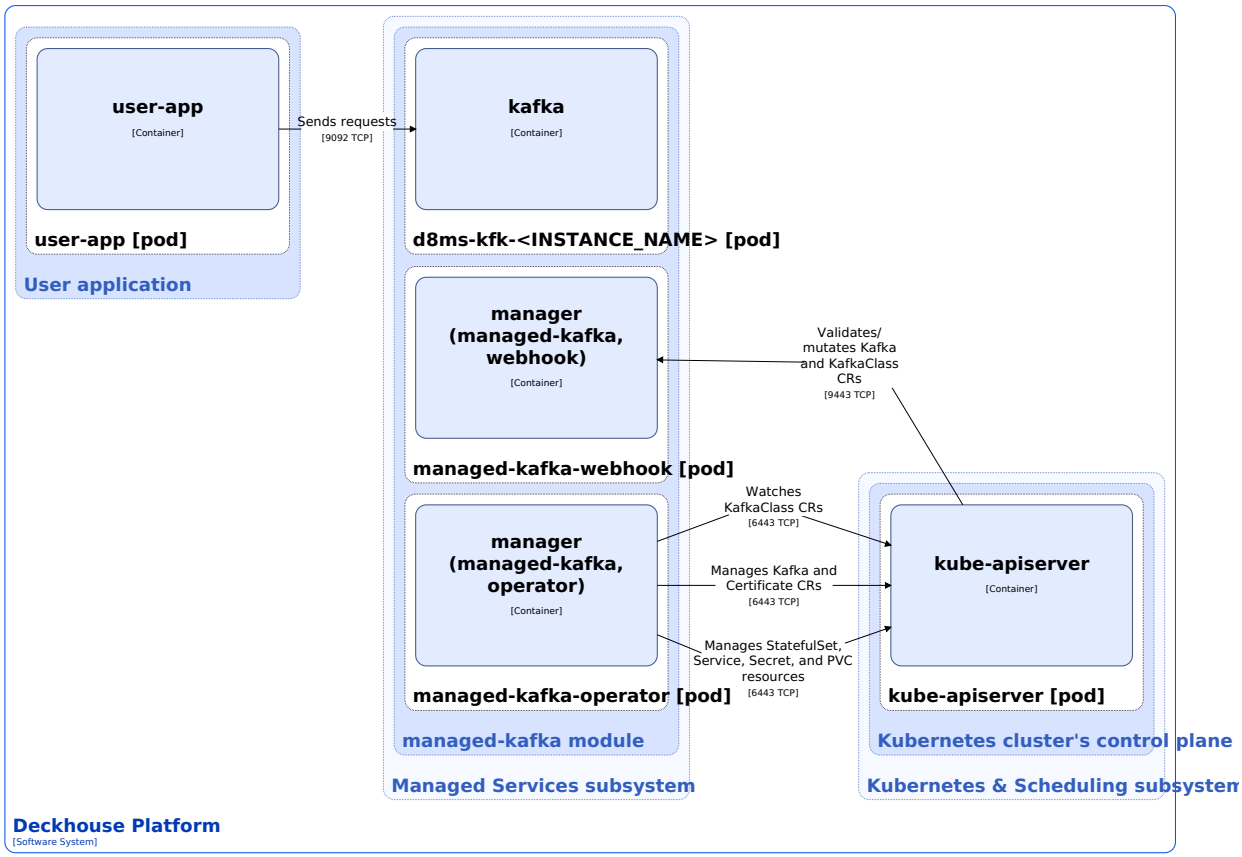
Managed-kafka module

The `managed-kafka` module manages Apache Kafka instances in Deckhouse Platform (DP). Apache Kafka is a distributed Open Source data streaming platform and message broker. The module provides:



- **Automatic Deployment**: Creates a Kafka instance using a simple YAML configuration.
- **Configuration Management**: Separate KafkaClass resource for templating service creation and flexible validation of user parameters.
- **Long-term Storage**: Supports PersistentVolumeClaim parameters for data.
- **Status**: Displays the current status of the deployed Kafka instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-kafka` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-kafka-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - Reconciles Kafka custom resources in all user namespaces. The Kafka and KafkaClass custom resources define the settings of the Kafka instance.

    - Creates and manages StatefulSet, Service, Secret, and PersistentVolumeClaim resources related to the Kafka instance.

2. **Managed-kafka-webhook** (Deployment): A component consisting of a single container **manager**.

   It validates and mutates Kafka and KafkaClass custom resources using the Validating/Mutating Admission Controllers mechanism.

3. **D8ms-kfk-<INSTANCE_NAME>** (StatefulSet): A component consisting of a single **kafka** container that starts and runs the Kafka instance. It is created by the managed-kafka-operator component.

Module interactions

The module interacts with the **kube-apiserver** component:

- Manages Kafka and Certificate custom resources.
- Watches KafkaClass custom resources.
- Manages StatefulSet, Service, Secret, and PersistentVolumeClaim resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Kafka and KafkaClass custom resources.
2. **User applications**: Send requests to the Kafka instance.

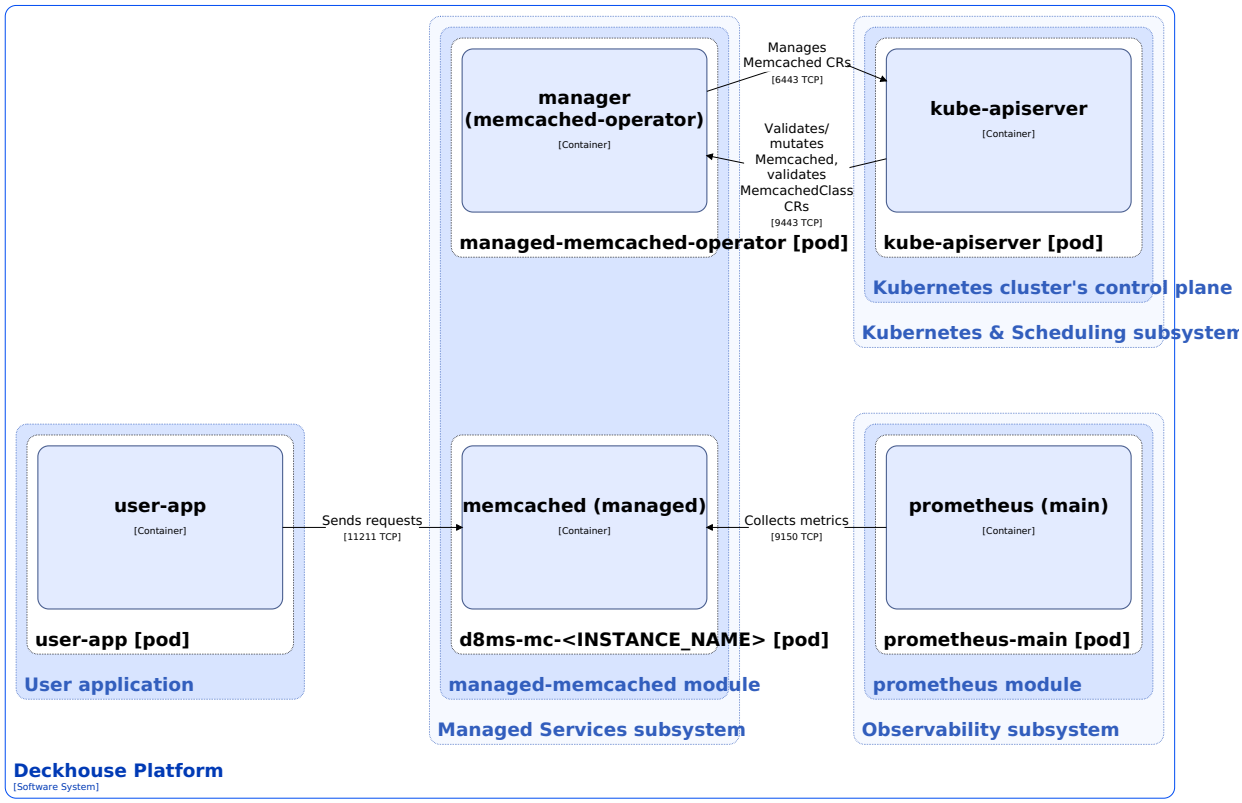
Additional resources

- Module `managed-kafka` documentation

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-memcached module

The `managed-memcached` module simplifies the deployment and management of Memcached instances in Deckhouse Platform (DP). It provides:



- **Automated Deployment**: Deploy Memcached instances with a simple YAML configuration.
- **High Availability**: Support for both standalone (Standalone) and group (Group) deployments.
- **Configuration Management**: Flexible configuration with validation and constraints through MemcachedClass.
- **Resource Management**: Automatic resource allocation and scaling.
- **Monitoring**: Built-in status tracking and health monitoring.
- **Security**: Distroless images and proper RBAC configuration.
- **Validation**: CEL rules for configuration validation.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> **i** The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica per Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-memcached` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-memcached-operator**: Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - It reconciles Memcached custom resources in all user namespaces. The Memcached resource defines the settings of the Memcached instance, including the topology and the deployment type.
   - It validates Memcached and MemcachedClass custom resources, and mutates Memcached custom resources using the Validating/Mutating Admission Controllers mechanism.
2. **d8ms-mc-<INSTANCE_NAME>** (StatefulSet): One or more Memcached instances, depending on the deployment type. They are created by the managed-memcached-operator component.

   It consists of a single container:
   - **memcached**: It is an Open Source project.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**: Manages Memcached custom resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates Memcached and MemcachedClass custom resources, mutates Memcached custom resources.
2. **Prometheus-main**: Collects metrics from Memcached instances.
3. **User applications**: Sends requests to the Memcached instances.

Additional resources

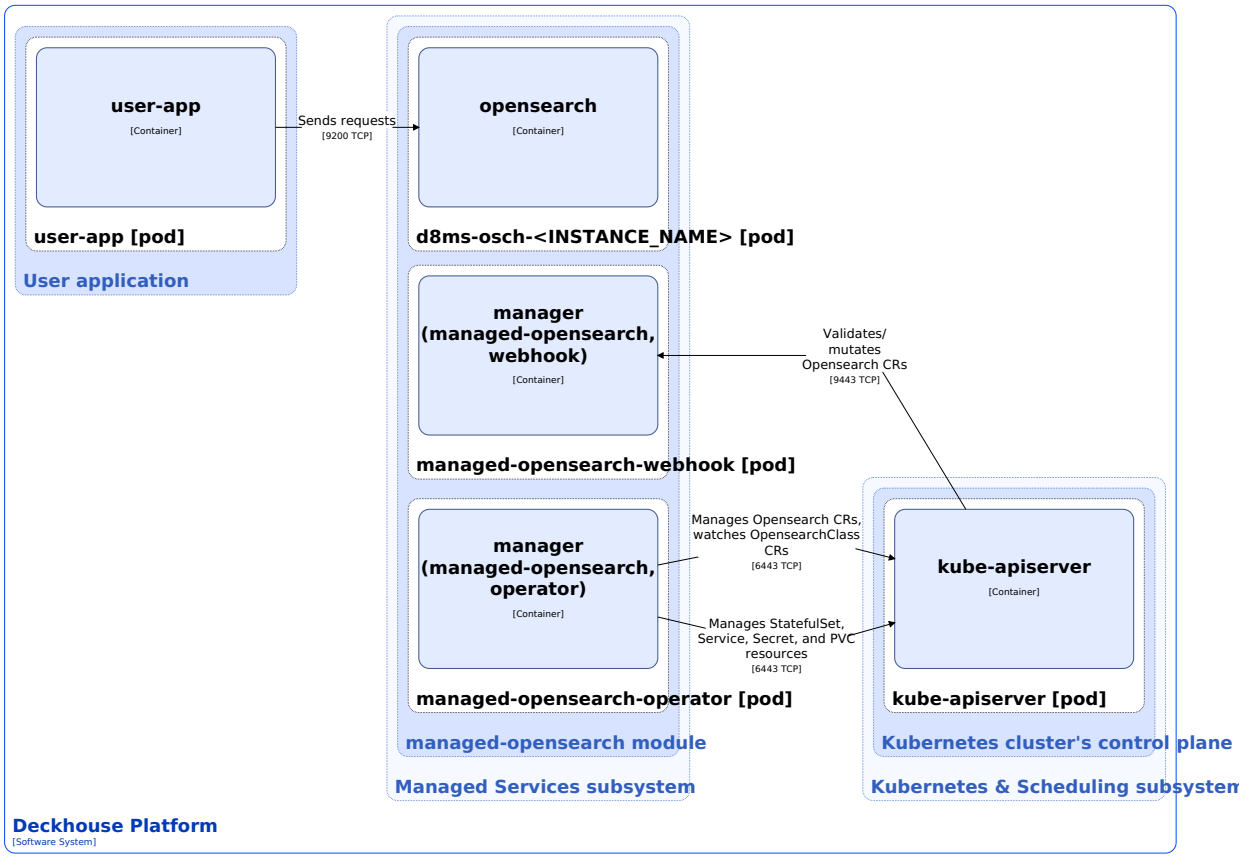
- Module `managed-memcached` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-opensearch module

The `managed-opensearch` module manages instances of OpenSearch in Deckhouse Platform (DP). OpenSearch is an

Open Source search and analytics engine designed for working with large volumes of data in real time. The module provides:



- **Automatic Deployment**: Creates an OpenSearch instance using a simple YAML configuration.
- **Configuration Management**: Separate OpensearchClass resource for templating service creation and flexible validation of user parameters.
- **Class-oriented Management**: Supports sizing policies and CEL validations.
- **Long-term Storage**: Supports PersistentVolumeClaim parameters for data.
- **Status**: Displays the current status of the deployed OpenSearch instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> **i** The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-opensearch` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-opensearch-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - Reconciles Opensearch custom resources in all user namespaces. The Opensearch and OpensearchClass custom resources define the settings of the OpenSearch instance.
   - Creates and manages StatefulSet, Service, Secret, and PersistentVolumeClaim resources related to the OpenSearch instance.
2. **Managed-opensearch-webhook** (Deployment): A component consisting of a single container **manager**.

   It validates and mutates Opensearch custom resources using the Validating/Mutating Admission Controllers mechanism.
3. **D8ms-osch-<INSTANCE_NAME>** (StatefulSet): A component consisting of a single **opensearch** container that starts and runs the OpenSearch instance. It is created by the managed-opensearch-operator component.

Module interactions

The module interacts with the **kube-apiserver** component:

- Manages Opensearch and Certificate custom resources.
- Watches OpensearchClass custom resources.
- Manages StatefulSet, Service, Secret, and PersistentVolumeClaim resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Opensearch custom resources.
2. **User applications**: Send requests to the OpenSearch instance.

Additional resources

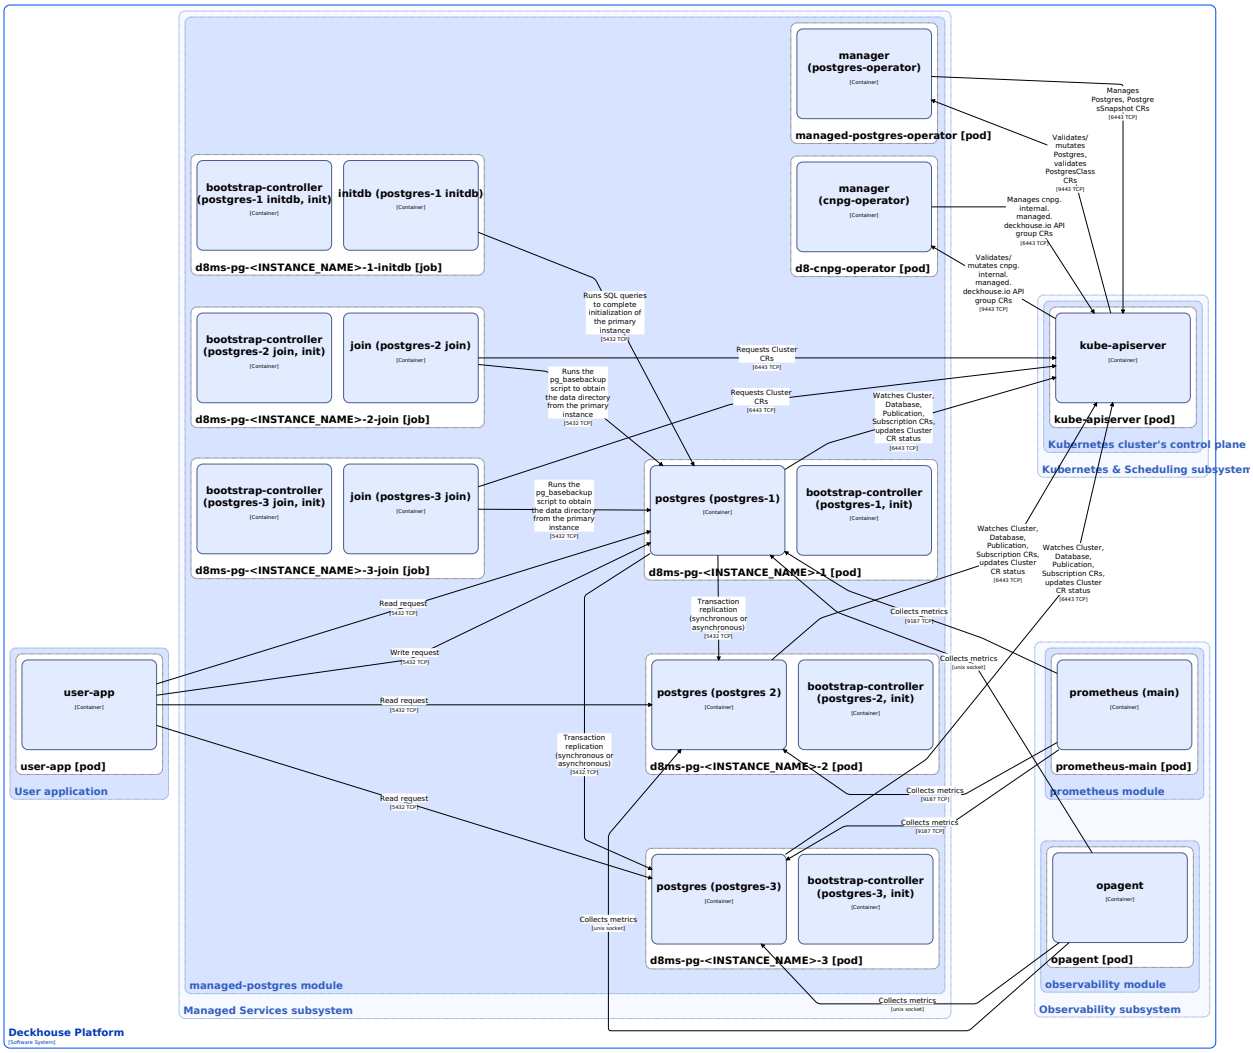
- Module `managed-opensearch` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-postgres module

The `managed-postgres` module manages PostgreSQL clusters in Deckhouse Platform (DP). It allows users to configure and scale PostgreSQL clusters according to their needs, ensuring optimal performance and security.

Main features:



- **Automatic Deployment**: Deploys a Postgres instance using a simple YAML configuration.
- **High Availability**: Supports deployment of a highly available Postgres cluster or a standalone instance of your choice.
- **Configuration Management**: Separate PostgresClass custom resource for templating the cluster creation approach with the ability to flexibly validate user configs.
- **User and Database Management**: Declarative model for creating users and logical databases.
- **Status**: Informative set of states for tracking the deployed Postgres.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica per Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-postgres` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-postgres-operator**: Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - It reconciles Postgres custom resources in all user namespaces. The Postgres resource defines the settings of the PostgreSQL cluster, including the topology and the replication mode, PostgreSQL instances configuration, and other parameters such as lists of logical databases and internal users.
   - It reconciles PostgresSnapshot custom resources. PostgresSnapshot resource designed for PostgreSQL instances backup and restore;
   - It performs Postgres and PostgresClass custom resources validation, as well as Postgres custom resources mutation using the Validating/Mutating Admission Controllers mechanism.

   Managed-postgres-operator uses the `cnpg.internal.managed.deckhouse.io` API group custom resources managed by the d8-cnpg-operator component as a backend.
2. **D8-cnpg-operator**: A fork of CloudNativePG, a Kubernetes operator that automates the management of PostgreSQL clusters. D8-cnpg-operator consists of a single container **manager** and performs the following operations:
   - It manages the following `cnpg.internal.managed.deckhouse.io` API group custom resources:
     - Cluster: Defines a PostgreSQL cluster.
     - Pooler: Defines connection pool settings.
     - FailoverQuorum: It is used to display a quorum status of PostgreSQL cluster replicas in high-availability configuration.
     - Database: Defines a logical database.
     - Backup: Defines a PostgreSQL instance backup.
     - ScheduledBackup: Defines a PostgreSQL scheduled backup settings.
     - Subscription: Defines a logical replication destination.
     - Publication: Defines a logical replication source.
     - ImageCatalog: Defines PostgreSQL images for user namespaces.
     - ClusterImageCatalog: Defines cluster-wide PostgreSQL images.
   - It performs `cnpg.internal.managed.deckhouse.io` API group custom resources validation and mutation using the Validating/Mutating Admission Controllers mechanism.

> **i** The components for ConsistencyAndAvailability replication mode are described below. The components for other two replication modes are the part of components for ConsistencyAndAvailability mode.

3. **d8ms-pg-<INSTANCE_NAME>-1-initdb** (Job): A job created by the d8-cnpg-operator component that runs SQL queries to complete initialization of the primary PostgreSQL instance.

   It consists of the following containers:

   - **bootstrap-controller**: Init container that installs `manager` executable file of d8-cnpg-operator component.
   - **initdb**: Main container that runs `manager` executable file, which executes the SQL queries described above.

4. **d8ms-pg-<INSTANCE_NAME>-2-join** (Job): A job created by the d8-cnpg-operator component that runs `pg_basebackup` script to get `data` directory from primary instance for first replica. This job uses a Cluster custom resource to configure the replica.

   It consists of the following containers:

   - **bootstrap-controller**: Init container that installs `manager` executable file of d8-cnpg-operator component.
   - **join**: Main container that runs `manager` executable file, which executes the script described above.

5. **d8ms-pg-<INSTANCE_NAME>-3-join** (Job): A job created by the d8-cnpg-operator component that runs `pg_basebackup` script to get `data` directory from primary instance for second replica. This job uses a Cluster custom resource to configure the replica.

   It consists of the following containers:

   - **bootstrap-controller**: Init container that installs `manager` executable file of d8-cnpg-operator component.
   - **join**: Main container that runs `manager` executable file, which executes the script described above.

6. **d8ms-pg-<INSTANCE_NAME>-1**: PostgreSQL primary instance. It is created by the d8-cnpg-operator component.

   It consists of the following containers:

   - **bootstrap-controller**: Init container that installs `manager` executable file of d8-cnpg-operator component.
   - **postgres**: Main container that runs `manager` executable file, which performs the following operations:
     - It starts PostgreSQL processes.
     - It manages PostgreSQL instance lifecycle, including server monitoring, handling server shutdown and restart.
     - It participates in `switchover`/`failover` procedures. `Switchover` is a planned and controlled process in which an active primary instance is intentionally decommissioned and an assigned backup instance (replica) is promoted to the primary instance role. Its main goal is to ensure zero data loss: before transferring the role to the replica, the system waits until all current transactions are replicated. A `failover` is an emergency situation: the primary instance has failed, become unavailable, or cannot be safely used to write data. In this case, the designated backup instance (replica) is promoted to the primary instance role, and data loss is possible.
     - It interacts with the operator and publishes instance status;
     - It watches Cluster, Database, Publication and Subscription custom resources.

7. **d8ms-pg-<INSTANCE_NAME>-2**: PostgreSQL first replica. It is created by the d8-cnpg-operator component.

   It consists of the following containers:

   - **bootstrap-controller**: Init container that installs `manager` executable file of d8-cnpg-operator component.
   - **postgres**: Main container that runs `manager` executable file, which performs operations described for PostgreSQL primary instance.

8. **d8ms-pg-<INSTANCE_NAME>-3**: PostgreSQL second replica. It is created by the d8-cnpg-operator component.

   It consists of the following containers:

   - **bootstrap-controller**: Init container that installs `manager` executable file of d8-cnpg-operator component.
   - **postgres**: Main container that runs `manager` executable file, which performs operations described for PostgreSQL primary instance.

Module interactions

The module interacts with the following components:

1. **Kube-apiserver**:
   - Manages Postgres and PostgresSnapshot custom resources.
   - Manages `cnpg.internal.managed.deckhouse.io` API group custom resources.

The following external components interact with the module:

1. **Kube-apiserver**:
   - Validates Postgres and PostgresClass custom resources, mutates Postgres custom resources.
   - Validates and mutates `cnpg.internal.managed.deckhouse.io` API group custom resources.
2. **Prometheus-main**: Collects PostgreSQL cluster instances metrics (which are exported by `manager` executable file of d8-cnpg-operator component that is run in postgres container of PostgreSQL instance pod).
3. **opAgent**: Collects PostgreSQL cluster instances metrics (connecting directly to PostgreSQL cluster instances) and sends them to prometheus-main.

4. **User applications**: Sends requests to PostgreSQL cluster instances. Write requests are sent to the primary instance via the **d8ms-pg-<INSTANCE_NAME>-rw** service. The primary instance replicates transactions to replicas. Read requests are balanced to PostgreSQL instances via **d8ms-pg-<INSTANCE_NAME>-r** or **d8ms-pg-<INSTANCE_NAME>-ro** services.

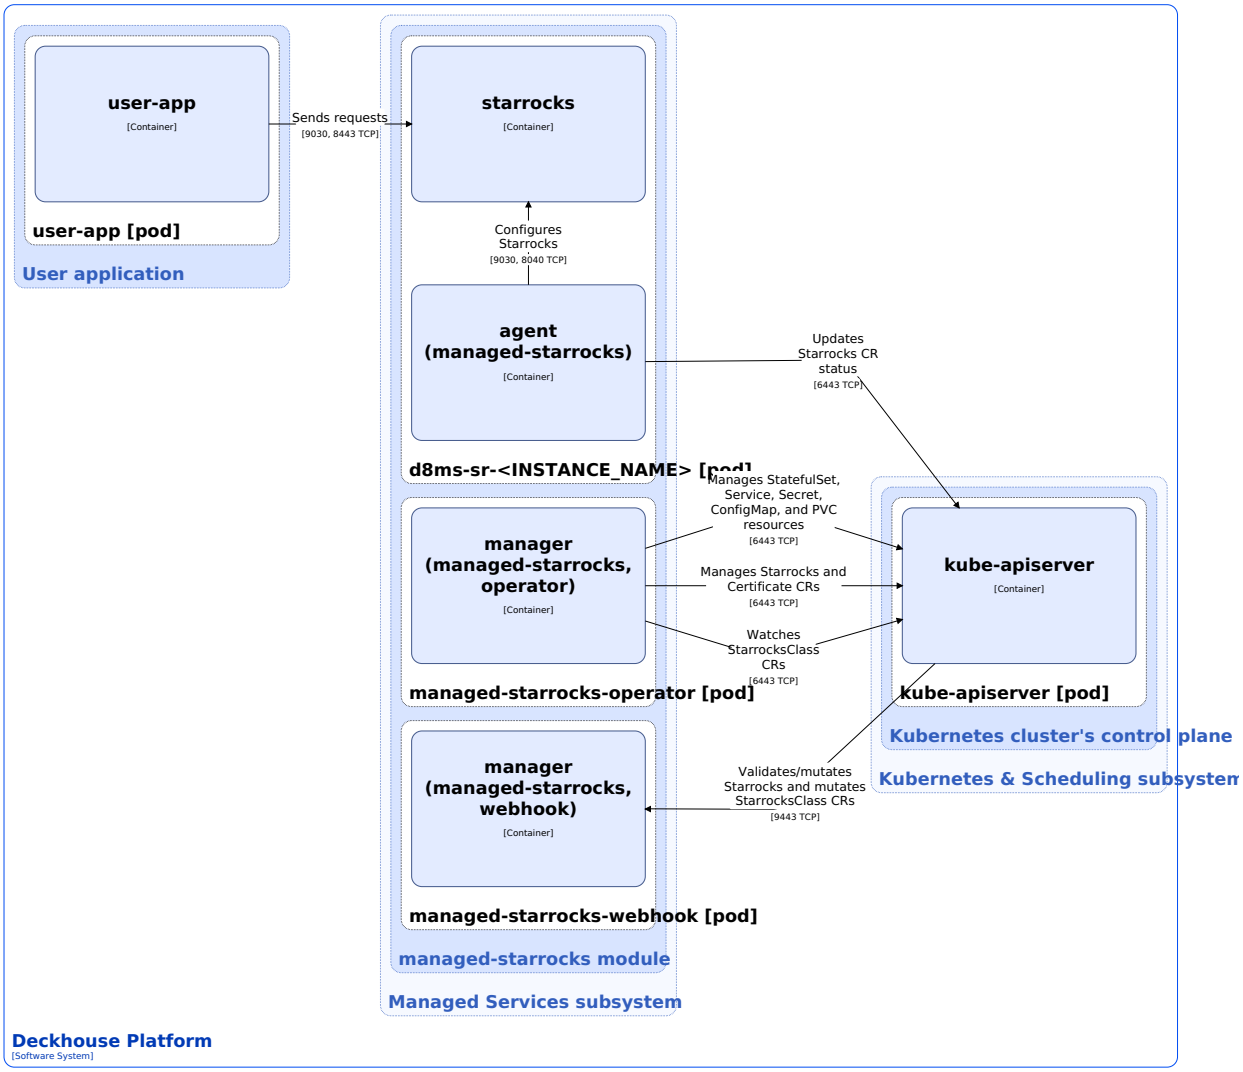
Managed-starrocks module

The `managed-starrocks` module manages StarRocks instances in Deckhouse Platform (DP). StarRocks is a high-performance analytical DBMS (OLAP) for real-time analytics, data warehouses, and BI workloads.

The module provides:



- **Automatic Deployment**: Creates a StarRocks instance using a simple YAML configuration.
- **Configuration Management**: Separate StarrocksClass resource for templating service creation and flexible validation of user parameters.
- **Analytics Tuning**: Supports data load parameters (`streamingLoadMaxMb`, `loadProcessMaxMemoryLimitPercent`) and catalog management (`catalogTrashExpireSecond`).
- **Status**: Displays the current status of the deployed StarRocks instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-starrocks` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-starrocks-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - Reconciles Starrocks custom resources in all user namespaces. The Starrocks and StarrocksClass custom resources define the settings of the StarRocks instance.
   - Creates and manages the Certificate custom resource and StatefulSet, Service, Secret, ConfigMap, and PersistentVolumeClaim resources related to the StarRocks instance.
2. **Managed-starrocks-webhook** (Deployment): A component consisting of a single container **manager**.

   It validates and mutates Starrocks custom resources, and mutates StarrocksClass custom resources using the Validating/Mutating Admission Controllers mechanism.
3. **D8ms-sr-<INSTANCE_NAME>** (StatefulSet): A component that starts and runs the StarRocks instance. It is created by the managed-starrocks-operator component.

   It consists of the following containers:
   - **agent**: Sidecar container that monitors and updates the TLS certificate status, and configures the instance.
   - **starrocks**: Main container.

Module interactions

The module interacts with the **kube-apiserver** component:

- Manages Starrocks and Certificate custom resources.
- Watches StarrocksClass custom resources.
- Manages StatefulSet, Service, Secret, ConfigMap, and PersistentVolumeClaim resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Starrocks custom resources, mutates StarrocksClass custom resources.
2. **User applications**: Send requests to the StarRocks instance.

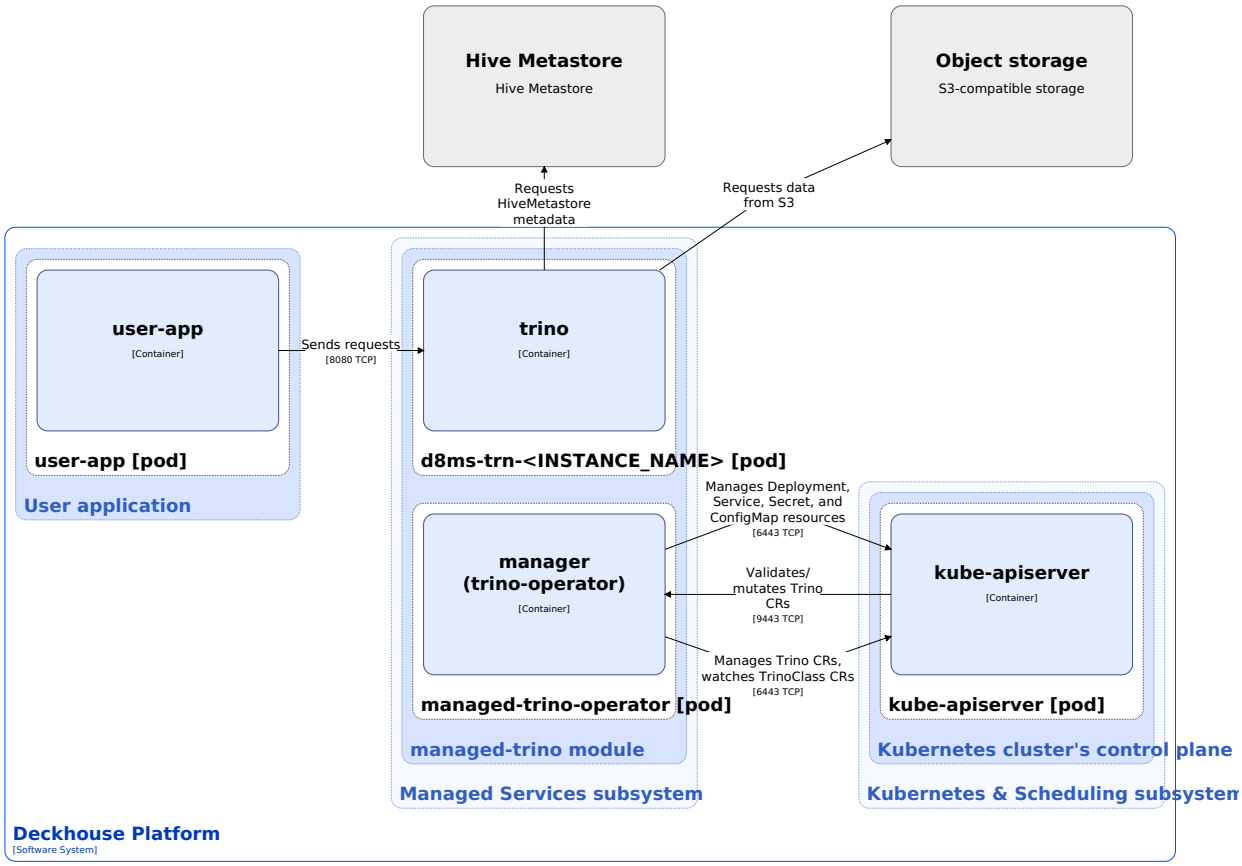
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-trino module

The `managed-trino` module manages Trino instances in Deckhouse Platform (DP). Trino is a fast Open Source distributed SQL engine built for big data analytics. The module provides:



- **Automatic Deployment**: Creates a Trino instance using a simple YAML configuration.
- **Standalone**: Supports deployment of a standalone instance.
- **External Connections**: Supports working with the Hive Metastore metadata store, as well as with S3 storage.
- **Configuration Management**: Separate TrinoClass resource for templating service creation and flexible validation of user parameters.
- **Status**: Displays the current status of the deployed Trino instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-trino` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-trino-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:

    - Reconciles Trino custom resources in all user namespaces. The Trino and TrinoClass custom resources define the settings of the Trino instance.
    - Creates and manages Deployment, Service, Secret, and ConfigMap resources related to the Trino instance.
    - Validates and mutates Trino custom resources using the Validating/Mutating Admission Controllers mechanism.
2. **D8ms-trn-<INSTANCE_NAME>** (Deployment): A component consisting of a single **trino** container that starts and runs the Trino instance. It is created by the managed-trino-operator component for each Trino custom resource.

Module interactions

The module interacts with the following components:

1. **Hive Metastore instance**: Processes data in the metadata store.
2. **Object storage**: Processes data in the object storage.
3. **Kube-apiserver**:
    - Manages Trino custom resources.
    - Watches TrinoClass custom resources.
    - Manages Deployment, Service, Secret, and ConfigMap resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Trino custom resources.
2. **User applications**: Send requests to the Trino instance.

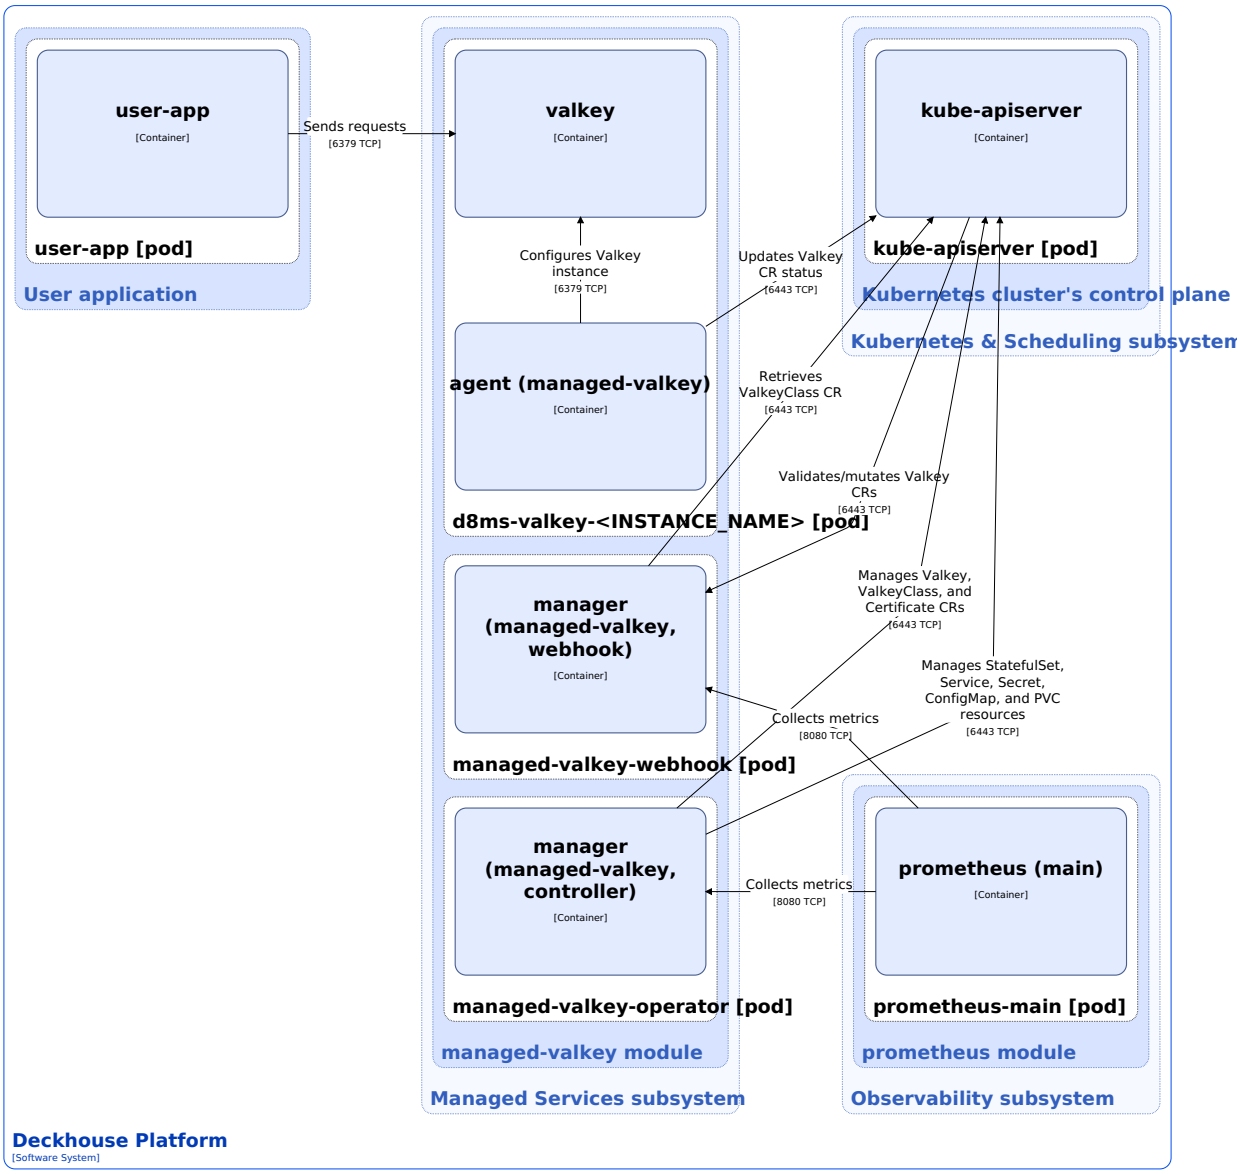
Additional resources

- Module `managed-trino` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Managed-valkey module

The `managed-valkey` module manages Valkey instances (a Redis-compatible in-memory data store) in Deckhouse Platform (DP). It provides:



- **Automatic Deployment**: Creates a Valkey instance using a simple YAML configuration.
- **Standalone**: Supports deployment of a standalone instance.
- **Persistent Storage**: Allows configuring different data storage options: `AOF`, `RDB`, `AOF+RDB`.
- **Configuration Management**: Separate ValkeyClass resource for templating service creation and flexible validation of user parameters.
- **Status**: Displays the current status of the deployed Valkey instance.

For more details about module settings and usage examples, refer to the module documentation.

Module architecture

> The following assumptions are used to simplify the diagram:
>
> - The diagram shows direct communication between containers in different Pods. In practice, components communicate through Kubernetes Services (internal load balancers). Service names are omitted when obvious from context. In other cases, a service name is shown above the arrow.
> - Pods can run with multiple replicas, but only one replica of each Pod is shown in the diagram.

The level-2 C4 architecture of the `managed-valkey` module and its interactions with other components of DP are shown in the following diagram:

Module components

The module consists of the following components:

1. **Managed-valkey-operator** (Deployment): Kubernetes operator consisting of a single container **manager** that performs the following operations:
   - It reconciles Valkey custom resources in all user namespaces. The Valkey and ValkeyClass custom resources define the settings of the Valkey instance.
   - It creates and manages StatefulSet, Secret, ConfigMap, and PersistentVolumeClaim resources related to the Valkey instance.
2. **Managed-valkey-webhook** (Deployment): Component consisting of a single container **manager**.

   The managed-valkey-webhook component validates and mutates Valkey custom resources, and mutates ValkeyClass custom resources using the Validating/Mutating Admission Controllers mechanism.
3. **D8ms-valkey-<INSTANCE_NAME>** (StatefulSet): Component that starts and prepares the Valkey instance. It is created by the managed-valkey-operator component.

   It consists of two containers:
   - **valkey**: Main container. It is an open-source project.
   - **agent**: Sidecar container that configures the main container according to the parameters in the Valkey resource.

Module interactions

The module interacts with the **kube-apiserver** component, through which:

- It manages Valkey, ValkeyClass, and Certificate custom resources.
- It manages StatefulSet, Secret, ConfigMap, and PersistentVolumeClaim resources.

The following external components interact with the module:

1. **Kube-apiserver**: Validates and mutates Valkey custom resources, mutates ValkeyClass custom resources.
2. **Prometheus-main**: Collects metrics from the managed-valkey-operator and managed-valkey-webhook components.
3. **User applications**: Send requests to the Valkey instance.

Additional resources

- Module `managed-valkey` documentation

>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtualization subsystem

This subsection describes the architecture of the Virtualization subsystem of Deckhouse Platform (DP).

The Virtualization subsystem is represented by the `virtualization` module, which allows you to declaratively create, run, and manage virtual machines (VM) and their resources.

The `virtualization` module consists of the following components:

- Virtualization API: A controller that implements a user API for creating and managing VM resources.
- A module core: It is based on the KubeVirt project and uses QEMU/KVM + libvirtd to run VMs. KubeVirt is an open-source project that allows you to launch, deploy, and manage VMs using Kubernetes as an orchestration platform. It enables a cooperation between traditional VMs and container workloads in the same Kubernetes cluster, providing a single control plane.
- Deckhouse Virtualization Container Registry (DVCR): A container registry for storing and caching VM images.
- Auxiliary components: Components that implement the following auxiliary functions:
  - Security events audit.
  - Forwarding USB devices to VMs.
  - Updating network routes.
  - Deleting resources before deactivating the `virtualization` module.

For more details about the module, refer to the module documentation section.

Additional resources

- Module `virtualization` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Virtualization API

The Virtualization API component of the `virtualization` module manages custom resources of the following API groups:

1. `virtualization.deckhouse.io`: The main group, it includes the following custom resources:
   - VirtualMachine: A resource that describes the virtual machine (VM) configuration and status.
   - VirtualMachineClass: A resource that describes a set of parameters for VirtualMachine resources, such as CPU and RAM specification, `NodeSelector`, and `Tolerations`.
   - VirtualMachinePool: A resource that declaratively manages a group of identical VMs.
   - VirtualDisk: A resource that describes desired VM disk configuration.
   - VirtualImage: A resource that describes:
     - a VM disk image that can be used as a data source for new VirtualDisk resources.
     - an ISO installation image that can be mounted directly into a VirtualMachine resource.

   The full list of the main API group resources is given in the module documentation.

   Virtualization-controller manages the resources of the main group.

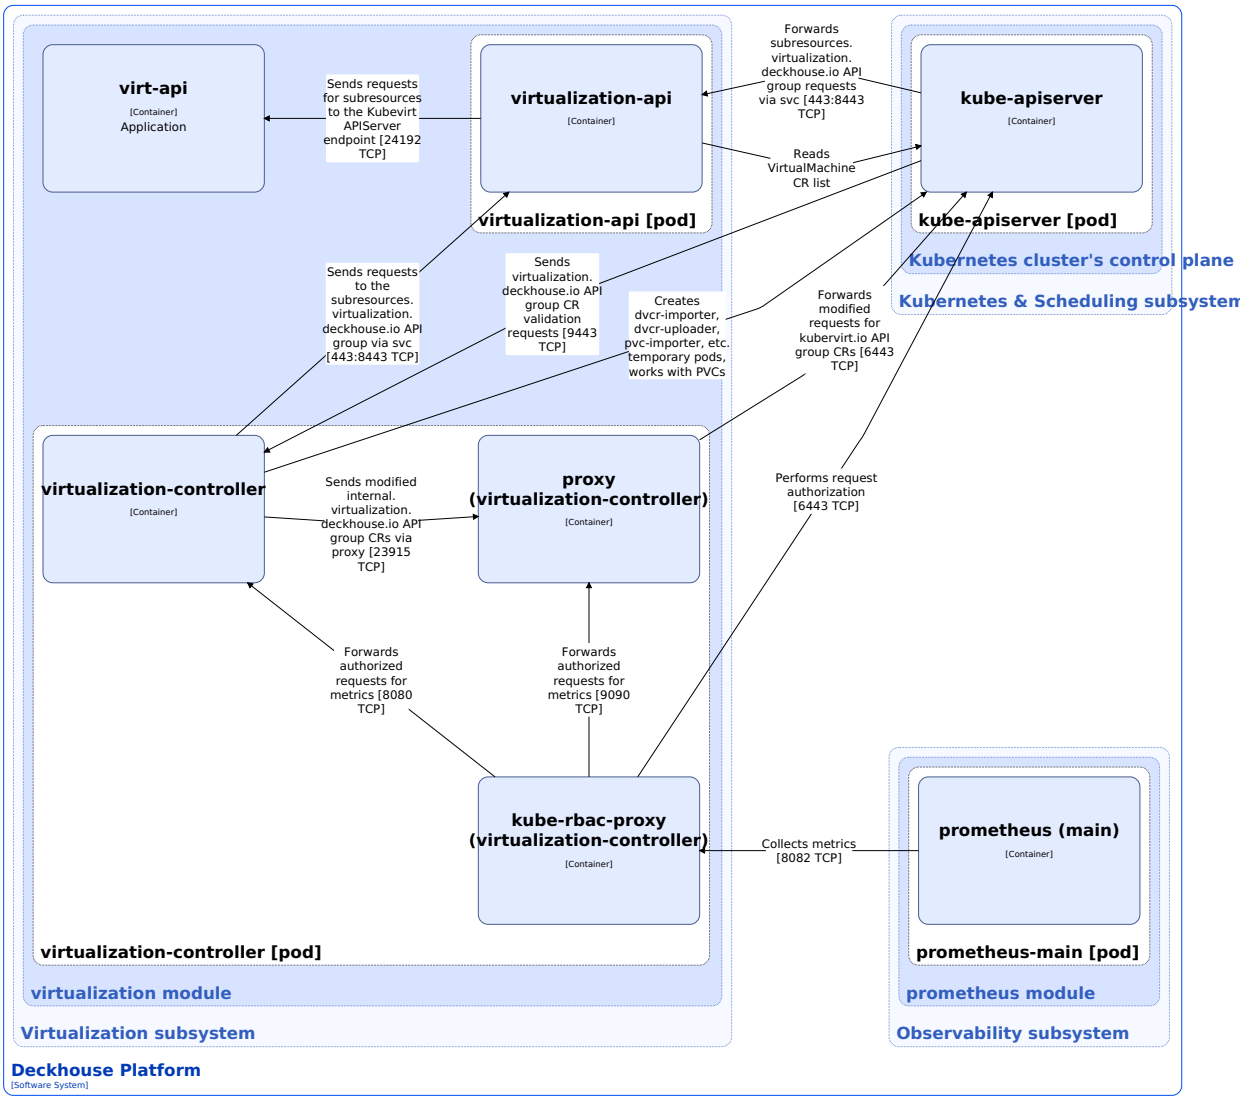
2. `subresources.virtualization.deckhouse.io`: Subresources group. Subresources are additional operations or actions that can be performed on core resources (for example, VirtualMachine) via the Kubernetes API. They provide interfaces for managing specific aspects of resources without affecting the entire object. Instead of the declarative resource familiar to Kubernetes, they are endpoints for imperative operations.

   The group includes the following subresources:

   - `virtualmachines/console`;
   - `virtualmachines/vnc`;
   - `virtualmachines/portforward`;

- `virtualmachines/addvolume`;
- `virtualmachines/removevolume`;
- `virtualmachines/freeze`;
- `virtualmachines/unfreeze`;
- `virtualmachines/addresourceclaim`;
- `virtualmachines/removeresourceclaim`.

Virtualization-api manages subresources.



The Virtualization API component of the module uses KubeVirt custom resources as a backend to manage VMs, VM disks, and images.

> **i** KubeVirt is an open-source project that allows you to launch, deploy, and manage VMs using Kubernetes as an orchestration platform. It enables cooperation between traditional VMs and container workloads in the same Kubernetes cluster, providing a single control plane.

Virtualization API architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the Virtualization API component of the `virtualization` module and its interactions with other components of Deckhouse Platform (DP) are shown in the following diagram:

Virtualization API components

Virtualization API consists of the following components:

1. **Virtualization-api**: A Kubernetes Extension API Server that serves requests to the `subresources.virtualization.deckhouse.io` API group. Virtualization-api uses `subresources.kubevirt.io` API group subresources as a backend. Virtualization-api accesses the virt-api endpoint directly, which is a Kubernetes Extension API Server that handles requests to similar `subresources.kubevirt.io` API group subresources. It consists of the **virtualization-api** container.

2. **Virtualization-controller**: A controller that performs the following operations:

   - Manages custom resources of the main `virtualization.deckhouse.io` API group. Virtualization-controller will not change the main portion of these custom resources: `labels`, `annotations`, and `spec`. Virtualization-controller can make the following changes to custom resources:

     - Adding and removing finalizers in the `metadata.finalizers` attribute.
     - Adding and removing entries in the `metadata.ownerReferences` attribute.
     - Modifying the `status` subresource.

     Virtualization-controller uses `kubevirt.io` API group custom resources as a backend.

   - Validation of `virtualization.deckhouse.io` API group resources using the Validating Admission Controllers mechanism.
   - Launching `dvcr-importer`, `dvcr-uploader` and `pvc-importer` pods to import and upload VM disks and images. For more details, see Importing and uploading VM images and disks.
   - Performing operations on VMs by making requests to some subresources of the `subresources.virtualization.deckhouse.io` API group, for example `virtualmachines/freeze` and `virtualmachines/unfreeze`.

   The component consists of the following containers:

   - **virtualization-controller**: Main container that implements the controller and webhook server.
   - **proxy** (aka **kube-api-rewriter**): Sidecar container that performs modification of API requests passing through it, namely renaming the metadata of custom resources. This is necessary because KubeVirt components use API groups like `*.kubevirt.io`, and other components of the `virtualization` module use similar resources, but with API groups like `*.virtualization.deckhouse.io`. Kube-api-rewriter is a gateway that proxies requests between controllers that manage resources from different API groups and is an open-source project.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the metrics of the controller and the proxy sidecar container. It is an open-source project.

Virtualization API interactions

Virtualization-api interacts with the following components:

1. **Kube-apiserver**: Lists VirtualMachine custom resources, which are needed to process requests to subresources.
2. **Virt-api**: Sends requests to the KubeVirt subresources. Requests pass through a similar proxy sidecar container that renames metadata from the `subresources.virtualization.deckhouse.io` API group to the `subresources.kubevirt.io` API group and proxies them to the virt-api endpoint (Kubernetes Extension API Server KubeVirt).

Virtualization-controller interacts with the following components:

1. **Kube-apiserver**:

   - Sends modified virtualization module custom resources via a proxy sidecar container that renames `internal.virtualization.deckhouse.io` API group resource metadata to `kubevirt.io` API group resource metadata.
   - Authorizes requests for metrics.

The following external components interact with the Virtualization API component:

1. **Kube-apiserver**:

   - Forwards requests to `subresources.virtualization.deckhouse.io` API group subresources.
   - Sends `virtualization.deckhouse.io` API group resource validation requests.

2. **Prometheus-main**: Collects component metrics.

Additional resources

- Module `virtualization` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

The virtualization core

The `Virtualization` module core is directly responsible for working with virtual machines (VMs). The core is based on the KubeVirt project. KubeVirt is an open-source project that allows you to launch, deploy, and manage VMs using Kubernetes as an orchestration platform. It enables a cooperation between traditional VMs and container workloads in the same Kubernetes cluster, providing a single control plane. A fork of KubeVirt from the company “Flant” is used in the `virtualization` module.

To manage VMs, the module core uses custom resources of the following API groups:

1. `internal.virtualization.deckhouse.io`: The main group, an analog of the `kubevirt.io` API group of the original KubeVirt. It includes the following custom resources:

   - InternalVirtualizationVirtualMachine: A resource that describes the VM configuration and status.
   - InternalVirtualizationVirtualMachineInstance: A resource that describes a running VM. After VM shutdown, the InternalVirtualizationVirtualMachineInstance resource is deleted, but the InternalVirtualizationVirtualMachine resource that manages the InternalVirtualizationVirtualMachineInstance lifecycle remains.

   The resources of the main group are managed by the virt-controller component. The InternalVirtualizationVirtualMachine resources of the KubeVirt `internal.virtualization.deckhouse.io` main API group are used as the backend for the VirtualMachine resources of `virtualization.deckhouse.io` API group managed by the virtualization-controller.

   > **i** For simplification, the reduced VirtualMachine and VirtualMachineInstance names will be used for the InternalVirtualizationVirtualMachine and InternalVirtualizationVirtualMachineInstance resources (of the original KubeVirt `kubevirt.io` API group) respectively.

2. `subresources.kubevirt.io`: Subresources group. Subresources are additional operations or actions that can be performed on core resources (for example, VirtualMachineInstance) via the Kubernetes API. They provide interfaces for managing specific aspects of resources without affecting the entire object. Instead of the declarative resource familiar to Kubernetes, they are an endpoint for imperative operations. The following KubeVirt subresources are used in the `virtualization` module:

   - `virtualmachines/{name}/addvolume`;
   - `virtualmachines/{name}/removevolume`;
   - `virtualmachines/{name}/addresourceclaim`;
   - `virtualmachines/{name}/removeresourceclaim`;
   - `virtualmachineinstances/{name}/console`;
   - `virtualmachineinstances/{name}/vnc`;
   - `virtualmachineinstances/{name}/portforward`;
   - `virtualmachineinstances/{name}/freeze`;
   - `virtualmachineinstances/{name}/unfreeze`.

   The subresources are managed by the virt-api component. The KubeVirt subresources listed above are used as a backend for similar resources of `subresources.virtualization.deckhouse.io` API group managed by the virtualization-api component.

Module core architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `virtualization` module core and its interactions with other components of DP are shown in the following diagrams:

Module core components

The module core consists of the following components:

1. **Virt-api**: A Kubernetes Extension API Server that serves requests to the `subresources.kubevirt.io` API groups. The virt-api component performs validation and mutation of custom resources of the `internal.virtualization.deckhouse.io` API groups using the Validating/Mutating Admission Controllers mechanism. Requests pass through the **proxy** sidecar container that renames metadata from the `internal.virtualization.deckhouse.io` API group to the `kubevirt.io` API group and proxies them to the virt-api component endpoint.

   It consists of the following containers:

   - **virt-api**: Main container that implements controller and webhook server.
   - **proxy** (aka **kube-api-rewriter**): Sidecar container that performs modification of API requests passing through it, namely renaming the metadata of custom resources. This is necessary because KubeVirt components use API groups like `*.kubevirt.io`, and other components of the `virtualization` module use similar resources, but with API groups like `*.virtualization.deckhouse.io`. Kube-api-rewriter is a gateway that proxies requests between controllers that manage resources from different API groups.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the metrics of the proxy container. It is an open-source project.

2. **Virt-controller**: A controller that manages the `internal.virtualization.deckhouse.io` main API group custom resources and responsible for the virtualization functionality at the cluster wide level. For each VirtualMachineInstance resource it creates a separate pod in which the VM is started. Virt-controller monitors VirtualMachineInstance resources, updates their status, and manages the associated pods.

   It consists of the following containers:

- **virt-controller**: Main container.
- **proxy** (aka **kube-api-rewriter**): A sidecar container that performs modification of API requests passing through it (described above).
- **kube-rbac-proxy**: A sidecar container providing authorized access to the metrics of the virt-controller and proxy containers (described above).

3. **Virt-handler** (DaemonSet): A separate controller that runs on all nodes of the cluster. Virt-handler performs the following functions:

   - It extends the kubelet functionality, configuring the pod environment to run a VM inside it. At the moment virt-handler is responsible for creating network interfaces, also it is used to forward `dev/kvm` and other devices from the node into the pod. Virt-handler uses kubelet device plugins to forward devices.

   - Like virt-controller, virt-handler watches VirtualMachineInstance resources corresponding to VMs running on the node. When changes are detected, virt-handler sends a command to the virt-launcher process running in the compute container of the VM pod. Virt-launcher changes the VM state in accordance with the command received. Virt-handler also monitors VM events that virt-launcher returns and synchronizes the corresponding VirtualMachineInstance resource status.

   - It accepts commands from the virt-api component via the `console-port` that correspond to requests for subresources and forwards them to the virt-launcher for execution. By the subresources functionality ports are forwarded to the VM, as well as to the regular and VNC consoles.

     Virt-handler interacts with virt-launcher via the gRPC protocol and Unix socket.

   It consists of the following containers:

   - **virt-launcher**: Init container that runs `node-labeller.sh` script via virt-launcher binary. This script prepares CPU parameters, their functions, and machine types which virt-handler will use to set the appropriate labels on Node resources. These labels, in turn, will be used to schedule VMs to the nodes that support the appropriate parameters.
   - **virt-handler**: Main container.
   - **virt-launcher-image-holder**: A service sidecar container for virt-launcher image pre-loading. The container is on pause and performs only the function of storing the image.
   - **pr-helper**: QEMU persistent reservation helper is a service sidecar container that creates a listener socket that accepts incoming connections to communicate with QEMU. This is necessary because the operating system restricts sending SCSI commands with permanent redundancy to unprivileged programs, which prevents multiple VMs from sharing block SCSI devices, for example in the case of clusterization. QEMU is a free and open-source program for emulating the hardware of various platforms, which is used to run VMs in a pod.

4. **Virt-operator**: A Kubernetes operator that manages the KubeVirt components lifecycle using InternalVirtualizationKubeVirt custom resource. Virt-operator installs the virt-api, virt-controller and virt-handler in the cluster and also configures them.

   It consists of the following containers:

   - **virt-operator**: Main container.
   - **proxy** (aka **kube-api-rewriter**): Sidecar container that performs modification of API requests passing through it (described above).

5. **Virt-launcher-<VMI name>**: The pod where the VM is running (more exactly VirtualMachineInstance).

   It consists of one container:

   - **compute**: A container where the virt-launcher is run. Virt-launcher implements cmd-server (a gRPC server for the remote command execution).

     Depending on the command received from virt-handler, virt-launcher generates an XML specification of the VM being launched or updated and sends it to libvirtd. Libvirtd is a daemon of the server part of the libvirt virtualization management system. It runs on host servers and performs management tasks for virtual guest systems.

     Libvirtd, in turn, starts the VM and manages its lifecycle. The VM is started using QEMU and KVM. QEMU is an open-source emulator that supports hardware virtualization and works in conjunction with the KVM hypervisor.

     In fact libvirtd starts the QEMU process, which is the VM (more exactly VirtualMachineInstance).

     Virt-handler also constantly monitors the status of the running VM, returned by libvirtd via virt-launcher, and updates the VirtualMachineInstance status.

Module core interactions

The module core interacts with the following components:

1. **Kube-apiserver**:

   - Watches for KubeVirt custom resources and manages KubeVirt components.
   - Watches for VirtualMachineInstance custom resources, updates their status, and manages the associated pods.
   - Authorizes requests for metrics.

The following external components interact with the module core:

1. **Kube-apiserver**:

   - Sends InternalVirtualizationKubeVirt custom resource validating requests.
   - Sends `internal.virtualization.deckhouse.io` API group resource validating and mutating requests.

2. **Prometheus-main**: Collects module core components metrics.

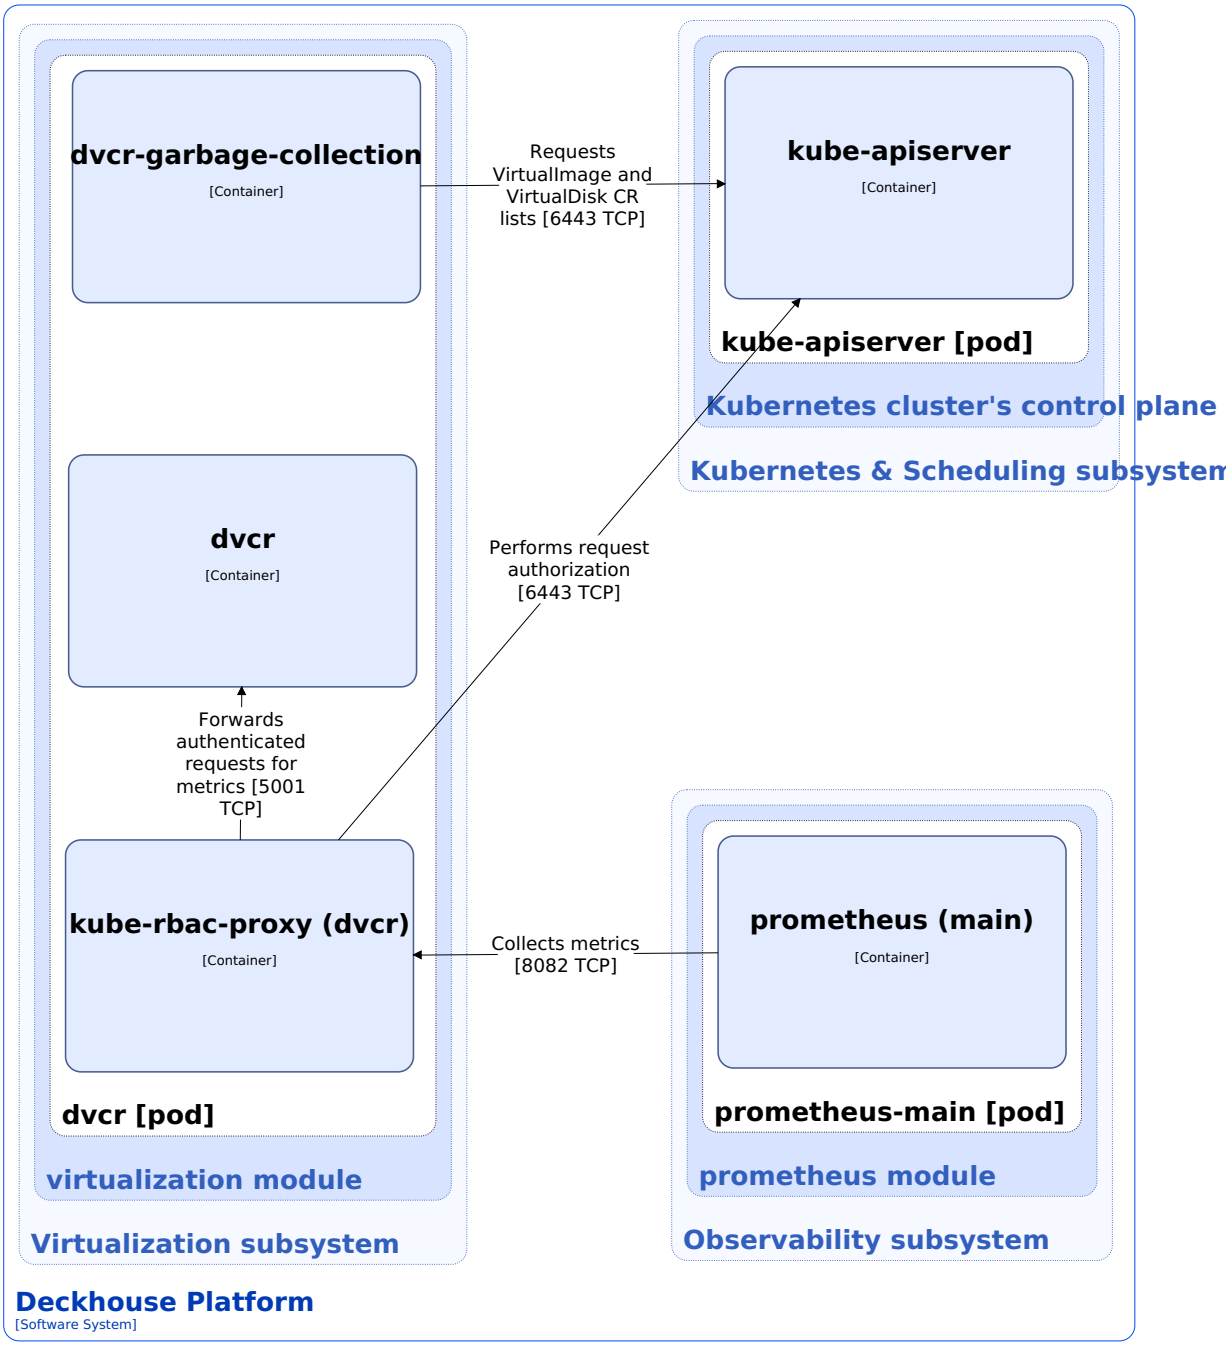
Deckhouse Virtualization Container Registry (DVCR)



The Deckhouse Virtualization Container Registry (DVCR) component of the `virtualization` module is a specialized container registry for storing and caching virtual machine (VM) images. Virtualization-controller of the Virtualization-API component of the `virtualization` module allows you to import images stored in DVCR into PVC volumes used as VM disks managed by KubeVirt. For more details, see Importing and uploading VM images and disks.

> KubeVirt is an open-source project that allows you to launch, deploy, and manage VMs using Kubernetes as an orchestration platform. It enables cooperation between traditional VMs and container workloads in the same Kubernetes cluster, providing a single control plane.

DVCR architecture

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the DVCR component of `virtualization` module and its interactions with other components of DP are shown in the following diagrams:

DVCR components

DVCR consists of the following components:

1. **Dvcr**: A container registry based on Distribution. Distribution is an open-source project that provides a framework for storing and distributing container images and other content using the OCI Distribution Specification. Dvcr is used for storing and caching VM images.

   It consists of the following containers:

   - **dvcr**: Main container.
   - **dvcr-garbage-collection**: Sidecar container that periodically deletes images which do not have the appropriate resources in the cluster.
   - **kube-rbac-proxy**: Sidecar container with an authorization proxy based on Kubernetes RBAC that provides secure access to the metrics of the dvcr container. It is an open-source project.

DVCR interactions

DVCR interacts with the following components:

1. **Kube-apiserver**: Sends `get`/`list`/`watch`-requests for VirtualImages, ClusterVirtualImages, and VirtualDisks to clean up unused images and for coordination.

The following external components interact with the DVCR component:

1. **Prometheus-main**: Collects metrics of the dvcr component.

Additional resources

- Module `virtualization` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

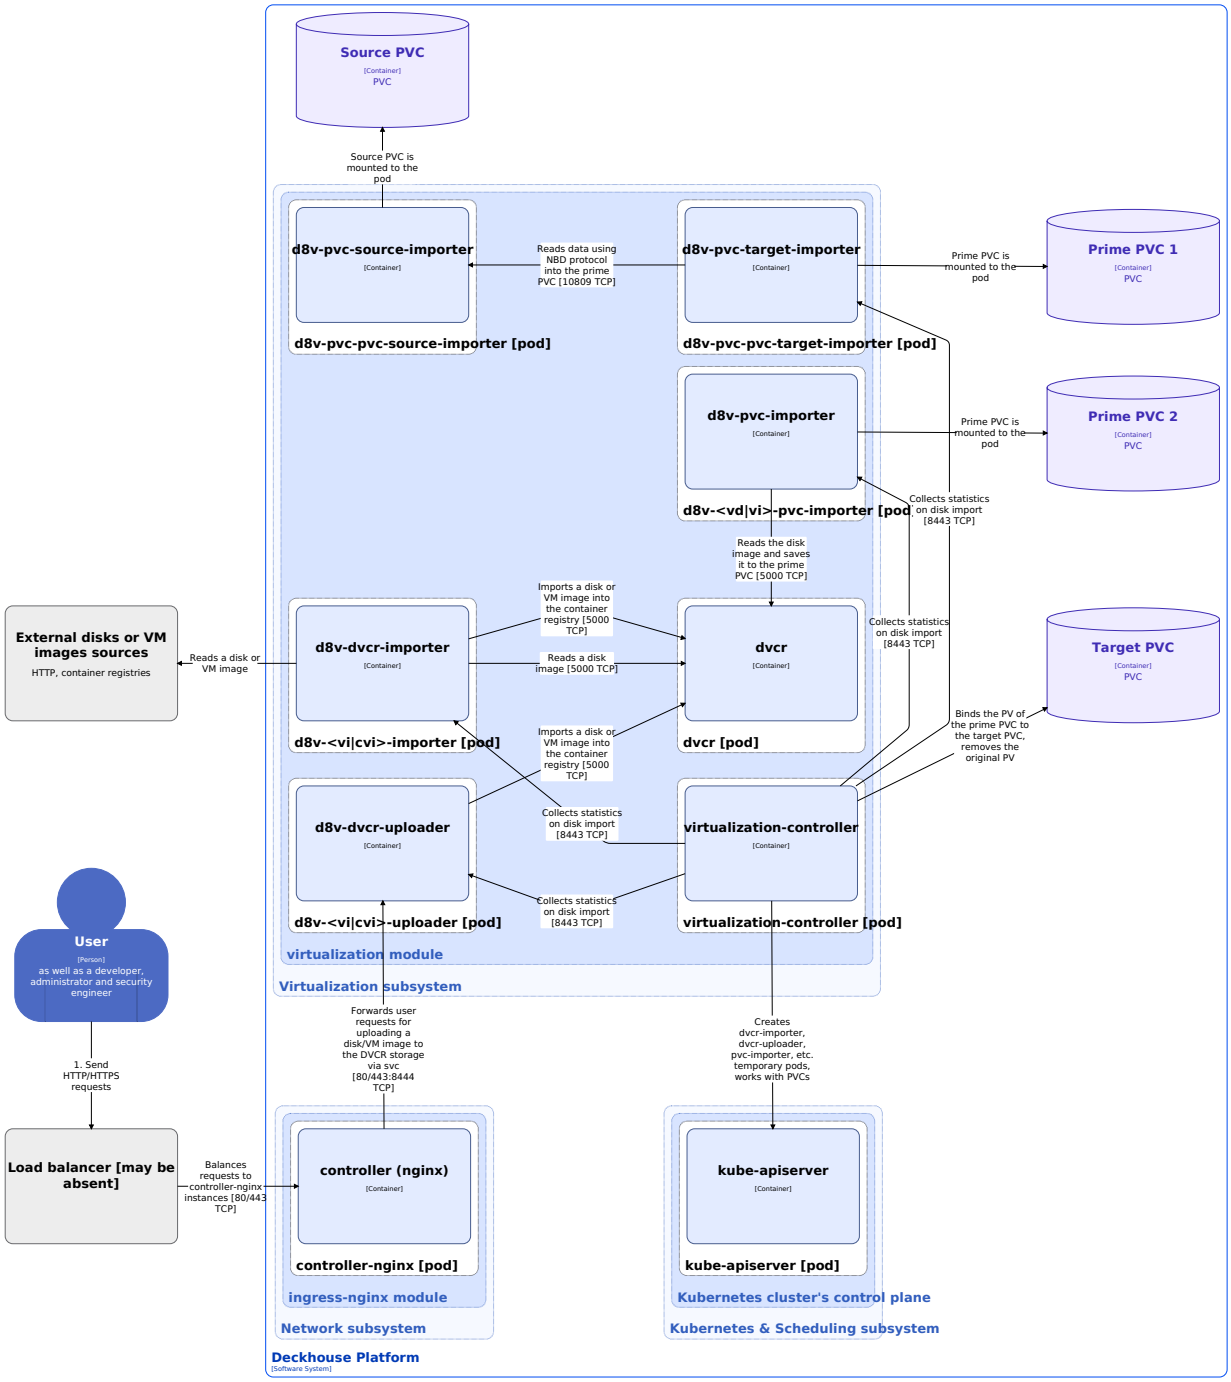
Importing and uploading VM images and disks

Virtualization-controller of the Virtualization-API component of the `virtualization` module allows you to import VM images and disks from different sources into PVC volumes used as VM disks managed by KubeVirt.

> KubeVirt is an open-source project that allows you to launch, deploy, and manage VMs using Kubernetes as an orchestration platform. It enables cooperation between traditional VMs and container workloads in the same Kubernetes cluster, providing a single control plane.

Depending on the scenarios for importing or uploading VM images and disks, virtualization-controller launches the following *temporary* pods:

1. **D8v-<vi|cvi>-importer**: Pod consisting of a single **d8v-dvcr-importer** container, that is launched to implement the following scenarios for importing VM images and disks to DVCR storage:
   - Import of a VM image from external sources (HTTP source available via URL or container registry).
   - Import of a VM image, disk or snapshot from VirtualImage, ClusterVirtualImage, VirtualDisk or VirtualDiskSnapshot resources.
2. **D8v-<vi|cvi>-uploader**: Pod consisting of a single **d8v-dvcr-uploader** container, that is launched to upload VM images and disks to DVCR storage *by the user*.
3. **D8v-<vd|vi>-pvc-importer**: Pod consisting of a single **d8v-pvc-importer** container, that is launched to import VM image from container registry (DVCR) into PVC volume. Only KubeVirt data import is supported, meaning the imported image must be a KubeVirt VM disk. If necessary, d8v-pvc-importer will automatically decompress and convert the file from the supported format to `raw` or `qcow2` format (depending on the volume mode). It will also resize the disk to use all available space. The data during the import process is saved to a temporary prime PVC. After successfully copying the data to the prime PVC, the virtualization-controller binds the target PVC to the PV of the prime PVC, and then the prime PVC as well as original PV of target PVC are deleted.
4. **D8v-pvc-pvc-source-importer** and **d8v-pvc-pvc-target-importer**: Pod consisting of a single **d8v-pvc-source-importer** container and pod consisting of a single **d8v-pvc-target-importer** container, respectively, that are launched to import a VM image from one PVC volume to another PVC volume (cloning over the network). The PVC source is mounted as a network block device using the Network Block Device (NBD) protocol in the d8v-pvc-pvc-source-importer pod, which is accessed by an application running in the d8v-pvc-pvc-target-importer pod container. The data during the import process is saved in a temporary primary (prime) PVC. After successfully copying the data to the primary PVC, the virtualization-controller binds the target PVC (PVC receiver) to the PV of the primary PVC, and then the prime PVC as well as original PV of target PVC are deleted.



During the import of a VM image or disk, virtualization-controller collects import statistics directly from the running temporary pod and, based on these statistics, calculates the download progress in percentage terms, as well as the average and current download speeds, to be displayed in the status of the corresponding custom resource (VirtualImage, ClusterVirtualImage, or VirtualDisk).

Virtualization-controller also supports the following scenarios for importing VM images and disks that do not require launching temporary pods:

- Importing a VM image from container registry into PVC volume.
- Importing a VM image from volume snapshot (VolumeSnapshot resource) into PVC volume.
- Importing a VM image from one PVC volume to another PVC volume (cloning by CSI driver).
- Creating an empty PVC volume.

> The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

Interactions of `virtualization` module components while importing and uploading VM images and disks are shown in the following diagram:

During the processes of importing and uploading VM images and disks `virtualization` module components interact with the following external components:

1. **External sources of VM disks and images**: Read disks or VM images when implementing some scenarios for importing to DVCR storage.
2. **Ingress-controller**: Forwards user requests to upload VM image or disk to DVCR storage via HTTP endpoint of dvcr-uploader service.

Additional resources

- Module `virtualization` documentation

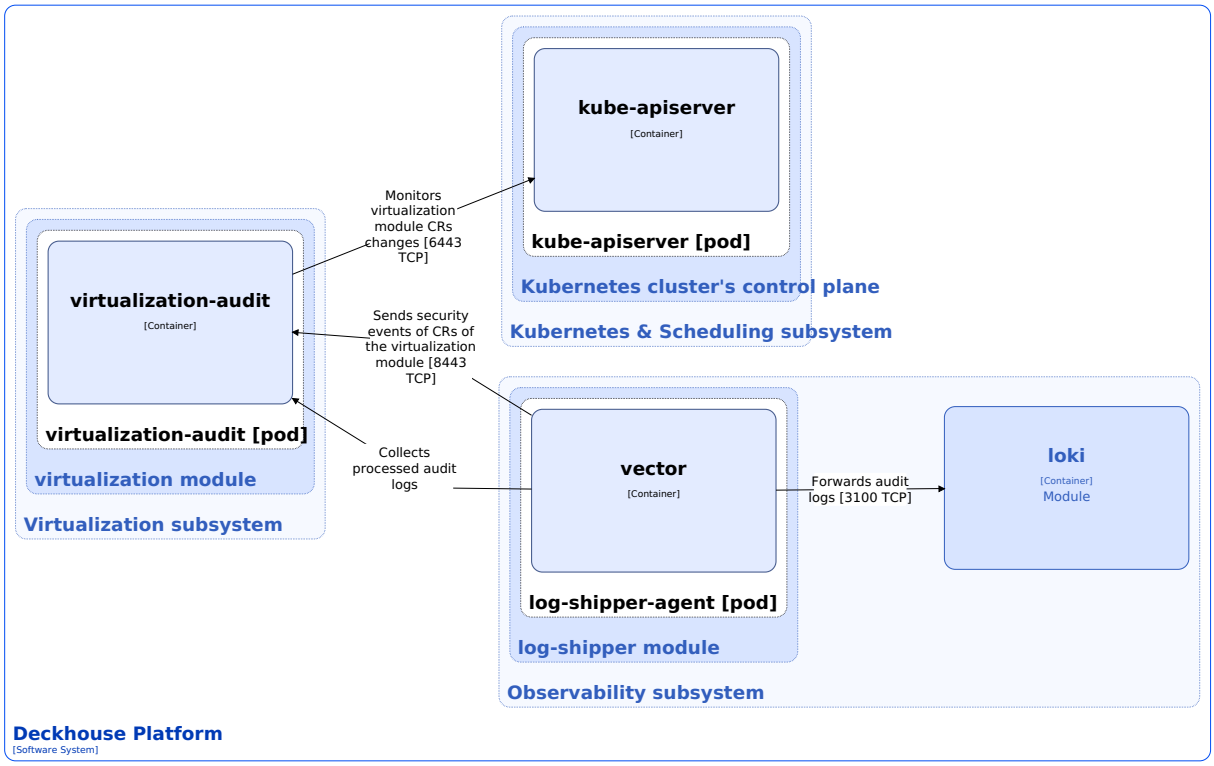
> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Auxiliary components

The `virtualization` module uses components that implement the following auxiliary functions:

- Security events audit.
- Forwarding USB devices to virtual machines (VMs).

- Updating network routes.
- Deleting resources before deactivating the `virtualization` module.



Security events audit

For instructions on `virtualization` module security events audit activation, refer to the module documentation.

Architecture

> **i** The following simplifications are made in the diagram:
>
> - The diagram shows containers in different pods interacting directly with each other. In reality, they communicate via the corresponding Kubernetes Services (internal load balancers). Service names are omitted if they are obvious from the diagram context. Otherwise, the Service name is shown above the arrow.
> - Pods may run multiple replicas. However, each pod is shown as a single replica in the diagram.

The Level 2 C4 architecture of the `virtualization` module auxiliary components for security events audit and their interactions with other components of DP is shown in the following diagram:

Components

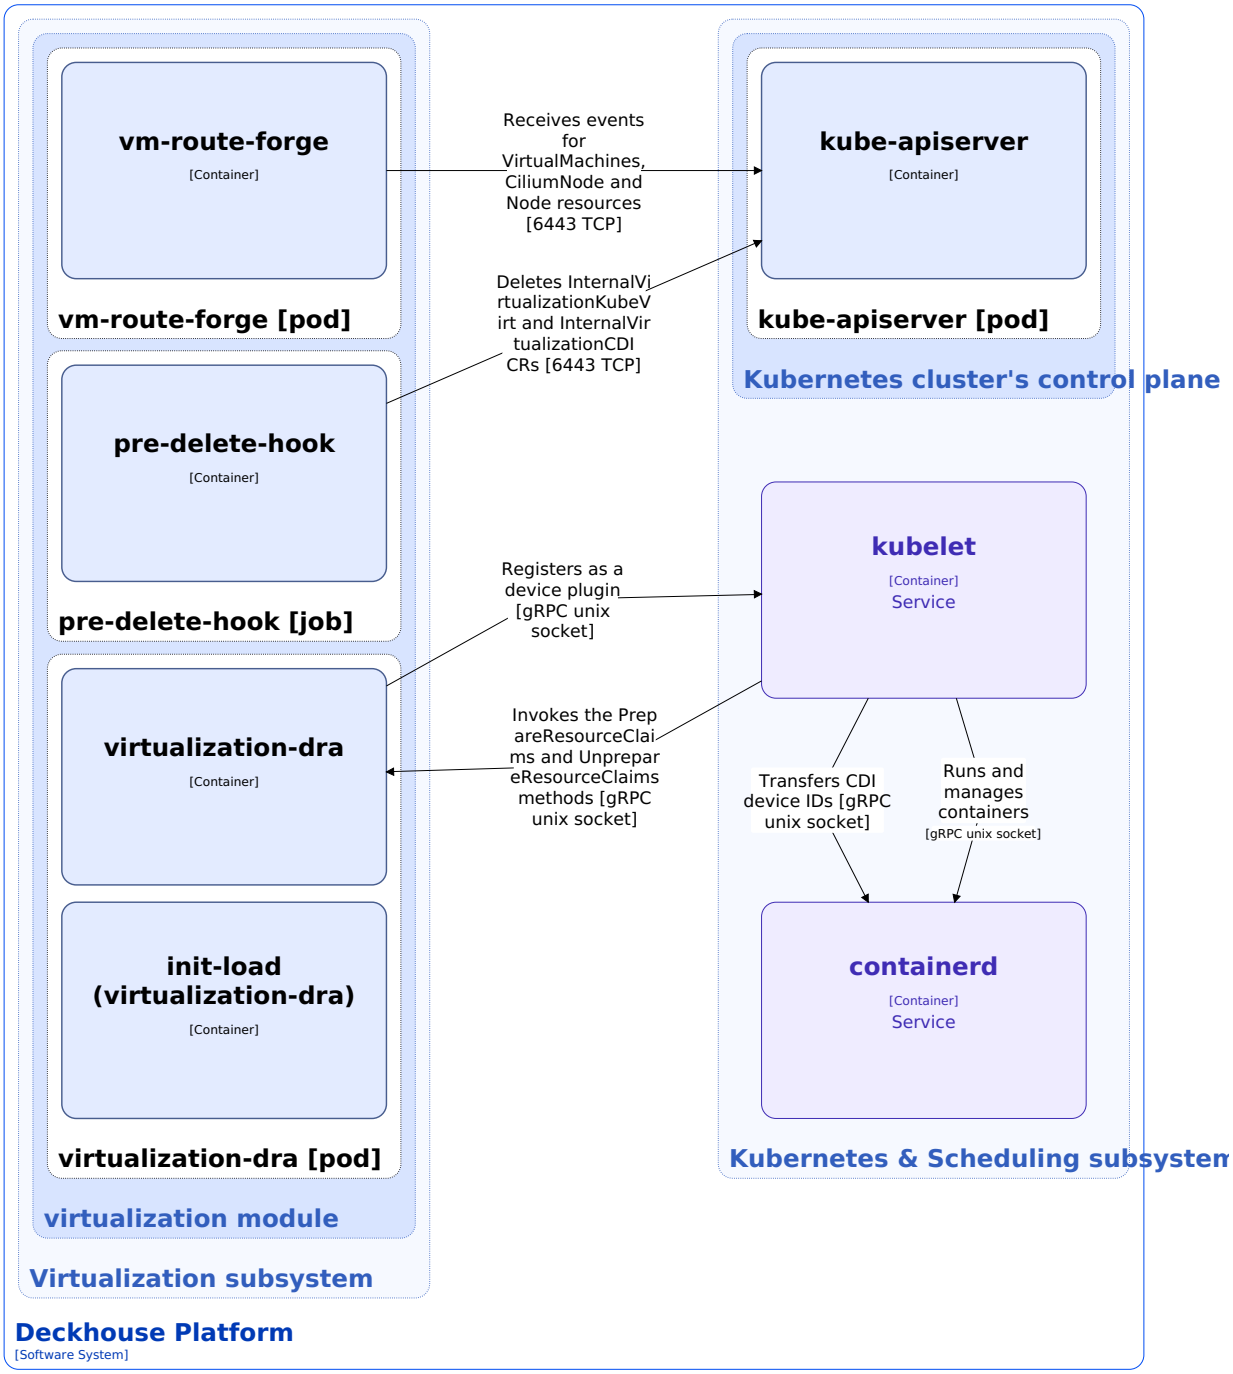
Virtualization-audit is a component consisting of a single container that receives the `virtualization` module security events stream. Sending events is implemented by the `log-shipper` module. The Vector logging agent, according to the settings in the ClusterLoggingConfig custom resources, selects events related to the `virtualization` module custom resources from the cluster's audit log and sends them to the virtualization-audit service endpoint. Virtualization-audit processes the received audit events, enriches them with data from the Kubernetes API, and saves the processed events to its own log.

You can forward security events to the cluster logging system (for example, Loki). In this case, ClusterLoggingConfig resources and the vector agent of the `log-shipper` module are used in a similar way.

Interactions

Virtualization-audit interacts with the following components:

1. **Kube-apiserver**: Watches for `virtualization` module custom resources.



The following external components interact with virtualization-audit:

1. **Log-shipper-agent**:
   - Sends `virtualization` module security events.
   - Collects processed audit logs.

Virtualization-dra and other components

Architecture

The Level 2 C4 architecture of other `virtualization` module auxiliary components and their interactions with other components of DP is shown in the following diagram:

Components

1. **Virtualization-dra** (DaemonSet): The DRA driver that forwards USB devices to VMs. The DRA (Dynamic Resource Allocation) technology is used to forward USB devices. DRA is a Kubernetes API, scheduler, and kubelet engine for describing, scheduling, and provisioning dynamically allocated resources through external drivers. The DRA driver performs the following operations:
   - Automatically detects USB devices on cluster nodes and publishes them as a ResourceSlice resource. virtualization-controller synchronizes this data into NodeUSBDevice custom resources, which are then used to configure USB device forwarding. For more information about configuring USB device forwarding, refer to the module documentation.
   - Registers in kubelet as the DRA kubelet plugin. The DRA kubelet plugin prepares and releases allocated resources for pods through the PrepareResourceClaims and UnprepareResourceClaims operations. The PrepareResourceClaims method returns CDI (Container Device Interface) device IDs that kubelet passes to containerd. Data on available USB devices is published via ResourceSlice, and device selection is performed by the Kubernetes DRA mechanism based on ResourceClaim/ResourceClaimTemplate and DeviceClass.

     The DRA driver interacts with kubelet via the gRPC protocol and Unix sockets.
   - Implements a USBIP server, so that the USB device is automatically forwarded over the network to the node where the VM is running. There is no need to manually place the VM on the same node where the device is located.

It consists of the following containers:

- **init-load**: Init container that loads the Linux kernel modules necessary for the DRA driver operation.
- **virtualization-dra**: Main container.

2. **Vm-route-forge**: A controller that monitors VirtualMachine custom resources of the `virtualization.deckhouse.io` API group and updates network routes on the node via Linux netlink/eBPF in routing tables used by CNI Cilium for routing traffic between VMs.
3. **Pre-delete-hook** (Job): A Job started by the Deckhouse controller before the `virtualization` module is deleted. It removes the InternalVirtualizationKubeVirt custom resource named `config`.

Interactions

Virtualization-dra interacts with the following components:

1. **Kubelet**: Registers in kubelet as the DRA kubelet plugin.

Vm-route-forge interacts with the following components:

1. **Kube-apiserver**: Receives events on VirtualMachine, CiliumNode and Node resources.
2. **Host network/Linux kernel**: Updates routes and routing rules on the node.
3. **Cilium data plane**: Uses data from the CiliumNode and Cilium routing tables to route VM traffic.

Pre-delete-hook interacts with the following components:

1. **Kube-apiserver**: Deletes InternalVirtualizationKubeVirt resource named `config`.

The following external components interact with Virtualization-dra:

1. **Kubelet**: Calls PrepareResourceClaims and UnprepareResourceClaims gRPC methods to prepare and release resources associated with USB devices.

Additional resources

- Module `log-shipper` documentation
- Module `virtualization` documentation

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Global configuration

Global configuration settings allow you to customize parameters that are used by default by all modules and components of the Deckhouse Platform. Some modules may override some of these parameters (this can be found in the settings section of the respective module's documentation).

The global configuration settings are stored in the ModuleConfig `global`.

> The publicDomainTemplate parameter specifies a DNS name template used by some Deckhouse modules to create Ingress resources. If this parameter is not specified, Ingress resources will not be created.
>
> If you don't have access to wildcard DNS records, you can use sslip.io or similar services for testing purposes.
>
> The domain specified in the template must not match or be a subdomain of the domain specified in the `network.clusterDomain` parameter of the `control-plane-manager` module. We do not recommend changing the cluster domain unless absolutely necessary.
>
> For the template to function correctly, you must first configure DNS services both in the networks where the cluster nodes will be located and in the networks from which clients will access the platform's service web interfaces.
>
> If the template matches the domain of the node network, use only A records to assign addresses of the nodes' Frontend interfaces to the platform's service web interfaces.
> For example, if the nodes are registered under the `company.my` zone and the template is `%s.company.my`.

Example of the `ModuleConfig/global`:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: global
spec:
  version: 2
  settings: # <-- Module parameters from the "Parameters" section below.
    defaultClusterStorageClass: 'default-fast'
    modules:
      publicDomainTemplate: '%s.kube.company.my'
      placement:
        customTolerationKeys:
        - dedicated.example.com
      storageClass: 'default-fast'
```

Conversions

Global configuration settings are configured using the `global` ModuleConfig, the schema of which contains a version number. When you apply an *old* version of the ModuleConfig schema in a cluster, automatic transformations are performed. To manually update the ModuleConfig schema version, the following steps must be completed **sequentially** for each version :

- Updates from version **1** to **2**:

  Move `storageClass` to `modules.storageClass`. Remove `modules.resourcesRequests.everyNode`, `modules.resourcesRequests.masterNode` and `modules.proxy` parameters.

- Updates from version **2** to **3**:

  Move `modules.ingressClass` to `modules.ingress.ingressClass`, and `modules.gatewayAPIGateway` to `modules.gatewayAPI.gateway`.

Parameters

Schema version: 3

- **settings**
  object
  - **settings.applications**
    object

    Common parameters of the Deckhouse ecosystem applications.

    - **settings.applications.https**
      object

      HTTPS access implementation method used by the Deckhouse ecosystem applications.

      Examples:

      ```
      https:
        certManager:
          clusterIssuerName: letsencrypt
        mode: CertManager
      ```

      ```
      https:
        mode: Disabled
      ```

      ```
      https:
        mode: OnlyInURI
      ```

      ```
      https:
        mode: CustomCertificate
        customCertificate:
          secretName: plainstring
      ```

      - **settings.applications.https.certManager**
        object
        - **settings.applications.https.certManager.clusterIssuerName**
          string

          ClusterIssuer name used by applications to obtain TLS certificates.

          The `cert-manager` module offers the following ClusterIssuer options:

          - `letsencrypt`
          - `letsencrypt-staging`
          - `selfsigned`

- `clouddns`
- `cloudflare`
- `digitalocean`
- `route53`

You can use your own ClusterIssuer if necessary.

Default: `letsencrypt`

- **settings.applications.https.customCertificate**
  object
  - **settings.applications.https.customCertificate.secretName**
    string

    Name of the Secret in the `d8-system` namespace containing a TLS certificate for applications.

    This Secret must be in the `kubernetes.io/tls` format.

    Default: `false`

- **settings.applications.https.mode**
  string

  HTTPS usage mode:

  - `CertManager`: Applications use HTTPS and obtain certificates automatically using the ClusterIssuer defined in the `certManager.clusterIssuerName` parameter.
  - `CustomCertificate`: Applications use HTTPS with the certificate from the `d8-system` namespace.
  - `Disabled`: Applications use HTTP only.
  - `OnlyInURI`: Applications use HTTP in the expectation that there is an external upstream HTTPS load balancer, which terminates HTTPS. This load balancer should be capable of redirecting requests from HTTP to HTTPS.

  Default: `CertManager`

  Allowed values: `Disabled`, `CertManager`, `CustomCertificate`, `OnlyInURI`

- **settings.applications.ingressClass**
  string

  Default IngressClass name used by the Deckhouse ecosystem applications when creating Ingress resources.

  Some applications support their own `ingressClass` parameter, which lets you use a different IngressClass instead of the default one.

  Default: `nginx`

  Pattern: `^[a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*$`

  Example:

  ```
  ingressClass: nginx
  ```

- **settings.applications.publicDomainTemplate**
  string

  DNS name template with two `%s` keys used as the dynamic parts of the string.

  Whenever a DNS is generated:

  - First key is replaced with the application instance name.
  - Second key is replaced with the application’s namespace.

  The Deckhouse ecosystem applications use this template when creating Ingress resources.

  For example, given the template `%s.%s.kube.company.my`, the application instance named `grafana` running in the `monitoring` namespace will get an Ingress resource at the address `grafana.monitoring.kube.company.my`.

  Usage notes:

  - If this parameter is not specified, Ingress resources will not be created.
  - The domain specified in the template must not match or be a subdomain of the domain specified in the `network.clusterDomain` parameter of the `control-plane-manager` module. Changing the cluster domain is not recommended unless necessary.
  - Before using the template, configure DNS services both in the networks where the cluster nodes will be located and in the networks from which clients will access the service web interfaces.
  - If the template domain matches the domain of the node network, use only A records to assign addresses of the frontend nodes to the platform service web interfaces. For example, if the nodes are registered under the `company.my` zone, the template must be `%s.%s.company.my`.

  Pattern: `^(%s([-a-z0-9]*[a-z0-9])?|[a-z0-9]([-a-z0-9]*)?%s([-a-z0-9]*)?[a-z0-9]|[a-z0-9]([-a-z0-9]*)?%s)\.(%s([-a-z0-9]*[a-z0-9])?|[a-z0-9]([-a-z0-9]*)?%s([-a-z0-9]*)?[a-z0-9]|[a-z0-9]([-a-z0-9]*)?%s)(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*$`

  Examples:

```
publicDomainTemplate: "%s.%s.company.my"
```

```
publicDomainTemplate: "%s.%s.kube.company.my"
```

- **settings.defaultClusterStorageClass**
  string

  The name of the StorageClass that DP will define as the default StorageClass used in the cluster.

  DP prohibits manually adding or modifying the default annotation (`storageclass.kubernetes.io/is-default-class='true'`) for StorageClass. Use the parameter to define or change the StorageClass that is used as the default in the cluster.

  If the parameter is omitted, the default StorageClass is either:

  - A StorageClass in the cluster that has the default annotation (`storageclass.kubernetes.io/is-default-class='true'`);
  - The first (alphabetically) StorageClass created by the cloud provider module (if any cloud provider module is used).

  Use this parameter to change the default StorageClass in the cluster, as manually adding the default annotation to a StorageClass is not allowed.

  Default:

- **settings.highAvailability**
  boolean

  A global switch to enable the *high availability* mode for modules that support it.

  If not defined, the value is determined automatically as `true` for clusters with more than one master node. Otherwise, it is determined as `false`.

  Examples:

  ```
  highAvailability: true
  ```

  ```
  highAvailability: false
  ```

- **settings.modules**
  object

  Common parameters of Deckhouse modules.

  - **settings.modules.gatewayAPI**
    object

    Common parameters for Gateway API usage by DP modules.

    - **settings.modules.gatewayAPI.enabled**
      boolean

      Enables the use of Gateway API resources (Gateway, HTTPRoute, etc.) by the DP modules that support it.

      Unlike ingressClass, there is no built-in default Gateway, so Gateway API is only actually used by a module if this flag is enabled **and** a Gateway can be resolved for it — either from this parameter's gateway field, a module-specific override, or a Gateway automatically discovered in the cluster.

      Modules that support Gateway API can override this setting with their own `gatewayAPI.enabled` parameter.

    - **settings.modules.gatewayAPI.gateway**
      object

      Reference to the Gateway object (from the Gateway API) used by DP modules when creating Gateway API resources.

      If not specified, modules use the Gateway automatically discovered in the cluster (if any).

      - **settings.modules.gatewayAPI.gateway.name**
        string

        Required value

        Name of the Gateway object.

      - **settings.modules.gatewayAPI.gateway.namespace**
        string

        Required value

        Namespace of the Gateway object.

  - **settings.modules.gatewayAPIGateway**
    Deprecated
    object

> **Deprecated**. Use settings.modules.gatewayAPI.gateway instead.

Reference to the Gateway object (from the Gateway API) used by DP modules when creating Gateway API resources.

If not specified, modules use the Gateway automatically discovered in the cluster (if any).

- **settings.modules.gatewayAPIGateway.name**
  string

  Required value

  Name of the Gateway object.

- **settings.modules.gatewayAPIGateway.namespace**
  string

  Required value

  Namespace of the Gateway object.

- **settings.modules.https**
  object

  HTTPS access implementation method used by the Deckhouse ecosystem modules.

  Examples:

```
https:
  certManager:
    clusterIssuerName: letsencrypt
  mode: CertManager
```

```
https:
  mode: Disabled
```

```
https:
  mode: OnlyInURI
```

```
https:
  mode: CustomCertificate
  customCertificate:
    secretName: plainstring
```

  - **settings.modules.https.certManager**
    object
    - **settings.modules.https.certManager.clusterIssuerName**
      string

      ClusterIssuer name used by modules to obtain TLS certificates.

      The `cert-manager` module offers the following ClusterIssuer options:

      - `letsencrypt`
      - `letsencrypt-staging`
      - `selfsigned`
      - `clouddns`
      - `cloudflare`
      - `digitalocean`
      - `route53`

      You can use your own ClusterIssuer if necessary.

      Default: `letsencrypt`

  - **settings.modules.https.customCertificate**
    object
    - **settings.modules.https.customCertificate.secretName**
      string

      Name of the Secret in the `d8-system` namespace containing a TLS certificate for modules.

      This Secret must be in the `kubernetes.io/tls` format.

      Default: `false`

  - **settings.modules.https.mode**
    string

    HTTPS usage mode:

    - `CertManager`: Modules use HTTPS and obtain certificates automatically using the

ClusterIssuer defined in the `certManager.clusterIssuerName` parameter.
- `CustomCertificate`: Modules use HTTPS with the certificate from the `d8-system` namespace.
- `Disabled`: Modules use HTTP only (some modules, such as `user-authn`, may not work).
- `OnlyInURI`: Modules use HTTP in the expectation that there is an external upstream HTTPS load balancer, which terminates HTTPS. This load balancer should be capable of redirecting requests from HTTP to HTTPS.

Default: `CertManager`

Allowed values: `Disabled`, `CertManager`, `CustomCertificate`, `OnlyInURI`

- **settings.modules.ingress**
  object

  Common parameters for Ingress usage by DP modules.

  - **settings.modules.ingress.enabled**
    boolean

    Enables the creation of Ingress resources by the DP modules that support it.

    Modules that support Ingress can override this setting with their own `ingress.enabled` parameter.

    Default: `true`

  - **settings.modules.ingress.ingressClass**
    string

    Default IngressClass name used by DP modules when creating Ingress resources.

    Some modules support their own `ingressClass` parameter, which lets you use a different IngressClass instead of the default one.

    Default: `nginx`

- **settings.modules.ingressClass**
  Deprecated
  string

  > **Deprecated**. Use settings.modules.ingress.ingressClass instead.

  Default IngressClass name used by DP modules when creating Ingress resources.

  Some modules support their own `ingressClass` parameter, which lets you use a different IngressClass instead of the default one.

  Default: `nginx`

  Pattern: `^[a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*$`

  Example:

  ```
  ingressClass: nginx
  ```

- **settings.modules.placement**
  object

  Parameters regulating the layout of Deckhouse module components.

  - **settings.modules.placement.customTolerationKeys**
    array of strings

    A list of custom toleration keys; use them to allow the deployment of some critical add-ons (such as cni and csi) on dedicated nodes.

    Example:

    ```
    customTolerationKeys:
    - dedicated.example.com
    - node-dedicated.example.com/master
    ```

- **settings.modules.publicDomainTemplate**
  string

  A DNS name template with the `%s` key used as a dynamic part of the string.

  Deckhouse modules use this template when creating Ingress resources.

  For example, given the template `%s.kube.company.my`, the `prometheus` module will create an Ingress resource at the address `grafana.kube.company.my` to provide access to Grafana.

  Pay attention to the following:

  - If this parameter is not specified, Ingress resources will not be created.
  - The domain specified in the template must not match or be a subdomain of the domain specified in

the `network.clusterDomain` parameter of the `control-plane-manager` module. It is not recommended to change the cluster domain unless absolutely necessary.
- For the template to function correctly, you must first configure DNS services both in the networks where the cluster nodes will be located and in the networks from which clients will access the platform's service web interfaces.
- If the template matches the domain of the node network, use only A records to assign addresses of the nodes' Frontend interfaces to the platform's service web interfaces. For example, if the nodes are registered under the `company.my` zone and the template is `%s.company.my`.

Pattern: `^(%s([-a-z0-9]*[a-z0-9])?|[a-z0-9]([-a-z0-9]*)?%s([-a-z0-9]*)?[a-z0-9]|[a-z0-9]([-a-z0-9]*)?%s)(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*$`

Examples:

```
publicDomainTemplate: "%s.kube.company.my"
```

```
publicDomainTemplate: kube-%s.company.my
```

- **settings.modules.resourcesRequests**
  object

  The amount of resources (CPU and memory) allocated to some components.

  More info in the Kubernetes documentation.

  - **settings.modules.resourcesRequests.controlPlane**
    Deprecated
    object

    > **i** **Deprecated**. Use `control-plane-manager` moduleconfig parameter `.spec.settings.resourcesRequests` instead.

    Amount of resources (CPU and memory) allocated to control-plane components on each master node.

    These settings do not apply if the cluster control plane is managed by a cloud provider (for example, Google Kubernetes Engine or Azure Kubernetes Service).

    Example:

    ```
    controlPlane:
      cpu: 1000m
      memory: 500M
    ```

    - **settings.modules.resourcesRequests.controlPlane.cpu**
      Deprecated
      string or number

      > **i** **Deprecated**. Use `controlPlaneManager.spec.settings.resourcesRequests.cpu` instead.

      The combined CPU requests for control-plane components on each master node.

      Pattern: `^[0-9]+m?$`

    - **settings.modules.resourcesRequests.controlPlane.memory**
      Deprecated
      string

      > **i** **Deprecated**. Use `controlPlaneManager.spec.settings.resourcesRequests.memory` instead.

      The combined memory requests for control-plane components on each master node.

      Pattern: `^[0-9]+(\.[0-9]+)?(E|P|T|G|M|K|Ei|Pi|Ti|Gi|Mi|Ki)?$`

- **settings.modules.storageClass**
  string

  The StorageClass to use with all Deckhouse Platform components (Prometheus, Grafana, OpenVPN, etc.) unless it is overridden in the module configuration.

  If the value is not specified, the default StorageClass set in the cluster is used.

  Important notes:

  - If the module's configuration defines its own `storageClass` parameter, the module's value takes precedence and the global `modules.storageClass` is not used.
  - If a PersistentVolumeClaim (PVC) for a module already exists, changing this parameter does not affect the existing PVC or require disk recreation. The module uses the existing PVC and its

StorageClass. See the prometheus module example for more details on how this parameter is applied.
- This parameter is applied during module activation when creating new PVCs.
- Use this parameter only in exceptional circumstances.

Default:

- **settings.prefix**
  string

  A prefix of the objects to be created in the cloud.

  Is used, for example, to distinguish objects created for different clusters, to configure routing, etc.

  This is the new home for the prefix that was previously set in `ClusterConfiguration.cloud.prefix`. If not set, the value from `ClusterConfiguration.cloud.prefix` is used.

  The prefix is used to name cloud objects such as disks (e.g. `<prefix>-kubernetes-data-0`). Cloud object names are limited to 63 characters, so the prefix is capped at 45 characters to leave room for the generated suffix. Depending on the provider and the number of master nodes, the effective limit may be lower; this is additionally enforced by a bootstrap preflight check.

  > **Warning.** This value names existing cloud infrastructure (security groups, route tables, resource groups, instances, etc.). It must match the prefix the cluster was bootstrapped with — setting a different value will break cloud integration. It is not intended to be changed in a running cluster.

  Pattern: `^[a-z0-9]([-a-z0-9]*[a-z0-9])?$`

  Maximum length: `45`

  Example:

  ```
  prefix: kube
  ```

- **settings.storageClass**
  Deprecated
  string

  > **Deprecated**. Use settings.modules.storageClass instead.

  The StorageClass to use with all Deckhouse Platform components (Prometheus, Grafana, OpenVPN, etc.).

  - If the value is not specified, the default StorageClass set in the cluster is used.
  - Use this parameter only in exceptional circumstances.
  - This parameter is applied during module activation.

  Default:

Additional resources

- Module `control-plane-manager` parameters

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Custom Resources

Application

Scope: Namespaced
Version: v1alpha1

Application defines an installed application instance in a namespace.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: Application
metadata:
  name: example
spec:
  maintenance: NoResourceReconciliation
  packageName: console
  packageRepositoryName: deckhouse
  packageVersion: v1.0.0
  releaseChannel: stable
```

- **spec**
  object

  Required value

  Application configuration.

  - **spec.maintenance**
    string

    Application maintenance mode.

    Supported modes:

    - `NoResourceReconciliation`: A mode for developing or debugging the application.

      In this mode:

      - Configuration or hook changes are not reconciled, which prevents resources from being updated automatically.
      - Resource monitoring is disabled, which prevents deleted resources from being restored.
      - All the application's resources are labeled with `maintenance.deckhouse.io/no-resource-reconciliation`.
      - The `ApplicationIsInMaintenanceMode` alert is triggered.

    Allowed values: `NoResourceReconciliation`

    Example:

    ```
    maintenance: NoResourceReconciliation
    ```

  - **spec.packageName**
    string

    Required value

    Name of the application package to install.

    Example:

    ```
    packageName: console
    ```

  - **spec.packageRepositoryName**
    string

    Name of the PackageRepository object where the application package is located.

    Example:

    ```
    packageRepositoryName: deckhouse
    ```

  - **spec.packageVersion**
    string

    Required value

    Version of the application package to install.

    Example:

    ```
    packageVersion: v1.0.0
    ```

  - **spec.resourceRequests**
    array of objects

    Resource settings, replica counts, and disk sizes for workloads deployed by the application.

    Specified values override the settings provided by the application package. Workloads, containers, and disks not listed in this parameter retain their settings from the package.

    Each workload is identified by a combination of kind (`kind`) and name (`name`). Only one entry is allowed for each combination.

Resource settings, replica count, and disk sizes for a single application workload.

- **spec.resourceRequests.containers**
  array of objects

  Compute resources of the workload’s containers.

  If the specified container does not exist in the workload, the entry is ignored.

  Resource settings for a single workload container.

  - **spec.resourceRequests.containers.name**
    string

    Required value

    Name of the container inside the workload.

    Example:

    ```
    name: controller
    ```

  - **spec.resourceRequests.containers.resources**
    object

    Container resource requests and limits, or the range within which VerticalPodAutoscaler sets the container’s requests.

    Requests and limits use the same format as the `resources` field of a Pod container. Supports `cpu`, `memory`, and `ephemeral-storage`.

    Specified values are merged with the settings from the application package separately for each resource. For example, if only `memory` is specified, the `cpu` value from the package is retained.

    Resource requests or limits defined in the package cannot be removed. Their values can only be overridden.

    If VerticalPodAutoscaler controls the container’s `cpu` or `memory`, a request set for that resource remains fixed. If a `cpu` or `memory` limit is set, VPA does not change the container’s limits. The `ApplicationVerticalPodAutoscalerPinned` alert is triggered if a request or limit is set for a resource controlled by VPA.

    To let VPA choose requests within a range, set `min` and `max` instead of `cpu` and `memory` requests and limits.

    - **spec.resourceRequests.containers.resources.claims**
      array of objects

      List of resource claims used by the container.

      Each entry references a resource claim defined in `pod.spec.resourceClaims`. Requires the `DynamicResourceAllocation` feature gate to be enabled.

      This field is immutable. It can only be set for containers.

      Resource claim used by the container.

      - **spec.resourceRequests.containers.resources.claims.name**
        string

        Required value

        Name of a ResourceClaim defined in `pod.spec.resourceClaims`.

        The referenced claim makes its resources available to the container.

      - **spec.resourceRequests.containers.resources.claims.request**
        string

        Name of a request defined in the referenced resource claim.

        If specified, only the resources allocated for this request are made available to the container. If omitted, all resources allocated for the claim are made available.

    - **spec.resourceRequests.containers.resources.limits**
      object

      Maximum amount of compute resources available to the container.

    - **spec.resourceRequests.containers.resources.max**
      object

      Upper bound of the container’s `cpu` and `memory` requests that VerticalPodAutoscaler sets (`maxAllowed` in its policy for the container).

      Set together with `min` for the same resources. Within the range, the requests are chosen by VPA, so a container with `min` and `max` cannot have `cpu` or `memory` requests or limits. A resource bound cannot be less than in `min`.

      If no VerticalPodAutoscaler of the application sets a resource of the container, for example,

because the `vertical-pod-autoscaler` module is disabled, the container gets `min` as the request and `max` as the limit of the resource, and the `ApplicationVerticalPodAutoscalerMissing` alert is triggered.

- **spec.resourceRequests.containers.resources.max.cpu**
  integer or string

  Bound of the `cpu` request.

  Pattern: `^(\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))(([KMGTPE]i)|[numkMGTPE]|([eE](\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))))?$`

  Example:

  ```
  cpu: 250m
  ```

- **spec.resourceRequests.containers.resources.max.memory**
  integer or string

  Bound of the `memory` request.

  Pattern: `^(\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))(([KMGTPE]i)|[numkMGTPE]|([eE](\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))))?$`

  Example:

  ```
  memory: 256Mi
  ```

- **spec.resourceRequests.containers.resources.min**
  object

  Lower bound of the container's `cpu` and `memory` requests that VerticalPodAutoscaler sets (`minAllowed` in its policy for the container).

  Set together with `max` for the same resources. Within the range, the requests are chosen by VPA, so a container with `min` and `max` cannot have `cpu` or `memory` requests or limits. To fix a resource at one value, specify the same value in `min` and `max`.

  If no VerticalPodAutoscaler of the application sets a resource of the container, for example, because the `vertical-pod-autoscaler` module is disabled, the container gets `min` as the request and `max` as the limit of the resource, and the `ApplicationVerticalPodAutoscalerMissing` alert is triggered.

  - **spec.resourceRequests.containers.resources.min.cpu**
    integer or string

    Bound of the `cpu` request.

    Pattern: `^(\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))(([KMGTPE]i)|[numkMGTPE]|([eE](\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))))?$`

    Example:

    ```
    cpu: 250m
    ```

  - **spec.resourceRequests.containers.resources.min.memory**
    integer or string

    Bound of the `memory` request.

    Pattern: `^(\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))(([KMGTPE]i)|[numkMGTPE]|([eE](\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))))?$`

    Example:

    ```
    memory: 256Mi
    ```

- **spec.resourceRequests.containers.resources.requests**
  object

  Minimum amount of compute resources required by the container.

  If this parameter is not specified, the `limits` value is used if explicitly set. Otherwise, the value is implementation-defined.

  The `requests` value cannot exceed `limits`.

- **spec.resourceRequests.kind**
  string

  Required value

  Kind of workload for which resource settings are specified.

  Allowed values: `Deployment`, `StatefulSet`, `DaemonSet`, `ReplicaSet`, `Pod`, `Job`, `CronJob`

  Example:

```
kind: Deployment
```

- **spec.resourceRequests.maxReplicas**
  integer

  Maximum number of workload replicas for the HorizontalPodAutoscaler that the application deploys for the workload.

  Applies only to Deployment, StatefulSet, and ReplicaSet. Set together with `minReplicas`. Cannot be set together with `replicas`: within the range, the number of replicas is chosen by the HorizontalPodAutoscaler.

  If the application does not deploy a HorizontalPodAutoscaler for the workload, the workload runs `minReplicas` replicas, and the `ApplicationHorizontalPodAutoscalerMissing` alert is triggered.

  Allowed values: `1 <= X`

  Example:

  ```
  maxReplicas: 10
  ```

- **spec.resourceRequests.minReplicas**
  integer

  Minimum number of workload replicas for the HorizontalPodAutoscaler that the application deploys for the workload.

  Applies only to Deployment, StatefulSet, and ReplicaSet. Set together with `maxReplicas`. Cannot be set together with `replicas`: within the range, the number of replicas is chosen by the HorizontalPodAutoscaler. Cannot be greater than `maxReplicas`.

  If the application does not deploy a HorizontalPodAutoscaler for the workload, the workload runs `minReplicas` replicas, and the `ApplicationHorizontalPodAutoscalerMissing` alert is triggered.

  Allowed values: `1 <= X`

  Example:

  ```
  minReplicas: 2
  ```

- **spec.resourceRequests.name**
  string

  Required value

  Workload name as specified in the application package.

  Example:

  ```
  name: controller
  ```

- **spec.resourceRequests.replicas**
  integer

  Number of workload replicas.

  Applies only to workloads that support replica management: Deployment, StatefulSet, and ReplicaSet. Cannot be set together with `minReplicas` or `maxReplicas`.

  If the application deploys a HorizontalPodAutoscaler for the workload, its `minReplicas` and `maxReplicas` are set to this value, so the number of replicas does not change, and the `ApplicationHorizontalPodAutoscalerPinned` alert is triggered. To let HorizontalPodAutoscaler scale the workload, set `minReplicas` and `maxReplicas` instead. The value `0` applies only to the workload: HorizontalPodAutoscaler does not scale a workload with no replicas.

  Allowed values: `0 <= X`

  Example:

  ```
  replicas: 3
  ```

- **spec.resourceRequests.volumeClaimTemplates**
  array of objects

  Disk sizes for the StatefulSet's volume claim templates.

  Applies only to StatefulSet. Each template is identified by its name, the `metadata.name` of an entry in `spec.volumeClaimTemplates`. If the specified template does not exist in the StatefulSet, the entry is ignored.

  The size cannot be less than the size of the existing disks: a disk can only be expanded. Expanding requires the StorageClass of the disks to allow volume expansion (`allowVolumeExpansion: true`).

  Disk size for a single volume claim template of a StatefulSet.

  - **spec.resourceRequests.volumeClaimTemplates.name**

string

Required value

Name of the volume claim template in the StatefulSet.

Example:

```
name: data
```

- **spec.resourceRequests.volumeClaimTemplates.storage**
  integer or string

  Required value

  Disk size requested from the template for each StatefulSet replica.

  Pattern: `^(\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))(([KMGTPE]i)|[numkMGTPE]|([eE](\+|-)?(([0-9]+(\.[0-9]*)?)|(\.[0-9]+))))?$`

  Example:

  ```
  storage: 10Gi
  ```

- **spec.settings**
  object

  Configuration application settings.

- **spec.settingsVersion**
  number

  Version of the settings schema the settings are written for. Distinct from packageVersion, which selects the application package.

  Settings of an older version are converted to the latest one the package provides. If not specified, version 1 is used.

- **spec.update**
  object

  Application update settings: update mode and update windows.

  If this parameter is not specified, the `Manual` update mode is used.

  Update notifications cannot be configured for an application: the `update.notification` settings of the `deckhouse` module are used.

  Example:

  ```
  update:
    mode: Auto
    windows:
    - from: '8:00'
      to: '15:00'
      days:
      - Tue
      - Sat
  ```

  - **spec.update.mode**
    string

    Update mode of the application on its release channel.

    - `AutoPatch`: Automatic update mode for patch versions.

      To change a minor version (for example, from `v1.2.*` to `v1.3.*`), confirmation is required.

      A patch version update (for example, from `v1.3.1` to `v1.3.2`) is applied taking into account the update windows, if they are set.

    - `Auto`: Automatic update mode for all versions.

      Minor version updates (for example, from `v1.2.*` to `v1.3.*`) and patch version updates (for example, from `v1.3.1` to `v1.3.2`) are applied taking into account the update windows, if they are set.

    - `Manual`: Manual update mode for all versions.

      Confirmation is required for updating both minor and patch versions.

    Allowed values: `AutoPatch`, `Auto`, `Manual`

    Examples:

    ```
    mode: AutoPatch
    ```

```
mode: Auto
```

```
mode: Manual
```

- **spec.update.windows**
  array of objects

  List of application update windows.

  Time interval during the day when application updates are allowed.

  - **spec.update.windows.days**
    array of strings

    Days of the week on which the update window is applied.

    If the parameter is omitted, the update window is applied every day.

    - **Element of the array**
      string

      Allowed values: `Mon`, `Tue`, `Wed`, `Thu`, `Fri`, `Sat`, `Sun`

  - **spec.update.windows.from**
    string

    Required value

    Start time of the update window (UTC timezone).

    Should be earlier than the end time of the update window.

    Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

    Example:

    ```
    from: '13:00'
    ```

  - **spec.update.windows.to**
    string

    Required value

    End time of the update window (UTC timezone).

    Should be later than the start time of the update window.

    Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

    Example:

    ```
    to: '18:30'
    ```

- **status**
  object

  Current state of the application.

  - **status.conditions**
    array of objects

    Conditions reflecting the current state of the application.

    Condition reflecting an aspect of the current state of the application.

    - **status.conditions.lastTransitionTime**
      string

      Required value

      Time when the condition status last changed.

    - **status.conditions.message**
      string

      Required value

      Message with additional information about the condition.

      Maximum length: `32768`

    - **status.conditions.observedGeneration**
      integer

      Value of `.metadata.generation` for which the condition was set.

      Indicates whether the condition corresponds to the current generation of the instance.

Allowed values: `0 <= X`

- **status.conditions.reason**
  string

  Required value

  Programmatic identifier indicating the reason for the last condition status change.

  Pattern: `^[A-Za-z]([A-Za-z0-9_,:]*[A-Za-z0-9_])?$`

  Length: `1..1024`

- **status.conditions.status**
  string

  Required value

  Condition status.

  Allowed values: `True`, `False`, `Unknown`

- **status.conditions.type**
  string

  Required value

  Condition type in CamelCase or in the format `foo.example.com/CamelCase`.

  Pattern: `^([a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*/)?(([A-Za-z0-9][-A-Za-z0-9_.]*)?[A-Za-z0-9])$`

  Maximum length: `316`

- **status.currentVersion**
  object

  Information about the currently installed application version.

  - **status.currentVersion.version**
    string

    Installed application version in SemVer format.

- **status.lastAppliedConfiguration**
  object

  Application configuration used during the last successful apply.

  Includes user-defined settings and default values defined in the configuration schema.

- **status.summary**
  object

  Summary of the application state, including messages and recommendations for the user.

  The controller updates this information during each reconciliation. Each application has exactly one lifecycle state.

  Use this information to display the application state in the web interface. Do not recalculate the state from conditions.

  - **status.summary.message**
    string

    Description of the current application state.

  - **status.summary.state**
    string

    Current application lifecycle state.

    Examples:

    ```
    state: Pending
    ```

    ```
    state: Failed
    ```

    ```
    state: Updating
    ```

    ```
    state: Configuring
    ```

    ```
    state: Ready
    ```

    ```
    state: Degraded
    ```

```
state: Suspended
```

```
state: Deleting
```

- **status.summary.tip**
  string

  Recommended action for the current application state.

  May be empty if no additional action is required.

- **status.tracking**
  object

  Nelm report on application status.

- **status.update**
  object

  Update of the application: the update plan, the version the automatic update moves to next and the notification sent about the pending update.

  Empty before the first version is installed.

  - **status.update.automaticVersion**
    string

    Version the automatic update installs next. It changes only after the previous one is installed and ready. Empty in the `Manual` update mode.

  - **status.update.notified**
    object

    Notification sent about the pending update: the version it announced and when it was sent.

    It is sent to the webhook of the `update.notification` settings of the `deckhouse` module. The update is installed no earlier than `minimalNotificationTime` after the notification. Cleared once a new version is installed or the update is cancelled.

    - **status.update.notified.time**
      string

      Required value

      Time the notification was sent.

    - **status.update.notified.version**
      string

      Required value

      Version the notification announced.

  - **status.update.plan**
    array of strings

    Update path after the automatic version in every update mode. The path follows the compatibility rules to the newest version in the cluster, or to the newest version the rules reach; each step is the newest version from which the end of the path is still reached.

- **status.urls**
  array of objects

  Application endpoint URLs obtained from Ingress, HTTPRoute, and ServiceAccount resources in the application chart with the `packages.deckhouse.io/application-endpoint-description` annotation. A ServiceAccount gives the in-cluster address of the Kubernetes API, `https://kubernetes.default.svc/`.

  Application endpoint defined by an Ingress, HTTPRoute, or ServiceAccount resource in the application chart.

  - **status.urls.description**
    string

    Endpoint description from the `packages.deckhouse.io/application-endpoint-description` annotation.

    The description is empty if the annotation value is `"true"`.

  - **status.urls.url**
    string

    Required value

    Application endpoint URL.

ApplicationPackage

Short names: ap

Scope: Cluster

Version: v1alpha1

ApplicationPackage defines an application package available for installation.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ApplicationPackage
metadata:
  name: example
```

- **status**
  object

  Current state of the application package.

  - **status.availableRepositories**
    array of strings

    List of repository names where the application package is available.

  - **status.releaseChannels**
    object

    Application package versions associated with release channels in each repository.

    The first-level key is the package repository name, and the second-level key is the release channel name.

  - **status.usedBy**
    array of objects

    List of applications installed from this package.

    Application installed from the package.

    - **status.usedBy.name**
      string

      Name of the application instance.

    - **status.usedBy.namespace**
      string

      Namespace where the application is installed.

    - **status.usedBy.repositoryName**
      string

      Name of the PackageRepository from which the application was installed.

    - **status.usedBy.version**
      string

      Package version used by the application.

  - **status.usedByCount**
    integer

    Number of applications installed from this package.

    Equals the number of entries in `usedBy`.

ApplicationPackageVersion

Short names: apv

Scope: Cluster
Version: v1alpha1

ApplicationPackageVersion defines a version of an application package.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ApplicationPackageVersion
metadata:
  name: example
spec:
  packageName: console
  packageRepositoryName: deckhouse
  packageVersion: v1.0.0
```

- **spec**
  object

  Application package version parameters.

- **spec.packageName**
  string

  Required value

  Name of the application package.

  Example:

  ```
  packageName: console
  ```

- **spec.packageRepositoryName**
  string

  Required value

  Name of the package repository containing the package.

  Example:

  ```
  packageRepositoryName: deckhouse
  ```

- **spec.packageVersion**
  string

  Required value

  Version of the application package.

  Example:

  ```
  packageVersion: v1.0.0
  ```

- **status**
  object

  Current state of the application package version.

  - **status.conditions**
    array of objects

    Conditions reflecting the current state of the application package version.

    Condition reflecting an aspect of the current state of the package version.

    - **status.conditions.lastTransitionTime**
      string

      Required value

      Time when the condition status last changed.

    - **status.conditions.message**
      string

      Required value

      Message with additional information about the condition.

      May be empty.

      Maximum length: `32768`

    - **status.conditions.observedGeneration**
      integer

      Value of `.metadata.generation` for which the condition was set.

      Indicates whether the condition corresponds to the current generation of the instance.

      Allowed values: `0 <= X`

    - **status.conditions.reason**
      string

      Required value

      Programmatic identifier indicating the reason for the last condition status change.

      Pattern: `^[A-Za-z]([A-Za-z0-9_,:]*[A-Za-z0-9_])?$`

      Length: `1..1024`

    - **status.conditions.status**
      string

      Required value

      Condition status.

Allowed values: `True`, `False`, `Unknown`

- **status.conditions.type**
  string

  Required value

  Condition type in CamelCase or in the format `foo.example.com/CamelCase`.

  Pattern: `^([a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*/)?(([A-Za-z0-9][-A-Za-z0-9_.]*)?[A-Za-z0-9])$`

  Maximum length: `316`

- **status.observedGeneration**
  integer

  Value of `.metadata.generation` for which the current status was calculated.

  If the value is lower than the current `.metadata.generation`, the status does not yet reflect the latest changes to the instance.

  Allowed values: `0 <= X`

- **status.packageMetadata**
  object

  Application package version metadata, including the description, requirements, disable options, and version compatibility rules.

  - **status.packageMetadata.category**
    string

    Application package category.

  - **status.packageMetadata.changelog**
    object

    Information about changes in this package version.

    - **status.packageMetadata.changelog.features**
      array of strings

      List of new features in this package version.

    - **status.packageMetadata.changelog.fixes**
      array of strings

      List of bugs fixed in this package version.

  - **status.packageMetadata.description**
    object

    Localized descriptions of the application package.

    - **status.packageMetadata.description.en**
      string

      English description of the application package.

    - **status.packageMetadata.description.ru**
      string

      Russian description of the application package.

  - **status.packageMetadata.disableOptions**
    object

    Parameters of package disable protection.

    - **status.packageMetadata.disableOptions.confirmation**
      boolean

      Indicates whether confirmation is required to disable the application package.

    - **status.packageMetadata.disableOptions.messages**
      object

      Localized messages displayed when confirming package disabling.

      - **status.packageMetadata.disableOptions.messages.en**
        string

        Disable confirmation message in English.

      - **status.packageMetadata.disableOptions.messages.ru**
        string

        Disable confirmation message in Russian.

  - **status.packageMetadata.licensing**
    object

Application package licensing information for different editions.

- **status.packageMetadata.licensing.editions**
  object

  Licensing settings for different application package editions.

  - **status.packageMetadata.licensing.editions.<KEY_NAME>**
    object

    `<KEY_NAME>` — item (key) name.

    - **status.packageMetadata.licensing.editions.<KEY_NAME>.available**
      boolean

      Indicates whether the edition is available for use.

    - **status.packageMetadata.licensing.editions.<KEY_NAME>.enabledInBundles**
      array of strings

      Bundles in which the package is enabled by default in this edition.

      Not used for application packages.

- **status.packageMetadata.requirements**
  object

  System requirements for installing and running the application.

  - **status.packageMetadata.requirements.deckhouse**
    object

    Required Deckhouse Platform version.

    - **status.packageMetadata.requirements.deckhouse.constraint**
      string

      Deckhouse Platform version constraint in SemVer format.

  - **status.packageMetadata.requirements.kubernetes**
    object

    Required Kubernetes version.

    - **status.packageMetadata.requirements.kubernetes.constraint**
      string

      Kubernetes version constraint in SemVer format.

  - **status.packageMetadata.requirements.modules**
    object

    Deckhouse Platform module requirements: required and optional dependencies, groups of alternative modules, and groups of incompatible modules.

    - **status.packageMetadata.requirements.modules.anyOf**
      array of objects

      Groups of alternative modules.

      At least one module in each group must be enabled. If a version constraint is specified for a module, its version must satisfy that constraint.

      These groups do not add edges to the dependency graph.

      Group of alternative modules, at least one of which must be enabled.

      - **status.packageMetadata.requirements.modules.anyOf.description**
        string

        Human-readable description of the group’s purpose.

      - **status.packageMetadata.requirements.modules.anyOf.modules**
        array of objects

        Required value

        Alternative modules in the group.

        Module with an optional version constraint in SemVer format.

        If no constraint is specified, any version is allowed.

        - **status.packageMetadata.requirements.modules.anyOf.modules.constraint**
          string

          Module version constraint in SemVer format.

        - **status.packageMetadata.requirements.modules.anyOf.modules.name**
          string

          Required value

Module name.

- **status.packageMetadata.requirements.modules.anyOf.name**
  string

  Required value

  Stable identifier used by the scheduler in diagnostics.

- **status.packageMetadata.requirements.modules.conditional**
  array of objects

  Optional modules with version constraints.

  The module does not have to be enabled. If it is enabled, its version must satisfy the specified constraint.

  Replaces the deprecated `!optional` suffix from the v1 requirements format.

  Optional module with a version constraint in SemVer format.

  If no constraint is specified, any version is allowed.

  - **status.packageMetadata.requirements.modules.conditional.constraint**
    string

    Module version constraint in SemVer format.

  - **status.packageMetadata.requirements.modules.conditional.name**
    string

    Required value

    Module name.

- **status.packageMetadata.requirements.modules.mandatory**
  array of objects

  Modules required for the application to run.

  Each specified module must be enabled. If a version constraint is specified, the module version must satisfy it.

  Required module with an optional version constraint in SemVer format.

  If no constraint is specified, any version is allowed.

  - **status.packageMetadata.requirements.modules.mandatory.constraint**
    string

    Module version constraint in SemVer format.

  - **status.packageMetadata.requirements.modules.mandatory.name**
    string

    Required value

    Module name.

- **status.packageMetadata.requirements.modules.noneOf**
  array of objects

  Groups of incompatible modules.

  For the application to run, none of the modules in these groups may be enabled with an incompatible version.

  If no version constraint is specified, all versions of the module are considered incompatible. If a constraint is specified, only versions satisfying that constraint are considered incompatible.

  These groups do not add edges to the dependency graph.

  Group of incompatible modules.

  None of the listed modules may be enabled with an incompatible version.

  - **status.packageMetadata.requirements.modules.noneOf.description**
    string

    Human-readable description of the group’s purpose.

  - **status.packageMetadata.requirements.modules.noneOf.modules**
    array of objects

    Required value

    Incompatible modules in the group.

    Module with an optional version constraint in SemVer format.

    If no constraint is specified, all versions of the module are considered incompatible.

    - **status.packageMetadata.requirements.modules.noneOf.modules.constraint**

string

Module version constraint in SemVer format defining the range of incompatible versions.

- **status.packageMetadata.requirements.modules.noneOf.modules.name**
  string

  Required value

  Module name.

- **status.packageMetadata.requirements.modules.noneOf.name**
  string

  Required value

  Stable identifier used by the scheduler in diagnostics.

- **status.packageMetadata.stage**
  string

  Life cycle stage of the application package.

  Examples:

```
stage: Experimental
```

```
stage: Preview
```

```
stage: General Availability
```

```
stage: Deprecated
```

- **status.packageMetadata.versionCompatibilityRules**
  object

  Version compatibility rules for upgrades and downgrades.

  - **status.packageMetadata.versionCompatibilityRules.downgrade**
    object

    Compatibility rules for downgrading from this application version.

    Default: `{"step":{"major":0,"minor":0,"patches":-1}}`

    - **status.packageMetadata.versionCompatibilityRules.downgrade.step**
      object

      Compatibility rule step.

      - **status.packageMetadata.versionCompatibilityRules.downgrade.step.major**
        integer

        Number of major versions that can be skipped during a downgrade.

        The `-1` value removes all limits, `0` forbids the change.

        Defaults to `0`.

        Allowed values: `-1 <= X`

      - **status.packageMetadata.versionCompatibilityRules.downgrade.step.minor**
        integer

        Number of minor versions that can be skipped during a downgrade.

        The `-1` value removes all limits, `0` forbids the change.

        Defaults to `0`.

        Allowed values: `-1 <= X`

      - **status.packageMetadata.versionCompatibilityRules.downgrade.step.patches**
        integer

        Number of patch versions that can be skipped during a downgrade.

        The `-1` value removes all limits, `0` forbids the change.

        Defaults to `-1`.

        Allowed values: `-1 <= X`

  - **status.packageMetadata.versionCompatibilityRules.upgrade**
    object

    Compatibility rules for upgrading to and from this application version.

Default: `{"step":{"major":0,"minor":1,"patches":-1}}`

- **status.packageMetadata.versionCompatibilityRules.upgrade.from**
  string

  SemVer constraint on the application versions from which the application can be upgraded to this version.

  If specified, the constraint takes priority over the `step` limits of the version being upgraded from: the application is upgraded to this version only from the versions that satisfy the constraint, regardless of those limits. This applies to the update plan, the automatic update, and a change of `spec.packageVersion` of the Application. An invalid constraint forbids upgrading to this version.

  If not specified, the `step` limits of the version being upgraded from apply.

- **status.packageMetadata.versionCompatibilityRules.upgrade.step**
  object

  Compatibility rule step.

  - **status.packageMetadata.versionCompatibilityRules.upgrade.step.major**
    integer

    Number of major versions that can be skipped during an upgrade.

    The `-1` value removes all limits, `0` forbids the change.

    Defaults to `0`.

    Allowed values: `-1 <= X`

  - **status.packageMetadata.versionCompatibilityRules.upgrade.step.minor**
    integer

    Number of minor versions that can be skipped during an upgrade.

    The `-1` value removes all limits, `0` forbids the change.

    Defaults to `1`.

    Allowed values: `-1 <= X`

  - **status.packageMetadata.versionCompatibilityRules.upgrade.step.patches**
    integer

    Number of patch versions that can be skipped during an upgrade.

    The `-1` value removes all limits, `0` forbids the change.

    Defaults to `-1`.

    Allowed values: `-1 <= X`

- **status.packageSchemas**
  object

  OpenAPI schemas for validating user-defined application settings and final values passed to package hooks and templates.

  - **status.packageSchemas.settingsConversions**
    array of objects

    Conversions that bring settings written for an older settings schema version to the latest one, ordered by version.

    Empty when the package has a single settings schema version.

    PackageSettingsConversion converts settings of the previous settings schema version to Version.

    - **status.packageSchemas.settingsConversions.descriptions**
      object

      Localized description of the changes in this settings schema version.

      - **status.packageSchemas.settingsConversions.descriptions.en**
        string

        English description of the conversion.

      - **status.packageSchemas.settingsConversions.descriptions.ru**
        string

        Russian description of the conversion.

    - **status.packageSchemas.settingsConversions.expr**
      array of strings

      Required value

      jq expressions applied to the settings in order.

        - **status.packageSchemas.settingsConversions.version**
          integer

          Required value

          Settings schema version the conversion produces; it converts settings of the previous version.

      - **status.packageSchemas.settingsSchema**
        object

        OpenAPI v3 schema for validating user-defined application settings in `Application.spec.settings`.

        The schema is stored as an opaque object because it has a recursive JSON Schema structure. The controller validates it when loading the package metadata.

      - **status.packageSchemas.valuesSchema**
        object

        OpenAPI v3 schema for validating the final set of `values` passed to package hooks and templates.

        The final set is formed by merging default values with user-defined application settings.

        The schema is stored as an opaque object because it has a recursive JSON Schema structure. The controller validates it when loading the package metadata.

  - **status.usedBy**
    array of objects

    List of applications installed from this package version.

    Application installed from the package version.

    - **status.usedBy.name**
      string

      Name of the application instance.

    - **status.usedBy.namespace**
      string

      Namespace where the application is installed.

  - **status.usedByCount**
    integer

    Number of applications installed from this package version.

    Equals the number of entries in `usedBy`.

    Allowed values: `0 <= X`

ClusterConfiguration

Version: deckhouse.io/v1

General parameters of a cluster.

Defines, for example, network and CRI parameters. Some parameters can be changed after the cluster is bootstrapped, during its operation.

To change the `ClusterConfiguration` resource in a running cluster, run the following command:

```
d8 system edit cluster-configuration
```

Example:

```
apiVersion: deckhouse.io/v1
kind: ClusterConfiguration
podSubnetNodeCIDRPrefix: '24'
podSubnetCIDR: 10.244.0.0/16
serviceSubnetCIDR: 192.168.0.0/16
clusterDomain: k8s.internal
clusterType: Cloud
cloud:
  prefix: k8s-dev
  provider: Yandex
proxy:
  httpProxy: https://user:password@proxy.company.my:8443
  httpsProxy: https://user:password@proxy.company.my:8443
  noProxy:
  - company.my
```

- **apiVersion**
  string

Required value

Version of the Deckhouse API.

Allowed values: `deckhouse.io/v1`, `deckhouse.io/v1alpha1`

- **cloud**
  object

  Cloud provider-related settings (if the `Cloud` clusterType is used).

  - **cloud.prefix**
    Deprecated
    string

    A prefix of the objects to be created in the cloud.

    Deprecated. Use `prefix` in the `global` ModuleConfig instead.

    This field is still used by the installer (dhctl) to name cloud infrastructure at bootstrap and must remain set for cloud clusters; the ModuleConfig value is the source for in-cluster consumers and must match it.

    Is used, for example, to distinguish objects created for different clusters, to configure routing, etc.

    Cloud object names (e.g. disks named `<prefix>-kubernetes-data-0`) are limited to 63 characters, so the prefix is capped at 45 characters. The effective limit may be lower depending on the provider and the number of master nodes; this is additionally enforced by a bootstrap preflight check.

    Pattern: `^[a-z0-9]([-a-z0-9]*[a-z0-9])?$`

    Maximum length: `45`

  - **cloud.provider**
    string

    Required value

    Cloud provider.

    Allowed values: `OpenStack`, `AWS`, `GCP`, `Yandex`, `vSphere`, `Azure`, `VCD`, `Zvirt`, `Dynamix`, `Huaweicloud`, `DVP`

- **clusterDomain**
  Deprecated
  string

  Deprecated. Use `clusterDomain` in the `network` section of the `control-plane-manager` ModuleConfig instead.

  Cluster domain (used for local routing).

  Please note: the domain must not match the domain used in the DNS name template in the publicDomainTemplate parameter. For example, you cannot set `clusterDomain: cluster.local` and `publicDomainTemplate: %s.cluster.local` at the same time.

  > **i** If you need to change a parameter in a running cluster, it is recommended to use instructions

  The field still works, but it will be removed in a future release. Until the value is moved to the ModuleConfig, the cluster reports the `D8ObsoleteClusterDomainInClusterConfiguration` alert. Remove it here only after the ModuleConfig carries the domain.

- **clusterType**
  string

  Required value

  Type of the cluster infrastructure:

  - `Static` — a cluster on bare metal (physical servers) or virtual machines. In the case of virtual machines, it is assumed that Deckhouse doesn't have access to the API for managing virtual machines (they are managed by the administrator using the usual cloud infrastructure tools);
  - `Cloud` — a cluster deployed on the resources of a cloud infrastructure. This type implies that Deckhouse has access to the cloud infrastructure API for managing virtual machines.

  Allowed values: `Cloud`, `Static`

- **defaultCRI**
  string

  The container runtime type that used on cluster nodes (NodeGroups) by default.

  If the value `NotManaged` is used, then Deckhouse does not manage the container runtime (and doesn't install it). In this case, it is necessary to use images for NodeGroups on which the container runtime is already installed.

  If `ContainerdV2` is set, `CgroupsV2` will be used (providing improved security and resource management). To use `ContainerdV2` as the container runtime, cluster nodes must meet the following requirements:

  - Support for `CgroupsV2`.
  - Linux kernel version 5.8 or newer, except for the ranges 6.12.0–6.12.28 or 6.14.0–6.14.6 (these versions are affected by CVE-2025-37999 in EROFS).

  - Systemd version `244` or newer.
  - Support for `erofs` kernel module.

  Default: `Containerd`

  Allowed values: `Containerd`, `ContainerdV2`, `NotManaged`

- **encryptionAlgorithm**
  Deprecated
  string

  Deprecated. Use `encryptionAlgorithm` in the `control-plane-manager` ModuleConfig instead.

  When the ModuleConfig field is set, it takes precedence over this field.

  Starting from version **1.31**, kubeadm use the specified asymmetric encryption algorithm when generating keys and certificates for the following control-plane components:

  - `apiserver`
  - `apiserver-kubelet-client`
  - `apiserver-etcd-client`
  - `front-proxy-client`
  - `etcd-server`
  - `etcd-peer`
  - `etcd-healthcheck-client`

  Certificates for the components listed above will be reissued using the selected algorithm and key length.

  > **Warning.** When reissuing certificates, the root certificate (**CA**) is not rotated. The root certificate is created with the selected algorithm only during the initial cluster bootstrap.

  Allowed values: `RSA-2048`, `RSA-3072`, `RSA-4096`, `ECDSA-P256`

- **kind**
  string

  Required value

  Allowed values: `ClusterConfiguration`

- **kubernetesVersion**
  Deprecated
  string

  Deprecated. Use `kubernetesVersion` in the `control-plane-manager` ModuleConfig instead (`d8 k edit mc control-plane-manager`).

  The cluster Kubernetes version is resolved in the following order: `kubernetesVersion` parameter in the `control-plane-manager` ModuleConfig, then this field, then the version the current DP release defaults to. The ModuleConfig setting wins whenever it is set, `Default` included.

  This field is optional. While it pins a version and the `kubernetesVersion` in the `control-plane-manager` ModuleConfig setting is unset, this field is what decides the cluster version. The `D8ObsoleteKubernetesVersionFieldInClusterConfiguration` alert appears in the cluster simply because the field is present — including when the ModuleConfig setting already decides the version — and clears it once the field is removed.

  Do not change this field in a running cluster to upgrade or downgrade Kubernetes — change `kubernetesVersion` in the `control-plane-manager` ModuleConfig instead.

  If `Automatic` is specified, then the control plane version is used, which is considered stable at the moment. If the stable version of control plane is less than the maximum version that has ever been installed in the cluster, more than 1 minor version, then the version of the cluster will not be changed. The version may change when the minor version of the Deckhouse release is changed (see a corresponding release message).

  Allowed values: `1.33`, `1.34`, `1.35`, `1.36`, `1.37`, `Automatic`

- **podSubnetCIDR**
  Deprecated
  string

  Deprecated. Use `podSubnetCIDR` in the `network` section of the `control-plane-manager` ModuleConfig instead.

  Address space of the cluster's Pods.

  Must be an address with a prefix length, for example `10.111.0.0/16`. A value written without one is rejected when the configuration is loaded.

  > **Warning!** Changing this parameter in a running cluster is **extremely dangerous** and can lead to complete cluster failure. The change is blocked by default. To bypass this protection, use `dhctl config edit cluster-configuration --yes-i-am-sane-and-i-understand-what-i-am-doing` command. However, it is **strongly recommended to recreate the cluster** instead of changing this parameter. See documentation for details.

  Pattern: `^(([0-9]|[1-9][0-9]|1[0-9]{2}|2[0-4][0-9]|25[0-5])\.){3}([0-9]|[1-9][0-9]|1[0-9]{2}|2[0-`

`4][0-9]|25[0-5])(\/(3[0-2]|[1-2][0-9]|[0-9]))$`

- **podSubnetNodeCIDRPrefix**
  Deprecated
  string

  Deprecated. Use `podSubnetNodeCIDRPrefix` in the `network` section of the `control-plane-manager` ModuleConfig instead.

  The prefix size of the Pod network allocated to each node.

  This parameter determines how many IP addresses are available for Pods on each individual node. For example, if `podSubnetCIDR: 10.111.0.0/16` and `podSubnetNodeCIDRPrefix: "24"`, each node will receive a `/24` subnet (e.g., `10.111.0.0/24`, `10.111.1.0/24`, etc.), providing up to 254 IP addresses per node (253 usable for Pods, accounting for network and broadcast addresses).

  Calculation examples:

  - With `/16` network and `/24` prefix: maximum **256 nodes** (2^(24-16) = 256)
  - With `/16` network and `/25` prefix: maximum **512 nodes**, but only **126 IPs per node**
  - Each Pod network IP can support up to 2 Pods (one running + one terminating)

  > **Warning!** Changing this parameter in a running cluster is **extremely dangerous** and can lead to complete cluster failure. The change is blocked by default. To bypass this protection, use `dhctl config edit cluster-configuration --yes-i-am-sane-and-i-understand-what-i-am-doing` command. However, it is **strongly recommended to recreate the cluster** instead of changing this parameter. See documentation for details.

  If the parameter is set in neither place, `24` is used.

- **proxy**
  object

  Available in editions: BE, SE, SE+, Ultimate/EE

  Global proxy setup (mainly for working in air-gapped environments).

  The parameters described in this section will be translated into the environment variables `HTTP_PROXY`, `HTTPS_PROXY`, and `NO_PROXY` for all cluster nodes and Deckhouse components. This will result in HTTP(S) requests (curl, git, registry, etc.) to all resources not listed in the `noProxy` parameter being made through a proxy. Note that the `podSubnetCIDR` and `serviceSubnetCIDR` subnets, as well as the `clusterDomain` domain are added to `noProxy` automatically.

  > **Caution!** To avoid using proxies in requests between pods and services located in the cluster node network, make sure you list all the host subnets in the `noProxy` parameter.

  - **proxy.httpProxy**
    string

    Available in editions: BE, SE, SE+, Ultimate/EE

    Proxy URL for HTTP requests.

    If necessary, specify the proxy server’s username, password, and port.

    Pattern: `^https?://([!*'();&=+$,/?%#\[\]0-9a-zA-Z\.\-\_]+(\:[!*'();:@&=+$,/?%#\[\]0-9a-zA-Z\.\-\_]+)?@)?[0-9a-zA-Z\.\-]+(\:[0-9]{1,5})?$`

    Examples:

    ```
    httpProxy: http://proxy.company.my
    ```

    ```
    httpProxy: https://user:password@proxy.company.my:8443
    ```

    ```
    httpProxy: https://DOMAIN%5Cuser:password@proxy.company.my:8443
    ```

    ```
    httpProxy: https://user%40domain.local:password@proxy.company.my:8443
    ```

  - **proxy.httpsProxy**
    string

    Available in editions: BE, SE, SE+, Ultimate/EE

    Proxy URL for HTTPS requests.

    If necessary, specify the proxy server’s username, password, and port.

    Pattern: `^https?://([!*'();&=+$,/?%#\[\]0-9a-zA-Z\.\-\_]+(\:[!*'();:@&=+$,/?%#\[\]0-9a-zA-Z\.\-\_]+)?@)?[0-9a-zA-Z\.\-]+(\:[0-9]{1,5})?$`

    Examples:

```
httpsProxy: http://proxy.company.my
```

```
httpsProxy: https://user:password@proxy.company.my:8443
```

```
httpsProxy: https://DOMAIN%5Cuser:password@proxy.company.my:8443
```

```
httpsProxy: https://user%40domain.local:password@proxy.company.my:8443
```

- **proxy.noProxy**
  array of strings

  Available in editions: BE, SE, SE+, Ultimate/EE

  List of no proxy IP and domain entries.

  For wildcard domains, use a domain name with a dot prefix, e.g., “.example.com”.

  > **Caution.** If the cluster is supposed to have pods interacting with services located in the cluster node network, then specify the list of subnets that are used on the nodes.

  - **Element of the array**
    string

    Pattern: `^[a-z0-9\-\./]+$`

- **serviceSubnetCIDR**
  Deprecated
  string

  Deprecated. Use `serviceSubnetCIDR` in the `network` section of the `control-plane-manager` ModuleConfig instead.

  Address space of the cluster’s services.

  Must be an address with a prefix length, for example `10.222.0.0/16`. A value written without one is rejected when the configuration is loaded.

  > **Warning!** Changing this parameter in a running cluster is **extremely dangerous** and can lead to complete cluster failure. The change is blocked by default. To bypass this protection, use `dhctl config edit cluster-configuration --yes-i-am-sane-and-i-understand-what-i-am-doing` command. However, it is **strongly recommended to recreate the cluster** instead of changing this parameter. See documentation for details.

  Pattern: `^(([0-9]|[1-9][0-9]|1[0-9]{2}|2[0-4][0-9]|25[0-5])\.){3}([0-9]|[1-9][0-9]|1[0-9]{2}|2[0-4][0-9]|25[0-5])(\/(3[0-2]|[1-2][0-9]|[0-9]))$`

CNIMigration

Short names: cnim

Scope: Cluster
Version: v1alpha1

Defines the configuration for CNI migration.

- **spec**
  object

  Defines the desired state of CNI migration.

  - **spec.targetCNI**
    string

    The target CNI to migrate to.

- **status**
  object

  Defines the observed state of CNI migration.

  - **status.conditions**
    array of objects

    Reflect the state of the migration as a whole.

    - **status.conditions.lastTransitionTime**
      string

      Required value

    - **status.conditions.message**

string

Required value

- **status.conditions.reason**
  string

  Required value

- **status.conditions.status**
  string

  Required value

- **status.conditions.type**
  string

  Required value

- **status.currentCNI**
  string

  The detected CNI from which the switch is being made.

- **status.failedSummary**
  array of objects

  Details about nodes that failed the migration.

  - **status.failedSummary.node**
    string
  - **status.failedSummary.reason**
    string
- **status.nodesFailed**
  integer

  The number of nodes where an error occurred.

- **status.nodesSucceeded**
  integer

  The number of nodes that have successfully completed the current phase.

- **status.nodesTotal**
  integer

  The total number of nodes involved in the migration.

- **status.phase**
  string

  The current step of the migration process.

CNINodeMigration

Short names: cninm

Scope: Cluster
Version: v1alpha1

Defines the configuration for CNI migration on a specific node.

- **spec**
  object

  Defines the desired state of CNI migration on a node.

- **status**
  object

  Defines the observed state of CNI migration on a node.

  - **status.conditions**
    array of objects

    A list of conditions for this migration.

    - **status.conditions.lastTransitionTime**
      string

      Required value

    - **status.conditions.message**
      string

      Required value

    - **status.conditions.reason**
      string

      Required value

        - **status.conditions.status**
          string

          Required value

        - **status.conditions.type**
          string

          Required value

    - **status.phase**
      string

      The current phase of the migration on the node.

DeckhouseRelease

Scope: Cluster
Version: v1alpha1

Determines the state and parameters for applying a specific release (version) of the Deckhouse Platform (DP) in the cluster.

DeckhouseRelease objects are automatically created by DP upon the discovery of new DP versions on the selected release channel. Modifying DeckhouseRelease enables the management of the process for applying the corresponding DP version. More details about configuring DP updates can be found in the documentation.

The current versions of DP and modules by release channels can be found at releases.deckhouse.ru.

- **approved**
  boolean

  Allows or disables manual updates.

  Used only if the `deckhouse` module is configured for manual update mode (update.mode parameter is set to `Manual`). Ignored if the update mode is set to `Auto` or `AutoPatch`.

  For more information on confirming manual updates, refer to the documentation.

  Default: `false`

- **spec**
  object

  Required value

    - **spec.applyAfter**
      string

      Marks release as a part of canary-release. This release will be delayed until the specified time. If the release is waiting to be applied, check `.status.message` for the reason.

    - **spec.changelog**
      object

      A structure containing a list of DP changes (and modules included in the DP) of the release.

      For more information about DP release changelogs, refer to Updating.

    - **spec.changelogLink**
      string

      Link to site with full changelog for this release.

    - **spec.disruptions**
      Deprecated
      array of strings

      Disruptive changes in the release.

    - **spec.requirements**
      object

      A structure containing a list of requirements for installing the release. It is used by the DP core. If the requirements are not met, the release may be skipped or blocked from installation.

      Reports on unmet requirements can be found in the field `.status.message` of the DeckhouseRelease object.

    - **spec.version**
      string

      Required value

      DP version.

      Example:

      ```
      version: v1.73.2
      ```

- **status**

object
- **status.approved**
  boolean

  The status of the release's readiness for deployment. It makes sense only for Manual updates (`update.mode: Manual`).
- **status.message**
  string

  Detailed status or error message.
- **status.phase**
  string

  Current status of the release.

  Allowed values: `Pending`, `Deployed`, `Outdated`, `Suspended`, `Superseded`, `Skipped`
- **status.transitionTime**
  string

  Time of release status change.

InitConfiguration

Version: deckhouse.io/v1

Deckhouse configuration to start after installation.

Example:

```
apiVersion: deckhouse.io/v1
kind: InitConfiguration
deckhouse:
  imagesRepo: nexus.company.my/deckhouse/ee
  registryDockerCfg:
eyJhdXRocyI6IHsgIm5leHVzLmNvbXBhbnkubXkiOiB7InVzZXJuYW1lIjoibmV4dXMtdXNlciIsInBhc3N3b3JkIjoibmV4dX
MtcEBzc3cwcmQiLCJhdXRoIjoiYm1WNGRYTXRkWE5sY2pwdVpYaDFjeTF3UUhOemR6QnlaQW89In19fQo=
  registryScheme: HTTPS
  registryCA: |
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----
```

- **apiVersion**
  string

  Required value

  Version of the Deckhouse API.

  Allowed values: `deckhouse.io/v1`, `deckhouse.io/v1alpha1`
- **deckhouse**
  Deprecated
  object

  Required value

  Initial parameters required to install Deckhouse.
  - **deckhouse.devBranch**
    Deprecated
    string

    The parameter is used for development needs. Will be replaced with the CLI-tools.
  - **deckhouse.imagesRepo**
    string

    Address of a container registry with Deckhouse images.

    Specify it if Deckhouse Enterprise Edition edition or third-party registry (e.g. proxy server in a closed environment) is used.

    The address matches the edition of Deckhouse used. The public container registry address for Deckhouse Enterprise Edition is `registry.deckhouse.io/deckhouse/ee`.

    Default: `registry.deckhouse.io/deckhouse/ce`

    Pattern: `^[0-9a-zA-Z\.\-]+(\:[0-9]{1,5})?(\/[0-9a-zA-Z\.\-\_\/]+)?$`
  - **deckhouse.registryCA**
    string

    Root CA certificate to validate the container registry's HTTPS certificate (if self-signed certificates are used).

  - **deckhouse.registryDockerCfg**
    string

    A Base64-encoded string from the Docker client configuration file (in Linux it is usually `$HOME/.docker/config.json`), for accessing a third-party container registry.

    For example, to access the container registry `registry.company.my` under the user `username` with the password `password` it will be `eyJhdXRocyI6eyJyZWdpc3RyeS5jb21wYW55Lm15Ijp7ImF1dGgiOiJkWE5sY201aGJXVTZjR0Z6YzNkdmNtUT0ifX19Cg==` (string `{"auths":{"registry.company.my":{"auth":"dXNlcm5hbWU6cGFzc3dvcmQ="}}}` in Base64).

    Default:

    Example:

    ```
    registryDockerCfg: eyJhdXRocyI6IHsgInJlZ2lzdHJ5LmRlY2tob3VzZS5pbyI6IHt9fX0=
    ```

  - **deckhouse.registryScheme**
    string

    Registry access scheme (HTTP or HTTPS).

    Default: `HTTPS`

    Allowed values: `HTTP`, `HTTPS`

- **kind**
  string

  Required value

  Allowed values: `InitConfiguration`

Module

Scope: Cluster

- v1beta1
- v1alpha1

Module represents a module instance managed via the package system.

- **spec**
  object

  Required value

  Spec defines the behavior of a Module.

  - **spec.enabled**
    boolean

    Enables or disables the module. Unset leaves the decision to the platform.

  - **spec.maintenance**
    string

    Defines the module maintenance mode.

    - `NoResourceReconciliation`: A mode for developing or tweaking the module.

      In this mode:

      - Configuration or hook changes are not reconciled, which prevents resources from being updated automatically.
      - Resource monitoring is disabled, which prevents deleted resources from being restored.
      - All the module's resources are labeled with `maintenance.deckhouse.io/no-resource-reconciliation`.
      - The `ModuleIsInMaintenanceMode` alert is triggered.

    Allowed values: `NoResourceReconciliation`

  - **spec.packageRepositoryName**
    string

    Name of the repository where the package is located. If not specified, the default repository is used.

    Example:

    ```
    packageRepositoryName: deckhouse
    ```

  - **spec.packageVersion**
    string

    Required value

    Version of the module package to install.

    Example:

```
packageVersion: v1.0.0
```

- **spec.releaseChannel**
  string

  Release channel for the module package.

- **spec.settings**
  object

  Configuration settings for the module.

- **spec.settingsVersion**
  number

  Version of the settings schema. Distinct from packageVersion, which selects the module package.

- **spec.update**
  object

  Module update settings: update mode, update windows, and blocking updates when alerts are present.

  If this parameter is not specified, the Deckhouse Platform update settings are applied.

  Example:

```
update:
  mode: Auto
  windows:
  - from: '8:00'
    to: '15:00'
    days:
    - Tue
    - Sat
  blockOnAlerts:
    enabled: true
    severity: 2
```

  - **spec.update.blockOnAlerts**
    object

    Settings for blocking module updates while there are alerts in the cluster.

    - **spec.update.blockOnAlerts.enabled**
      boolean

      Indicates whether to block module updates when the cluster has alerts with a severity level equal to or higher than the value specified in the `severity` parameter.

    - **spec.update.blockOnAlerts.severity**
      integer

      Alert severity level at which updates are blocked.

      Set as a value from `0` to `9`, where `0` is the highest severity and `9` is the lowest.

      Default: `4`

      Allowed values: `0 <= X <= 9`

  - **spec.update.mode**
    string

    Update mode of the module on its release channel.

    - `AutoPatch`: Automatic update mode for patch versions.

      To change a minor version (for example, from `v1.2.*` to `v1.3.*`), confirmation is required.

      A patch version update (for example, from `v1.3.1` to `v1.3.2`) is applied taking into account the update windows, if they are set.

    - `Auto`: Automatic update mode for all versions.

      Minor version updates (for example, from `v1.2.*` to `v1.3.*`) and patch version updates (for example, from `v1.3.1` to `v1.3.2`) are applied taking into account the update windows, if they are set.

    - `Manual`: Manual update mode for all versions.

      Confirmation is required for updating both minor and patch versions.

    Default: `AutoPatch`

    Allowed values: `AutoPatch`, `Auto`, `Manual`

    Examples:

```
mode: AutoPatch
```

```
mode: Auto
```

```
mode: Manual
```

- **spec.update.windows**
  array of objects

  List of module update windows.

  Time interval during the day when module updates are allowed.

  - **spec.update.windows.days**
    array of strings

    Days of the week on which the update window is applied.

    If the parameter is omitted, the update window is applied every day.

    - **Element of the array**
      string

      Allowed values: `Mon`, `Tue`, `Wed`, `Thu`, `Fri`, `Sat`, `Sun`

  - **spec.update.windows.from**
    string

    Required value

    Start time of the update window (UTC timezone).

    Should be earlier than the end time of the update window.

    Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

    Example:

    ```
    from: '13:00'
    ```

  - **spec.update.windows.to**
    string

    Required value

    End time of the update window (UTC timezone).

    Should be later than the start time of the update window.

    Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

    Example:

    ```
    to: '18:30'
    ```

- **status**
  object

  Status of a Module.

  - **status.conditions**
    array of objects

    Conditions reflecting the latest observations of the module state.

    Condition contains details for one aspect of the current state of this API Resource.

    - **status.conditions.lastTransitionTime**
      string

      Required value

      lastTransitionTime is the last time the condition transitioned from one status to another. This should be when the underlying condition changed. If that is not known, then using the time when the API field changed is acceptable.

    - **status.conditions.message**
      string

      Required value

      message is a human readable message indicating details about the transition. This may be an empty string.

      Maximum length: `32768`

    - **status.conditions.observedGeneration**

integer

observedGeneration represents the .metadata.generation that the condition was set based upon. For instance, if .metadata.generation is currently 12, but the .status.conditions[x].observedGeneration is 9, the condition is out of date with respect to the current state of the instance.

Allowed values: `0 <= X`

- **status.conditions.reason**
  string

  Required value

  reason contains a programmatic identifier indicating the reason for the condition's last transition. Producers of specific condition types may define expected values and meanings for this field, and whether the values are considered a guaranteed API. The value should be a CamelCase string. This field may not be empty.

  Pattern: `^[A-Za-z]([A-Za-z0-9_,:]*[A-Za-z0-9_])?$`

  Length: `1..1024`

- **status.conditions.status**
  string

  Required value

  status of the condition, one of True, False, Unknown.

  Allowed values: `True`, `False`, `Unknown`

- **status.conditions.type**
  string

  Required value

  type of condition in CamelCase or in foo.example.com/CamelCase.

  Pattern: `^([a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*/)?(([A-Za-z0-9][-A-Za-z0-9_.]*)?[A-Za-z0-9])$`

  Maximum length: `316`

- **status.currentVersion**
  object

  Information about the currently installed version.

  - **status.currentVersion.channel**
    string

    Release channel from which the version was installed.

  - **status.currentVersion.version**
    string

    Semantic version of the installed module.

- **status.enabled**
  boolean

  Reports whether the module is enabled: `spec.enabled` resolved against the edition bundle, the enabled-script and the module dependencies. It can differ from `spec.enabled` — an explicitly enabled module stays disabled while a module it requires is disabled. Absent until the first decision.

- **status.lastAppliedConfiguration**
  object

  LastAppliedConfiguration is the effective settings (user configuration merged with config-schema defaults) that drove the most recent successful apply.

- **status.summary**
  object

  Summary aggregates the high-level user-facing state, message and resolution hint for the module. The controller always populates it on reconcile — every module maps to exactly one lifecycle state — so it is the single source of truth for the UI; clients should not re-derive these values from the conditions. The pointer leaves it absent only before the first status computation.

  - **status.summary.message**
    string

    Message is a human-readable description of the current state.

  - **status.summary.state**
    string

    State is the high-level lifecycle state observed for the module. Always one of: Pending, Failed, Updating, Configuring, Ready, Degraded, Suspended, Deleting.

    Examples:

```
state: Pending
```

```
state: Failed
```

```
state: Updating
```

```
state: Configuring
```

```
state: Ready
```

```
state: Degraded
```

```
state: Suspended
```

```
state: Deleting
```

- **status.summary.tip**
  string

  Tip is a human-readable instruction on how to resolve the current state. Empty when no action is required.

- **status.tracking**
  object

  Nelm tracking.

Describes the module's status in the cluster. The `Module` object is created automatically after configuring the ModuleSource and successfully completing synchronization.

- **properties**
  object
  - **properties.accessibility**
    object

    Module accessibility settings.

    - **properties.accessibility.editions**
      object

      Module operation settings in Deckhouse editions.

      - **properties.accessibility.editions.<KEY_NAME>**
        object

        `<KEY_NAME>` — item (key) name.

        - **properties.accessibility.editions.<KEY_NAME>.available**
          boolean
        - **properties.accessibility.editions.<KEY_NAME>.enabledInBundles**
          array of strings
  - **properties.availableSources**
    array of strings

    Available sources for downloading the module.

  - **properties.critical**
    boolean

    Indicates whether the module critical or not.

  - **properties.disableOptions**
    object

    Parameters of module disable protection.

    - **properties.disableOptions.confirmation**
      boolean
    - **properties.disableOptions.message**
      string

      Deprecated: use Messages with localized ru/en fields instead.

    - **properties.disableOptions.messages**
      object

      Warning messages displayed when disabling the module, localized for different languages. If a message for the selected language is not defined, the value of the `message` field is used instead.

      - **properties.disableOptions.messages.en**
        string
      - **properties.disableOptions.messages.ru**

string
- **properties.exclusiveGroup**
  string

  Indicates the group where only one module can be active at a time.
- **properties.namespace**
  string

  Module namespace.
- **properties.releaseChannel**
  string

  Module release channel.
- **properties.requirements**
  object

  Module dependencies, a set of requirements that must be met for Deckhouse Kubernetes Platform (DKP) to run the module.
  - **properties.requirements.bootstrapped**
    string

    Required cluster installation status (for built-in DKP modules only).
  - **properties.requirements.deckhouse**
    string

    Required Deckhouse version.
  - **properties.requirements.kubernetes**
    string

    Required Kubernetes version.
  - **properties.requirements.modules**
    object

    A list of other enabled modules required for the module.
- **properties.source**
  string

  Source the module was downloaded from (otherwise will be blank).
- **properties.stage**
  string

  Current stage of the module lifecycle.
- **properties.subsystems**
  array of strings

  Module subsystems.
- **properties.updatePolicy**
  string

  Module update policy.
- **properties.version**
  string

  Module version.
- **properties.weight**
  integer

  Module *weight* (priority).

- **spec**
  object
- **status**
  object
  - **status.conditions**
    array of objects
    - **status.conditions.lastProbeTime**
      string
    - **status.conditions.lastTransitionTime**
      string
    - **status.conditions.message**
      string
    - **status.conditions.reason**
      string
    - **status.conditions.status**
      string
    - **status.conditions.type**
      string

- **status.hooksState**
  string

  Hooks status report.

- **status.phase**
  string

  Module phase.

  Allowed values: `Unavailable`, `Available`, `Downloading`, `DownloadingError`, `Reconciling`, `Installing`, `HooksDisabled`, `WaitSyncTasks`, `Downloaded`, `Conflict`, `Ready`, `Error`

  Examples:

  ```
  phase: Unavailable
  ```

  ```
  phase: Available
  ```

  ```
  phase: Downloading
  ```

  ```
  phase: DownloadingError
  ```

  ```
  phase: Reconciling
  ```

  ```
  phase: Installing
  ```

  ```
  phase: HooksDisabled
  ```

  ```
  phase: WaitSyncTasks
  ```

  ```
  phase: Downloaded
  ```

  ```
  phase: Conflict
  ```

  ```
  phase: Ready
  ```

  ```
  phase: Error
  ```

ModuleConfig

Short names: mc

Scope: Cluster
Version: v1alpha1

Defines the configuration of the Deckhouse Platform module (module parameters). The name of the ModuleConfig resource must match the name of the module (for example, `control-plane-manager` for the `control-plane-manager` module).

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: module-1
spec:
  enabled: true
  settings: {}
  version: 1
```

- **spec**
  object

  Required value

  - **spec.enabled**
    boolean

    Enables or disables the module.

    Example:

```
enabled: false
```

- **spec.maintenance**
  string

  Defines the module maintenance mode.

  - `NoResourceReconciliation`: A mode for developing or tweaking the module.

    In this mode:

    - Configuration or hook changes are not reconciled, which prevents resources from being updated automatically.
    - Resource monitoring is disabled, which prevents deleted resources from being restored.
    - All the module's resources are labeled with `maintenance: NoResourceReconciliation`.
    - The `ModuleIsInMaintenanceMode` alert is triggered.

  Allowed values: `NoResourceReconciliation`

  Example:

  ```
  maintenance: NoResourceReconciliation
  ```

- **spec.settings**
  object

  Module settings.

- **spec.source**
  string

  The source of the module it provided by one (otherwise empty).

- **spec.updatePolicy**
  string

  Module update policy.

  Example:

  ```
  updatePolicy: test-alpha
  ```

- **spec.version**
  number

  Version of settings schema.

  Example:

  ```
  version: 1
  ```

- **status**
  object
  - **status.message**
    string

    Additional information

  - **status.version**
    string

    Version of settings schema in use

ModulePullOverride

Short names: mpo

Scope: Cluster

- v1alpha2
- v1alpha1

Defines the resource configuration for downloading specific versions of Deckhouse modules.

> **Caution**. This resource is intended for development and debugging environments only. Using it in production clusters is not recommended. Support for the resource might be removed in future Deckhouse Platform versions.

- **spec**
  object

  Required value

  - **spec.imageTag**
    string

Required value

Module container image tag, which will be pulled.

- **spec.rollback**
  boolean

  Indicates whether the module release should be rollback after deleting mpo.

  Default: `false`

- **spec.scanInterval**
  string

  Scan interval for checking the image digest. If the digest changes, the module is updated. Supported units: `h`, `m`, `s`.

  Default: `15s`

  Pattern: `^(\d+h)?(\d+m)?(\d+s)?$`

- **status**
  object
  - **status.imageDigest**
    string

    Digest of the module image.

  - **status.message**
    string

    Details of the resource status.

  - **status.updatedAt**
    string

    When the module was last updated.

  - **status.weight**
    integer

    Module weight.

Deprecated resource. Support for the resource might be removed in a later release.

Defines the configuration.

- **spec**
  object

  Required value

  - **spec.imageTag**
    string

    Required value

    Module container image tag, which will be pulled.

  - **spec.rollback**
    boolean

    Indicates whether the module release should be rollback after deleting ModulePullOverride.

    Default: `false`

  - **spec.scanInterval**
    string

    Scan interval for checking the image digest. If the digest changes, the module is updated. Supported units: `h`, `m`, `s`.

    Default: `15s`

    Pattern: `^(\d+h)?(\d+m)?(\d+s)?$`

  - **spec.source**
    string

    Required value

    Reference to the ModuleSource with the module.

- **status**
  object
  - **status.imageDigest**
    string

    Digest of the module image.

  - **status.message**
    string

Details of the resource status.

- **status.updatedAt**
  string

  When the module was last updated.

- **status.weight**
  integer

  Module weight.

ModuleRelease

Short names: mr

Scope: Cluster
Version: v1alpha1

Defines the configuration for a Deckhouse release.

ModuleRelease resources are created by Deckhouse.

- **spec**
  object

  Required value

  - **spec.applyAfter**
    string

    Time until which the release will be delayed.

  - **spec.changelog**
    object

    Release's changelog for the module.

  - **spec.moduleName**
    string

    Required value

    Module name.

  - **spec.requirements**
    object

    Release dependencies, a set of requirements that must be met for Deckhouse Platform to run the module release.

    - **spec.requirements.deckhouse**
      string

      Required Deckhouse version.

    - **spec.requirements.kubernetes**
      string

      Required Kubernetes version.

    - **spec.requirements.modules**
      object

      A list of other modules required for the module release. Ensure the modules are enabled.

  - **spec.update**
    object

    Optional transition rules.

    - **spec.update.versions**
      array of objects

      List of `from` → `to` transition rules that allow skipping step-by-step updates. If the current installed module version (status `Deployed`) is not lower than `from`, and the cluster has a release whose version matches `to`, the controller will skip intermediate releases and update the module to the version from `to`. The `to` value can specify a minor line (`X.Y` — the latest available `X.Y.Z` will be selected). The rule is specified in the constrained release — the one whose version matches `to`.

      - **spec.update.versions.from**
        string

        Required value

        The minimum version from which the transition is allowed (format `X.Y`).

      - **spec.update.versions.to**
        string

        Required value

The end version of the range — a minor line (`X.Y`).

- **spec.version**
  string

  Required value

  Module version.

  Example:

  ```
  version: v1.0.0
  ```

- **spec.weight**
  integer

  Module *weight* (priority).

- **status**
  object
  - **status.approved**
    boolean

    Status indicating that the release is ready for deployment. For the Manual update mode only (`update.mode: Manual`).

  - **status.message**
    string

    Detailed status or error message.

  - **status.phase**
    string

    Current status of the release.

    Allowed values: `Pending` , `Deployed` , `Superseded` , `Suspended` , `Skipped` , `Terminating`

  - **status.pullDuration**
    string

    Module loading duration.

  - **status.size**
    integer

    Size of the module image.

  - **status.transitionTime**
    string

    Time of release status change.

ModuleSettingsDefinition

Scope: Cluster
Version: v1alpha1

It displays module settings. Defines a list of module settings versions.

- **spec**
  object

  Required value

  Specification of the module settings.

  - **spec.versions**
    array of objects

    List of module settings versions. Each version includes a name and a schema.

    - **spec.versions.conversions**
      array of objects

      List of conversion rules for this version.

      A single conversion rule with expressions and descriptions.

      - **spec.versions.conversions.descriptions**
        object

        Localized descriptions of the conversion.

        - **spec.versions.conversions.descriptions.en**
          string

          English description of the conversion.

        - **spec.versions.conversions.descriptions.ru**

string

Russian description of the conversion.

- **spec.versions.conversions.expr**
  array of strings

  Array of jq expressions to transform settings.

- **spec.versions.name**
  string

  Required value

  Module settings version.

- **spec.versions.schema**
  object

  Settings schema for the given module version.

ModuleSource

Short names: ms

Scope: Cluster
Version: v1alpha1

Defines the configuration of a source of Deckhouse modules.

For more information about installing the module from the source, see the section “Running the module in the DP cluster”.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleSource
metadata:
  name: example
spec:
  registry:
    repo: registry.example.io/modules-source
    dockerCfg: "<base64 encoded credentials>"
```

- **spec**
  object

  Required value

  - **spec.registry**
    object

    Required value

    - **spec.registry.ca**
      string

      Root CA certificate (PEM format) to validate the registry’s HTTPS certificate (if self-signed certificates are used).

      > **i** Creating a ModuleSource resource with the CA certificate spec will cause the container to restart on all nodes.

    - **spec.registry.dockerCfg**
      string

      Container registry access token in Base64. If using anonymous access to the container registry, do not fill in this field.

    - **spec.registry.repo**
      string

      Required value

      URL of the container registry.

      Example:

      ```
      repo: registry.example.io/deckhouse/modules
      ```

    - **spec.registry.scheme**
      string

      Protocol to access the registry.

Default: `HTTPS`

Allowed values: `HTTP`, `HTTPS`

- **spec.releaseChannel**
  Deprecated
  string

  Desirable default release channel for modules in the current source.

- **spec.scanInterval**
  string

  Interval for registry scan.

  Defines the frequency of checking the container registry for new modules and their versions.

  Defaults to 30 minutes. Explicit intervals shorter than 3 minutes are rounded up to 3 minutes.

  Default: `30m`

  Pattern: `^(\d+h)?(\d+m)?(\d+s)?$`

  Examples:

  ```
  scanInterval: 5m
  ```

  ```
  scanInterval: 1h
  ```

  ```
  scanInterval: 6h30m
  ```

- **status**
  object
  - **status.message**
    string
  - **status.modules**
    array of objects

    The list of modules available from the source and their update policies.

    - **status.modules.checksum**
      string

      The module checksum.

    - **status.modules.error**
      string

      The module processing error.

    - **status.modules.name**
      string

      The module name.

    - **status.modules.overridden**
      boolean

      If ModulePullOverride for this module exists.

    - **status.modules.policy**
      string

      The module policy name.

    - **status.modules.pullError**
      string

      The module pull error.

    - **status.modules.version**
      string

      The module version.

  - **status.modulesCount**
    integer

    The number of modules available.

  - **status.phase**
    string

    The current phase.

    Allowed values: `Active`, `Terminating`

  - **status.syncTime**
    string

When the repository was synchronized.

ModuleUpdatePolicy

Short names: mup

Scope: Cluster

- v1alpha2
- v1alpha1

Defines the update settings for a module's release.

Example:

```
apiVersion: deckhouse.io/v1alpha2
kind: ModuleUpdatePolicy
metadata:
  name: example-update-policy
spec:
  releaseChannel: Alpha
  update:
    mode: Auto
    windows:
    - days:
      - Mon
      - Wed
      from: '13:30'
      to: '14:00'
```

- **spec**
  object

  Required value

  - **spec.releaseChannel**
    string

    Desirable module release channel.

    The order in which the stability of the release channel increases (from **less** stable to **more** stable): `Alpha`, `Beta`, `EarlyAccess`, `Stable`, `RockSolid`.

    Default: `Stable`

    Allowed values: `Alpha`, `Beta`, `EarlyAccess`, `Stable`, `RockSolid`, `Lts`

  - **spec.update**
    object

    Required value

    Update settings for target modules.

    - **spec.update.mode**
      string

      Modules version update mode (release change).

      - `AutoPatch` — automatic update mode for patch releases.

        To change a minor version (for example, from `v1.15.*` to `v1.16.*`), confirmation is required.

        A patch version update (for example, from `v1.16.1` to `v1.16.2`) is applied according to the update windows, if they are set.

      - `Auto` — all updates are applied automatically.

        Modules minor version updates (for example, from `v1.15.*` to `v1.16.*`) and patch version updates (for example, from `v1.16.1` to `v1.16.2`) are applied according to the update windows or (if no update windows are set) as they appear on the corresponding release channel;

      - `Manual` — confirmation is required for updating both minor and patch versions.

      To confirm the update, add the `modules.deckhouse.io/approved="true"` annotation to the corresponding ModuleRelease resource.

      Default: `Auto`

      Allowed values: `Auto`, `Manual`, `AutoPatch`

    - **spec.update.windows**
      array of objects

      Modules update timetable.

      - **spec.update.windows.days**

array of strings

The days of the week on which the update window is applied.

Examples:

```
days: Mon
```

```
days: Wed
```

- **Element of the array**
  string

  Day of the week.

  Allowed values: `Mon`, `Tue`, `Wed`, `Thu`, `Fri`, `Sat`, `Sun`

  Example:

  ```
  Mon
  ```

- **spec.update.windows.from**
  string

  Required value

  Start time of the update window (UTC timezone).

  Should be less than the end time of the update window.

  Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

  Example:

  ```
  from: '13:00'
  ```

- **spec.update.windows.to**
  string

  Required value

  End time of the update window (UTC timezone).

  Should be more than the start time of the update window.

  Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

  Example:

  ```
  to: '18:30'
  ```

Deprecated resource. Support for the resource might be removed in a later release.

Defines the update settings for a module's release.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: ModuleUpdatePolicy
metadata:
  name: example-update-policy
spec:
  moduleReleaseSelector:
    labelSelector:
      matchLabels:
        source: example
        module: module-1
  releaseChannel: Alpha
  update:
    mode: Auto
    windows:
    - days:
      - Mon
      - Wed
      from: '13:30'
      to: '14:00'
```

- **spec**
  object

Required value

- **spec.moduleReleaseSelector**
  object

  Required value

  Selects target modules to apply update settings to.

  - **spec.moduleReleaseSelector.labelSelector**
    object

    Required value

    Label-selector-based filter to match target modules.

    If both `matchExpressions` and `matchLabels` parameters are set, their requirements are ANDed together — they must all be satisfied in order to match. If multiple `matchExpression` conditions are provided, they all must be satisfied in order to match.

    - **spec.moduleReleaseSelector.labelSelector.matchExpressions**
      array of objects

      An array of set-based expressions.

      - **spec.moduleReleaseSelector.labelSelector.matchExpressions.key**
        string

        Required value

        A label name.

      - **spec.moduleReleaseSelector.labelSelector.matchExpressions.operator**
        string

        Required value

        A comparison operator.

        Allowed values: `In`, `NotIn`, `Exists`, `DoesNotExist`

      - **spec.moduleReleaseSelector.labelSelector.matchExpressions.values**
        array of strings

        A label value.

    - **spec.moduleReleaseSelector.labelSelector.matchLabels**
      object

      A number of equality-based label filters.

      Example:

      ```
      matchLabels:
        source: deckhouse
        module: deckhouse-admin
      ```

- **spec.releaseChannel**
  string

  Desirable module release channel.

  The order in which the stability of the release channel increases (from **less** stable to **more** stable): `Alpha`, `Beta`, `EarlyAccess`, `Stable`, `RockSolid`.

  Default: `Stable`

  Allowed values: `Alpha`, `Beta`, `EarlyAccess`, `Stable`, `RockSolid`

- **spec.update**
  object

  Required value

  Update settings for target modules.

  - **spec.update.mode**
    string

    Modules version update mode (release change).

    - `AutoPatch` — automatic update mode for patch releases.

      To change a minor version (for example, from `v1.15.*` to `v1.16.*`), confirmation is required.

      A patch version update (for example, from `v1.16.1` to `v1.16.2`) is applied according to the update windows, if they are set.

    - `Auto` — all updates are applied automatically.

      Modules minor version updates (for example, from `v1.15.*` to `v1.16.*`) and patch version

updates (for example, from `v1.16.1` to `v1.16.2`) are applied according to the update windows or (if no update windows are set) as they appear on the corresponding release channel;

- `Manual` — confirmation is required for updating both minor and patch versions.

To confirm the update, add the `modules.deckhouse.io/approved="true"` annotation to the corresponding ModuleRelease resource.

- `Ignore` — updates are ignored.

Default: `AutoPatch`

Allowed values: `Auto`, `Manual`, `Ignore`, `AutoPatch`

- **spec.update.windows**
  array of objects

  Modules update timetable.

  - **spec.update.windows.days**
    array of strings

    The days of the week on which the update window is applied.

    Examples:

    ```
    days: Mon
    ```

    ```
    days: Wed
    ```

    - **Element of the array**
      string

      Day of the week.

      Allowed values: `Mon`, `Tue`, `Wed`, `Thu`, `Fri`, `Sat`, `Sun`

      Example:

      ```
      Mon
      ```

  - **spec.update.windows.from**
    string

    Required value

    Start time of the update window (UTC timezone).

    Should be less than the end time of the update window.

    Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

    Example:

    ```
    from: '13:00'
    ```

  - **spec.update.windows.to**
    string

    Required value

    End time of the update window (UTC timezone).

    Should be more than the start time of the update window.

    Pattern: `^(?:\d|[01]\d|2[0-3]):[0-5]\d$`

    Example:

    ```
    to: '18:30'
    ```

PackageRepository

Scope: Cluster
Version: v1alpha1

PackageRepository defines a package repository available in Deckhouse Platform.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: PackageRepository
metadata:
  name: example
spec:
  registry:
    ca: "<PEM-encoded CA certificate>"
    dockerCfg: "<base64 encoded credentials>"
    login: admin
    password: "<password>"
    repo: registry.example.io/packages
    scheme: https
  scanInterval: 5m
```

- **spec**
  object

  Required value

  Package repository configuration.

  - **spec.registry**
    object

    Required value

    Access parameters for the container registry where the package repository is located.

    - **spec.registry.ca**
      string

      Root certificate in PEM format used to verify the TLS certificate of the container registry when connecting over HTTPS.

      Used if the registry uses self-signed SSL certificates.

      Example:

      ```
      ca: "<PEM-encoded CA certificate>"
      ```

    - **spec.registry.dockerCfg**
      string

      Container registry access configuration in `~/.docker/config.json` format, encoded in Base64.

      Leave this field empty for anonymous access.

      Example:

      ```
      dockerCfg: "<base64 encoded credentials>"
      ```

    - **spec.registry.login**
      string

      Username for authenticating to the container registry.

      Example:

      ```
      login: admin
      ```

    - **spec.registry.password**
      string

      Password for authenticating to the container registry.

      Example:

      ```
      password: "<password>"
      ```

    - **spec.registry.repo**
      string

      Required value

      Address of the package repository in the container registry.

      Example:

      ```
      repo: registry.example.io/packages
      ```

    - **spec.registry.scheme**
      string

Protocol used to access the package repository, for example, `https`.

Example:

```
scheme: https
```

- **spec.scanInterval**
  string

  Interval between automatic scans of the package repository for discovering new packages and versions.

  Default: `6h`

  Pattern: `^(\d+h)?(\d+m)?(\d+s)?$`

  Examples:

  ```
  scanInterval: 5m
  ```

  ```
  scanInterval: 1h
  ```

  ```
  scanInterval: 6h30m
  ```

- **status**
  object

  Current state of the package repository.

  - **status.conditions**
    array of objects

    Conditions reflecting the current state of the package repository.

    Condition reflecting an aspect of the current state of the package repository.

    - **status.conditions.lastTransitionTime**
      string

      Required value

      Time when the condition status last changed.

    - **status.conditions.message**
      string

      Required value

      Message with additional information about the condition.

      May be empty.

      Maximum length: `32768`

    - **status.conditions.observedGeneration**
      integer

      Value of `.metadata.generation` for which the condition was set.

      Indicates whether the condition corresponds to the current generation of the instance.

      Allowed values: `0 <= X`

    - **status.conditions.reason**
      string

      Required value

      Programmatic identifier indicating the reason for the last condition status change.

      Pattern: `^[A-Za-z]([A-Za-z0-9_,:]*[A-Za-z0-9_])?$`

      Length: `1..1024`

    - **status.conditions.status**
      string

      Required value

      Condition status.

      Allowed values: `True`, `False`, `Unknown`

    - **status.conditions.type**
      string

      Required value

      Condition type in CamelCase or in the format `foo.example.com/CamelCase`.

Pattern: `^([a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*/)?(([A-Za-z0-9][-A-Za-z0-9_.]*)?[A-Za-z0-9])$`

Maximum length: `316`

- **status.lastChangeTime**
  string

  Time of the last scan that discovered at least one new package version.

  If no new versions are discovered, the value is not updated.

- **status.lastNewVersions**
  integer

  Number of new package versions discovered during the last scan.

  Equals `0` if no new versions were discovered.

- **status.lastScanTime**
  string

  Time of the last successfully completed scan.

  If a scan fails, the value is not updated, and the error is reflected in the `LastScanSucceeded` condition.

- **status.message**
  string

  Message with additional information about the state of the package repository.

- **status.packages**
  array of objects

  List of packages available in the repository.

  - **status.packages.name**
    string

    Required value

    Package name.

  - **status.packages.type**
    string

    Required value

    Package type.

- **status.packagesCount**
  integer

  Total number of packages in the repository.

- **status.phase**
  string

  Current phase of the repository.

PackageRepositoryOperation

Short names: pro

Scope: Cluster
Version: v1alpha1

PackageRepositoryOperation represents an operation for scanning or updating a package repository.

Example:

```
apiVersion: deckhouse.io/v1alpha1
kind: PackageRepositoryOperation
metadata:
  name: example
spec:
  packageRepositoryName: deckhouse
  type: Update
  update:
    fullScan: false
    timeout: 5m
```

- **spec**
  object

  Required value

  Package repository operation parameters.

- **spec.packageRepositoryName**
  string

  Required value

  Name of the package repository for which the operation is performed.

  Example:

  ```
  packageRepositoryName: deckhouse
  ```

- **spec.type**
  string

  Required value

  Operation type.

  Allowed values: `Update`

- **spec.update**
  object

  Update operation parameters.

  - **spec.update.fullScan**
    boolean

    Indicates whether to perform a full scan of the package repository.

  - **spec.update.timeout**
    string

    Operation timeout.

    Example:

    ```
    timeout: 5m
    ```

- **status**
  object

  Current state of the package repository operation.

  - **status.completionTime**
    string

    Time when the operation completed.

  - **status.conditions**
    array of objects

    Conditions reflecting the current state of the operation.

    The operation phase is determined by the `Completed` condition: while its status is `False`, the operation is in one of the intermediate phases (`Discover` or `Processing`). A `True` status indicates that the operation has completed with the `ScanSucceeded` or `ScanFailed` reason.

    Condition reflecting an aspect of the current state of the operation.

    - **status.conditions.lastTransitionTime**
      string

      Required value

      Time when the condition status last changed.

    - **status.conditions.message**
      string

      Required value

      Message with additional information about the condition.

      Maximum length: `32768`

    - **status.conditions.observedGeneration**
      integer

      Value of `.metadata.generation` for which the condition was set.

      Indicates whether the condition corresponds to the current generation of the instance.

      Allowed values: `0 <= X`

    - **status.conditions.reason**
      string

      Required value

Programmatic identifier indicating the reason for the last condition status change.

For the `Completed` condition, possible values are `Discover`, `Processing`, `ScanSucceeded`, and `ScanFailed`.

Pattern: `^[A-Za-z]([A-Za-z0-9_,:]*[A-Za-z0-9_])?$`

Length: `1..1024`

Examples:

```
reason: Discover
```

```
reason: Processing
```

```
reason: Succeeded
```

```
reason: Failed
```

- **status.conditions.status**
  string

  Required value

  Condition status.

  Allowed values: `True`, `False`, `Unknown`

- **status.conditions.type**
  string

  Required value

  Condition type in CamelCase or in the format `foo.example.com/CamelCase`.

  This resource uses the `Completed` condition, which indicates whether the operation has completed.

  Pattern: `^([a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*/)?(([A-Za-z0-9][-A-Za-z0-9_.]*)?[A-Za-z0-9])$`

  Maximum length: `316`

- **status.packages**
  object

  Information about packages processed during the operation.

  - **status.packages.discovered**
    array of objects

    Packages discovered during the operation and awaiting processing.

    The list is empty after the operation completes.

    - **status.packages.discovered.name**
      string

      Required value

      Name of the discovered package.

  - **status.packages.failed**
    array of objects

    Packages that could not be processed.

    - **status.packages.failed.errors**
      array of objects

      Required value

      Errors that occurred while processing the package.

      - **status.packages.failed.errors.message**
        string

        Required value

        Error message.

      - **status.packages.failed.errors.version**
        string

        Required value

        Package version for which the error occurred.

    - **status.packages.failed.name**

string

Required value

Name of the package that could not be processed.

- **status.packages.newVersionsOverall**
  integer

  Total number of new package versions discovered during the operation.

  A version is considered new if the corresponding ApplicationPackageVersion or ModulePackageVersion did not exist in the cluster.

  An ApplicationPackageVersion is also considered new if it was previously marked as missing from the container registry, but its image was discovered during the current operation.

- **status.packages.processed**
  array of objects

  Successfully processed packages.

  - **status.packages.processed.foundVersions**
    integer

    Number of package versions discovered during the operation.

  - **status.packages.processed.name**
    string

    Required value

    Name of the processed package.

  - **status.packages.processed.newVersions**
    integer

    Number of new package versions discovered during the operation.

    A version is considered new if the corresponding ApplicationPackageVersion or ModulePackageVersion did not exist in the cluster.

    An ApplicationPackageVersion is also considered new if it was previously marked as missing from the container registry, but its image was discovered during the current operation.

  - **status.packages.processed.type**
    string

    Package type.

- **status.packages.processedOverall**
  integer

  Total number of processed packages.

- **status.packages.total**
  integer

  Total number of discovered packages.

- **status.startTime**
  string

  Time when the operation started.

SSHConfig

Version: dhctl.deckhouse.io/v1

General dhctl SSH config.

Example:

```
apiVersion: dhctl.deckhouse.io/v1
kind: SSHConfig
sshUser: user
sshPort: 22
sshExtraArgs: "-vvv"
sshAgentPrivateKeys:
- key: "<ssh-private-key>"
```

- **apiVersion**
  string

  Version of the Deckhouse API.

  Allowed values: `dhctl.deckhouse.io/v1`

- **kind**
  string

  Allowed values: `SSHConfig`

- **legacyMode**
  boolean

  Switch to legacy SSH mode (clissh).

- **modernMode**
  boolean

  Switch to modern SSH mode (gossh).

- **sshAgentPrivateKeys**
  array of objects
  - **sshAgentPrivateKeys.key**
    string

    Required value

    Contents of the private SSH key.

    This field does not support passing a certificate. To authenticate with a certificate in `gossh` mode, load the key together with its certificate into an ssh-agent accessible to dhctl through `SSH_AUTH_SOCK`. This method is unavailable when `legacyMode: true`.

  - **sshAgentPrivateKeys.passphrase**
    string

    Password for SSH key.

- **sshBastionHost**
  string

  SSH bastion host.

- **sshBastionPassword**
  string

  A password for the bastion user.

- **sshBastionPort**
  integer

  Port of SSH bastion.

- **sshBastionUser**
  string

  Username for bastion.

- **sshExtraArgs**
  string

  Additional arguments for SSH connection.

- **sshPort**
  integer

  SSH port.

- **sshUser**
  string

  SSH username.

- **sudoPassword**
  string

  A sudo password for the user.

SSHHost

Version: dhctl.deckhouse.io/v1

General dhctl SSH host config.

Example:

```
apiVersion: dhctl.deckhouse.io/v1
kind: SSHHost
host: 172.16.0.0
```

- **apiVersion**
  string

  Required value

Version of the Deckhouse API.

Allowed values: `dhctl.deckhouse.io/v1`

- **host**
  string

  Required value

  Host.

- **kind**
  string

  Required value

  Allowed values: `SSHHost`

StaticClusterConfiguration

Version: deckhouse.io/v1

Parameters of a static (bare metal) cluster.

To change the `StaticClusterConfiguration` resource in a running cluster, run the following command:

```
d8 system edit static-cluster-configuration
```

Example:

```
apiVersion: deckhouse.io/v1
kind: StaticClusterConfiguration
internalNetworkCIDRs:
- 10.244.0.0/16
- 10.50.0.0/16
```

- **apiVersion**
  string

  Required value

  Version of the Deckhouse API.

  Allowed values: `deckhouse.io/v1`, `deckhouse.io/v1alpha1`

- **internalNetworkCIDRs**
  array of strings

  List of internal cluster networks.

  Internal cluster networks connect Kubernetes components (`kube-apiserver`, `kubelet`, etc.).

  The parameter is mandatory in the following cases:

  - Cluster nodes have more than one network interface
  - The cluster is deployed inside a Deckhouse Virtualization Platform

  > **i** When changing the value, subnets in the new list must include IP addresses of currently joined nodes.

  Example:

  ```
  internalNetworkCIDRs:
  - 192.168.42.0/24
  - 172.16.16.0/24
  ```

  - **Element of the array**
    string

    Pattern: `^(([0-9]|[1-9][0-9]|1[0-9]{2}|2[0-4][0-9]|25[0-5])\.){3}([0-9]|[1-9][0-9]|1[0-9]{2}|2[0-4][0-9]|25[0-5])(\/(3[0-2]|[1-2][0-9]|[0-9]))$`

- **kind**
  string

  Required value

  Allowed values: `StaticClusterConfiguration`

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Release channels

> For information on which versions of Deckhouse are available on which release channels as well as the planned date of the version update for a particular release channel, visit releases.deckhouse.io website.

Clusters, as infrastructure elements, usually have to meet various requirements.

A production cluster, unlike a development one, has higher requirements for reliability. In a production cluster, frequent component updates and changes are undesirable. All the cluster components must be thoroughly tested for stable and reliable operation.

Deckhouse uses **five release channels** which you can *soft-switch* between using the deckhouse module: just specify the desired release channel in the module configuration.

- Rock Solid
- Stable
- Early Access
- Beta
- Alpha

- The least stable release channel but with the most frequent appearance of new versions. Can bring new features but can be unstable.
- For more broad testing of new features to catch regressions
- **Recommended** release channel. Is mostly safe and can be used in non-critical environments or for local development
- Is mostly safe and we encourage you to use this version everywhere
- The most stable release channel and recommended for usage in critical environments with tight SLA

Supported Kubernetes and OS versions

Linux

The following Linux distributions are currently supported for nodes:

Linux Distribution	Supported versions	Supported in redactions	Notes
		CE, BE, SE, SE+, EE	
CentOS	**7**	✓	
	8	✓	
	9	✓	
	10	✓	
Debian	**10**	✓	
	11, 12, 13	✓	
openSUSE	**15.4, 15.5, 15.6**	✓	

Linux Distribution	Supported versions	Supported in redactions	Notes
		CE, BE, SE, SE+, EE	
Rocky Linux	**8**	✓	
	9	✓	
Ubuntu	**18.04**	✓	
	20.04	✓	
	22.04, 24.04, 26.04	✓	

Kubernetes

The following Kubernetes versions are currently supported:

Version	Status
1.33	The version is not recommended for use. It is planned for removal in future releases.
1.34	Production-ready fully supported version.
1.35	**Default version.** Production-ready fully supported version.
1.36	Production-ready fully supported version.
1.37	Early access version, which is not suitable for production environments.

Container registry

i Deckhouse Platform works with any container registry supporting Basic or Bearer authentication and OCI image format specification.

Container registries that Deckhouse is guaranteed to work with
Sonatype Nexus Repository
Harbor
JFrog Artifactory
CNCF Distribution Registry (Docker Registry)
Project Quay*

i **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Kubernetes conformance test results

Deckhouse Platform is tested against the Kubernetes conformance suite of the CNCF Certified Kubernetes Conformance Program. The tests are run with Sonobuoy in `certified-conformance` mode for each Kubernetes minor version listed below.

i The conformance test results listed below are valid only when the `multitenancy-manager` module is disabled.

Test results

- Kubernetes **1.37** — Download JUnit XML report

- Kubernetes **1.36** — Download JUnit XML report
- Kubernetes **1.35** — Download JUnit XML report
- Kubernetes **1.34** — Download JUnit XML report
- Kubernetes **1.33** — Download JUnit XML report

CNCF Kubernetes conformance (Sonobuoy)

This directory stores **certified conformance** artifacts per Kubernetes minor version: `e2e.log` and `junit_01.xml` produced by Sonobuoy in `certified-conformance` mode.

Use it when you need to refresh bundled results after upgrading or validating the supported Kubernetes line.

---

1. Cluster and Deckhouse

Deploy a cluster with Deckhouse at the target Kubernetes version and ensure `kubectl` points at it.

---

2. Adjust RBAC and admission (required for a clean run)

Pod Security Standards can also block workloads that the e2e suite expects. For the run, relax **Admission Policy Engine** defaults so workloads are not constrained below what the suite needs.

Apply once (review before production clusters):

```
kubectl apply -f - <<'EOF'
apiVersion: deckhouse.io/v1alpha1
kind: ModuleConfig
metadata:
  name: admission-policy-engine
spec:
  enabled: true
  settings:
    podSecurityStandards:
      defaultPolicy: Privileged
  version: 1
EOF
```

---

3. Install Sonobuoy CLI

Download a release from Sonobuoy releases, unpack the binary, and put it on your `PATH` (or run from the unpack directory).

Example for Linux `amd64` (replace the version with the one you want):

```
curl -sL -o sonobuoy.tgz \
  'https://github.com/vmware-
tanzu/sonobuoy/releases/download/v0.57.3/sonobuoy_0.57.3_linux_amd64.tar.gz'
tar -xzf sonobuoy.tgz sonobuoy
chmod +x sonobuoy
```

---

4. Run conformance

```
./sonobuoy run --mode=certified-conformance --kubeconfig=/etc/kubernetes/super-admin.conf
```

Wait until `./sonobuoy status` reports the run as **completed**. To see progress, check that namespaces are being created and deleted (tests run in isolated namespaces).

The run typically takes **2 hours**.

---

5. Fetch only `e2e.log` and `junit_01.xml`

From the machine where the CLI runs:

```
./sonobuoy retrieve . -f sb.tar.gz
tar -xzf sb.tar.gz \
  plugins/e2e/results/global/e2e.log \
  plugins/e2e/results/global/junit_01.xml
```

You will get:

`plugins/e2e/results/global/e2e.log`

`plugins/e2e/results/global/junit_01.xml`

Optional: remove the tarball when done (`rm -f sb.tar.gz`).

Additional resources

- Download JUnit XML report

> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Deckhouse Platform editions comparison

The Deckhouse Platform is available in several editions. They are with different functions and support options.

Starting with version 1.76, the list of supported editions has been updated. Information about the supported editions and their features is being updated and will be available later.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>

Container registry structure

This page provides a general overview of the container image registries used to install the Deckhouse Platform (DP).

Commercial editions container registry

The registry contains modules and components available in the commercial DP editions:

- EE (address `registry.deckhouse.io/deckhouse/ee`).
- SE (address `registry.deckhouse.io/deckhouse/se`).
- SE+ (address `registry.deckhouse.io/deckhouse/se-plus`).
- BE (address `registry.deckhouse.io/deckhouse/be`).

Key features:

- implements functionality according to the edition;
- security testing is performed as part of the secure software development lifecycle;
- delivered electronically.

Images are provided with technical support, including operational consultation.

Image build and update specifics:

- built from open-source software included in DP:
  - from upstream (as-is);
  - with deep modernization (fork).
- includes proprietary company developments;
- vulnerability remediation and package updates are performed only when upstream open-source packages are updated;
- updates are provided:
  - with new functionality;
  - with bug and vulnerability fixes;
  - with security incident resolution.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Network interaction of the platform components

If the infrastructure where Deckhouse Platform (DP) is running has requirements to limit host-to-host network communications, the following conditions must be met:

- Tunneling mode for traffic between pods is enabled (configuration for CNI Cilium, configuration for CNI Flannel).
- Traffic between `podSubnetCIDR` encapsulated within a VXLAN is allowed (if inspection and filtering of traffic within a VXLAN tunnel is performed).
- If there is integration with external systems (e.g. LDAP, SMTP or other external APIs), it is required to allow network communication with them.
- Local network communication is fully allowed within each individual cluster node.
- Inter-node communication is allowed on the ports shown in the tables on the current page. Note that most ports are in the 4200-4299 range. When new platform components are added, they will be assigned ports from this range (if it is possible).

How to check the current VXLAN port...

```
d8 k -n d8-cni-cilium get cm cilium-config -o yaml | grep tunnel
```

Example output:

```
routing-mode: tunnel
tunnel-port: "4298"
tunnel-protocol: vxlan
```

> Changes related to the addition, removal, or reassignment of ports in the tables are listed in the “Network” section of a respective DP version on the Release notes page.

Requirements for network latency between master nodes

> DP supports HA mode using arbiter nodes. The network latency requirements listed below also apply to arbiter nodes.

Etcd only commits a writing after the change has been replicated to a majority of master nodes. Therefore, the round-trip time (RTT) between master nodes directly determines the cluster’s performance. A single operation in the cluster typically consists of several consecutive writes, so as latency increases, the application of manifests, operator operations, and Kubernetes API responsiveness slow down noticeably.

The sum of RTT and jitter between master nodes must not exceed 100 ms.

> ⚠ Round-trip time (RTT) is specified, not one-way delay: for example, the `ping` command returns RTT.
>
> Jitter—the variation in latency—is added to the RTT. For example, with an RTT of 90 ms and jitter of 20 ms, the total is 110 ms, and the requirement is not met, even though the RTT value itself is within the 100 ms limit.

When planning a cluster, it is recommended to aim for a latency of no more than 50 ms between future master nodes—that is, a twofold margin relative to the requirement. This margin is necessary for the following reasons:

- Pre-deployment measurements are performed on an idle network and may underestimate actual values.

- You need to account for latency spikes and variation, as well as possible infrastructure operations—for example, migrating a virtual machine to a zone with higher latency.

Where does the 100 ms value come from...

DP uses the standard etcd values:

- `ETCD_HEARTBEAT_INTERVAL` — 100 ms, the frequency at which the leader sends heartbeat messages to the other cluster members.
- `ETCD_ELECTION_TIMEOUT` — 1000 ms, the timeout for heartbeat messages; after this time, a cluster member begins leader re-election.

The etcd documentation requires that the election timeout be at least 10x RTT. Hence, the maximum allowed value is:

```
1000 ms / 10 = 100 ms
```

Potential issues

The main consequence of increased RTT is a proportional slowdown of the cluster. Network latency is directly reflected in write times: with an RTT of 300 ms, each write to etcd will take at least 300 ms. There is no threshold here; performance degrades continuously as latency increases.

The second issue is etcd leader re-elections. These are triggered not by the magnitude of the latency, but by its complete loss: a cluster member initiates an election if it does not receive messages from the leader within the time specified by `ETCD_ELECTION_TIMEOUT` (taking into account etcd's built-in randomization mechanism—from 1,000 to 2,000 ms). With a 100-ms heartbeat interval, this corresponds to 10–20 consecutive missed heartbeat messages. Typical causes:

- A network outage or packet loss lasting 1–2 seconds.
- Disk write delays on the leader node, preventing etcd from sending heartbeat messages in time.
- A restart of the etcd process.

Isolated spikes in latency do not trigger re-elections: heartbeat messages arrive, albeit late. Only writes that occur during the spike are delayed.

However, a high RTT makes re-elections protracted when they do occur. Votes are collected within a single RTT and must fit within `ETCD_ELECTION_TIMEOUT`. If the RTT is close to this timeout, the election does not complete in time and restarts, leaving the cluster leaderless. A tenfold margin is required to ensure the election succeeds on the first attempt.

During leader re-elections, etcd does not process write requests, so the Kubernetes API returns errors. The `KubeEtcdHighNumberOfLeaderChanges` alert signals frequent leader re-elections—more than three leader re-elections in 10 minutes.

Checking current latencies

Latency and its variation can be measured using `ping`. The command is run on one of the master nodes, or—when planning the cluster—on the server intended to become a master node. ICMP is sufficient for this check, as it is already included in the requirements for traffic between nodes:

```
ping -c 100 -i 0.2 <IP address of another master node>
```

Example of the resulting output:

```
rtt min/avg/max/mdev = 25.085/25.502/35.933/1.185 ms
```

Here, `avg` is the average RTT, `mdev` is the delay variation (jitter), and `max` is the actual maximum—that is, the RTT including spikes. There is no need to add the RTT and jitter manually: you should compare the `max` value against the requirements. When planning a cluster, we recommend staying within 50 ms; for a live cluster, do not exceed 100 ms.

Network latency at the other nodes

The control plane has no requirements regarding network latency on nodes that are not master nodes: latency on these nodes does not affect the cluster's stability. The only factor that matters is the duration of the loss of communication with master nodes—by default, after 40 seconds, a node enters the `Unreachable` state, and after 5 minutes, its pods are migrated to other nodes. Both thresholds are configured using the nodeMonitorGracePeriodSeconds and failedNodePodEvictionTimeoutSeconds parameters.

These delays affect the performance of everything running on the nodes—including the platform's own components. For components that access the Kubernetes API (DP operators, Prometheus, Ingress controllers), latency to the master nodes is added to every request. Latency between nodes is added to every network request between pods and to DNS lookups, and—when using replicated storage—to the time it takes to write to disk.

Thus, the acceptable value is determined by the requirements of the running workload. For clusters distributed across remote sites, this means that the platform will continue to operate, but application latencies will reflect the geographic distribution of the nodes.

Traffic between master nodes

Port	Protocol	Purpose
`2379, 2380`	TCP	etcd replication
`4200`	TCP	Cluster API webhook handler
`4201`	TCP	Webhook handler for VMware Cloud Director cloud provider
`4223`	TCP	Deckhouse controller webhook handler
`4281`	TCP	`registry` storage: replication of images between the replicas on master nodes, and reads by `registry-packages-proxy` on a master node that has no `registry-agent` yet
`4290`	TCP	Node controller webhook handler
`4291`	TCP	Node controller metrics
`4292`	TCP	Node controller health probe

Traffic from master nodes to regular nodes

Port	Protocol	Purpose
`22`	TCP	SSH for static node bootstrapping by the static provider
`10250`	TCP	kubelet
`4221`	TCP	`bashible apiserver` for delivering node configurations
`4227`	TCP	`runtime-audit-engine` webhook handler

Traffic from nodes to master nodes

Port	Protocol	Purpose
`4234`	UDP	NTP for time synchronization between nodes
`6443`	TCP	`kube-apiserver` for controllers working in the node's host network namespace
`4203`	TCP	`machine-controller-manager` metrics
`4219`	TCP	Proxy for registry packages `registry-packages-proxy`
`4222`	TCP	Deckhouse controller metrics
`4281`	TCP	`registry` storage: image pulls by the `registry-agent` of every node, and reads by the `terraform-manager` pods from the pod network (air-gapped clusters)
`4283`	TCP	`registry` storage: publishing images through the `registry-push` Ingress (`d8 mirror push`); reached from the nodes running the Ingress controller
`4284`	TCP	`registry` storage metrics, the 127.0.0.1 upstream of its kube-rbac-proxy. The port carries no traffic between nodes and needs no firewall rule; it is listed because the storage runs on the host network and occupies this port on every master node
`4285`	TCP	`registry` storage metrics
`4296`	TCP	`control-plane-manager` metrics
`4294`	TCP	`fencing-controller` metrics of the `node-manager` module. The controller uses the host network on the master nodes. On the same port, it serves its health probes on 127.0.0.1

Port	Protocol	Purpose
`5002, 5004, 5051`	TCP	`registry` storage on 127.0.0.1: registry metrics and debug (5002), the internal upstream of the registry (5004), the token service (5051). The ports carry no traffic between nodes and need no firewall rule; they are listed because the storage runs on the host network and occupies these ports on every master node

Traffic between nodes

Port	Protocol	Purpose
—	ICMP	ICMP for node-to-node connectivity monitoring
`4202`	TCP	`sds-node-configurator` node agent metrics
`4204`	TCP	Deckhouse controller debug
`4205`	TCP	`ebpf-exporter` module metrics
`4206`	TCP	`node-exporter` module metrics
`4207`	TCP	`ingress-nginx` controller metrics for the `HostWithFailover` inlet
`4208`	TCP	`ingress-nginx` controller metrics for the `HostWithFailover` inlet
`4209`	TCP	Kubernetes control plane metrics
`4210`	TCP	`kube-proxy` metrics
`4211`	TCP	Cluster API metrics
`4212`	TCP	`runtime-audit-engine` module metrics
`4213`	TCP	`kube-router` metrics

Port	Protocol	Purpose
`4214`	TCP	API of the `sds-replicated-volume` module agent
`4215`	TCP	`sds-replicated-volume` agent metrics
`4216`	TCP	`storage-status` agent metrics, the address the proxy forwards to
`4217`	TCP	`storage-status` agent metrics
`4218`	TCP/UDP	Synchronization of the `speaker` components in `metallb` modules via memberlist protocol
`4220`	TCP	Metrics of the `speaker` components in `metallb` modules
`4224`	TCP	`node-local-dns` metrics
`4225`	TCP/UDP	Synchronization of the `speaker` components in `metallb` modules via memberlist protocol
`4226`	TCP	Metrics of the `speaker` components in `metallb` modules
`4228`	TCP	`sds-node-configurator` agent healthcheck
`4229`	TCP	`csi-nfs` CSI controller healthcheck
`4230`	TCP	`csi-nfs` CSI node healthcheck
`4231`	TCP	`csi-hpe` CSI controller healthcheck
`4232`	TCP	`csi-hpe` CSI node healthcheck
`4233`	TCP	`user-authz` authorization webhook metrics

Port	Protocol	Purpose
`4235`	TCP	`csi-s3` CSI controller healthcheck
`4236`	TCP	`csi-s3` CSI node healthcheck
`4237`	TCP	`csi-scsi-generic` CSI controller healthcheck
`4238`	TCP	`csi-scsi-generic` CSI node healthcheck
`4239`	TCP	`storage-status` agent healthcheck
`4240`	TCP	CNI Cilium node-to-node healthcheck
`4241`	TCP	CNI Cilium agent metrics
`4242`	TCP	CNI Cilium operator metrics
`4243`	TCP	`user-authz` authorization webhook metrics, the 127.0.0.1 upstream of its kube-rbac-proxy. The port carries no traffic between nodes and needs no firewall rule; it is listed because the webhook runs on the host network and occupies this port on every master node
`4244`	TCP	`cilium-hubble` module API
`4245`	TCP	`chrony-exporter` metrics
`4246`	TCP	`csi-ceph` CephFS CSI controller healthcheck
`4247`	TCP	`csi-ceph` RBD CSI controller healthcheck
`4248`	TCP	`csi-yadro-tatlin-unified` CSI controller healthcheck
`4249`	TCP	`csi-yadro-tatlin-unified` CSI node healthcheck

Port	Protocol	Purpose
`4250`	TCP	`fencing-agent` metrics of the `node-manager` module. The agents use the host network. Thus they occupy this port on every cluster node when fencing is enabled on at least one node group. On the same port, the agent serves its health probes on 127.0.0.1
`4251`	TCP	`csi-hitachi` CSI node healthcheck
`4252`	TCP	`csi-ceph` RBD CSI node healthcheck
`4253`	TCP	`csi-ceph` CephFS CSI node healthcheck
`4254`	TCP	`csi-netapp` CSI controller healthcheck
`4255`	TCP	`csi-netapp` CSI node healthcheck
`4256`	TCP	`csi-netapp` CSI controller metrics
`4257`	TCP	`csi-netapp` CSI controller API port
`4258`	TCP	`csi-huawei` CSI controller webhook port
`4259`	TCP	`csi-huawei` CSI node healthcheck
`4260`	TCP	`csi-huawei` CSI controller metrics
`4261`	TCP	`ipv4-options-guard` metrics of the `cni-flannel` and `cni-simple-bridge` agents
`4262`	TCP	`sds-replicated-volume` CSI node healthcheck
`4263`	TCP	`service-with-healthchecks` module metrics

Port	Protocol	Purpose
`4264`	TCP	`node-local-dns` safe-updater healthcheck
`4265`	TCP	`node-local-dns` safe-updater pprof
`4266`	TCP	`csi-scsi-generic` CSI controller metrics
`4267`	TCP	`csi-scsi-generic` CSI node metrics
`4268`	TCP	`sds-replicated-volume` CSI node metrics
`4269`	TCP	`sds-replicated-volume` agent healthcheck
`4270`	TCP	`sds-replicated-volume` agent metrics, the address the proxy forwards to
`4273`	TCP	`sds-replicated-volume` DRBD metrics of the agent
`4274`	TCP	`sds-replicated-volume` DRBD metrics of the agent, the address the proxy forwards to
`4275`	TCP	`sdn` agent healthcheck
`4276`	TCP	`user-authz` Permission Browser API server metrics
`4278`	TCP	`csi-mind-ustor` CSI node healthcheck
`4279`	TCP	`csi-hitachi` CSI controller healthcheck
`4135-4199`	TCP	`virtualization` live migration tunnels between cluster nodes
`4280`	TCP	`virtualization` USB over IP (usb/ip) protocol for sharing USB devices between cluster nodes

Port	Protocol	Purpose
`4282`	TCP	Bootstrap endpoint for downloading `rpp-get` from `registry-packages-proxy`
`4286`	TCP	Istio CNI metrics. On 127.0.0.1 of every node the same port is taken by the `registry-agent` metrics, which carry no traffic between nodes and need no firewall rule
`4287`	UDP	WireGuard port for traffic encryption in CNI Cilium
`4288`	TCP	`monitoring-ping` metrics
`4289`	TCP	`monitoring-ping` metrics
`4293`	TCP	Healthcheck of the `opagent` agent of the `observability` module
`4294`	TCP	CNI Cilium ClusterMesh etcd on control-plane nodes, connected to by kvstoremesh on the control-plane nodes of the peer clusters
`4295-4297`	UDP	Used by the `cni-cilium` module for VXLAN encapsulation of inter-pod traffic in multiple nested virtualization — when DP with the `virtualization` module enabled is deployed inside virtual machines that are also created in DP with the `virtualization` module enabled
`4298`	UDP	Used by the `cni-cilium` module for VXLAN encapsulation of traffic between pods if the cluster was deployed on DP version starting from **1.71** (for clusters deployed on DP versions up to **1.71**, see the note for ports `4299/UDP`, `8469/UDP`, and `8472/UDP`)

Port	Protocol	Purpose
`4299`	UDP	**For clusters deployed on DP versions 1.64–1.70.** Used by the `cni-cilium` module for VXLAN encapsulation of traffic between pods. Updating DP to newer versions will not change the port used unless the `virtualization` module is enabled. **Note** that in such clusters, enabling the `virtualization` module on DP up to version 1.70 changes the port to `4298/UDP`
`5001`	TCP	`registry-agent` on 127.0.0.1, through which the container runtime and Deckhouse pull images. The port carries no traffic between nodes and needs no firewall rule; it is listed because the agent runs on the host network and occupies this port on every node
`7000-7999`	TCP	`sds-replicated-volume` DRBD replication
`8469`	UDP	**For clusters deployed on DP version 1.63 and below with the `virtualization` module enabled prior to DP version 1.63.** Used by the `cni-cilium` module for VXLAN encapsulation of traffic between pods. Updating DP to newer versions will not change the occupied port

Port	Protocol	Purpose
`8472`	UDP	**For clusters deployed on DP version 1.63 and below.** Used by the `cni-cilium` module for VXLAN encapsulation of traffic between pods. Updating DP to newer versions will not change the occupied port if the `virtualization` module is not enabled. **Note** that in such clusters, enabling the `virtualization` module on DP before version 1.70 changes the port: • Enabling the `virtualization` module on DP version 1.63 and below will change it to `8469/UDP` and will not change with subsequent DP updates • Enabling the `virtualization` module on DP starting from version 1.64 will change it to `4298/UDP` and will not change with subsequent DP updates
`8500`	TCP/UDP	Gossip network of the `fencing-agent` components of the `node-manager` module (memberlist protocol). Open between the InternalIP addresses of all cluster nodes once fencing is enabled on at least one node group. If the second network of fencing (SystemNetwork) is set, also open UDP between the addresses of this network

Static `virtualization` ports on cluster nodes (`4100-4134/TCP` reserved)

Port	Protocol	Purpose
`4100`	TCP	`virtualization` `virt-handler` healthz and metrics
`4101`	TCP	`virtualization` `virt-handler` console server
`4102`	TCP	`virtualization` `virt-synchronization-controller` API that synchronizes the state of VM migrations between clusters. Used only with the `Peering` feature gate; the nodes of the other cluster connect to it

Port	Protocol	Purpose
`4103`	TCP	`virtualization virt-synchronization-controller` health check. Used only with the `Peering` feature gate
`4106`	TCP	`virtualization vm-route-forge` pprof in debug mode

External traffic to master nodes

Port	Protocol	Purpose
`22`	TCP	SSH for initializing Deckhouse Platform
`6443`	TCP	Direct access to the apiserver **Optional**. This port may be needed for direct access to `kube-apiserver` bypassing Ingress / Gateway API when publishing through a load balancer is not configured or unavailable due to infrastructure constraints

External traffic to frontend nodes

Port	Protocol	Purpose
`80, 443`	TCP	Application ports for requests to Ingress controllers over HTTP and HTTPS. Note that these ports are configurable in the IngressNginxController resource and may vary across installations
`5416`	UDP	OpenVPN **Optional**. Required only when the `openvpn` module is enabled
`5416`	TCP	OpenVPN **Optional**. Required only when the `openvpn` module is enabled

Port	Protocol	Purpose
`10256`	TCP	Healthcheck port for external balancers **Optional**. This is the Cilium healthz port checked by external load balancers, primarily cloud load balancers for `LoadBalancer` services. The port is not needed with `HostPort` / `HostPortWithProxyProtocol` inlets without an external load balancer
`30000-32767`	TCP	NodePort range **Optional**. Needed when `LoadBalancer` services are used. A cloud load balancer delivers traffic to nodes through a NodePort. The range is not needed with `HostPort` inlets

External traffic for all nodes

All ports in this section are used for outbound traffic from nodes.

Port	Protocol	Purpose
`53`	UDP	DNS
`53`	TCP	DNS
`123`	UDP	NTP for synchronization with external time servers
`179`	TCP	BGP peering with the infrastructure router for network traffic balancing (metallb module) **Optional**. Required only for the `metallb` module in BGP mode, from nodes running `speaker`. It is not required in L2 mode
`443`	TCP	Container registry

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

The list of alerts

The page displays a list of all alerts of monitoring in the Deckhouse Platform.

> The list does not contain alerts of modules from a source.

Alerts are grouped by modules. To the right of the alert name, there are icons indicating the minimum DP edition in which the alert is available, and the alert severity.

For each alert, a summary is provided, and if available, the detailed alert description can be viewed by expanding it.

Alert severity

Alert descriptions contain the Severity (S) parameter, which indicates the level of criticality. Its value varies from `S1` to `S9` and can be interpreted as follows:

- `S1` — maximum level, critical failure/crash (immediate action required);
- `S2` — high level, close to maximum, possible accident (rapid response required);
- `S3` — medium level, potentially serious problem (verification required);
- `S4`-`S9` — low level. There is a problem, but overall performance is not impaired.

Module admission-policy-engine

- ControllerPolicyViolation CE S4
  ▼ **Pod-creating controllers in the XXX namespace violate the XXX policy, so their Pods are denied.**

  The `XXX` policy (XXX) denies the Pods that violate it. For a transition period, it only warns about a violation in a pod-creating controller (Deployment, StatefulSet, DaemonSet, Job, CronJob, ReplicationController) instead of denying the controller. The controller is accepted, but it cannot create its Pods: the denial appears only in the events of the ReplicaSet or the controller.

  Controllers that violate the policy in the namespace: VALUE.

  The `d8-pod-security-baseline` and `d8-pod-security-restricted` policies are the Pod Security Standards.

  To list the violating controllers and the rules they break, run the following Prometheus query:

  ```
  count by (violating_kind, violating_name, kind, violation_msg) (
    d8_gatekeeper_exporter_constraint_violations{
      source_type="XXX",
      name=~"d8-controllers-XXXXXX-deny(-d8)?(-default)?XXX",
      violating_namespace="XXX"
    }
  )
  ```

  Bring the pod template of each controller in line with the policy. To deny such controllers instead of warning about them, set `spec.controllerValidation.mode: Enforce` in the policy, or the `podSecurityStandards.controllerValidationEnforcement` module parameter to `Policy`. You can also check the admission-policy-engine reports in the Deckhouse web interface.

- D8AdmissionPolicyEngineAuditUnavailable CE S4
  ▼ **The audit controller of admission-policy-engine has no available replicas.**

  The `gatekeeper-audit` Deployment in the `d8-admission-policy-engine` namespace has no available replicas.

  Admission of new objects is not affected, but the module stops reporting and stops picking up new

policies:

- Violations among the objects that already run are not collected, so the `PodSecurityStandardsViolation`, `OperationPolicyViolation` and `SecurityPolicyViolation` alerts go silent instead of reporting that all is well.
- The list of resources the webhook intercepts is not updated, so a policy added while the audit is down is not enforced on admission.

Find out why the replica is gone:

```
d8 k -n d8-admission-policy-engine get pods -l app=gatekeeper,control-plane=audit-controller
d8 k -n d8-admission-policy-engine describe pods -l app=gatekeeper,control-plane=audit-controller
d8 k -n d8-admission-policy-engine logs deploy/gatekeeper-audit -c manager --tail=200
d8 k -n d8-admission-policy-engine logs deploy/gatekeeper-audit -c constraint-exporter --tail=200
```

- D8AdmissionPolicyEngineNotBootstrapped CE S7
  ▼ Not every ConstraintTemplate of the admission-policy-engine module is ready for 10 minutes.

  Some ConstraintTemplates of the admission-policy-engine module are missing or not processed by Gatekeeper. The constraints of a template are applied only once Gatekeeper has established its CRD.

  On a new installation, the module also renders no webhooks and no policies until every template is ready. In a cluster where the module has already worked, the webhooks and the constraints of the other templates stay in effect.

  Steps to troubleshoot:

  1. Verify that the module's components are up and running:

     ```
     d8 k get pods -n d8-admission-policy-engine
     ```

  2. Check logs for issues, such as missing constraint templates or incomplete CRD creation:

     ```
     d8 k logs -n d8-system -lapp=deckhouse --tail=1000 | grep admission-policy-engine
     ```

- D8AdmissionPolicyEngineWebhookDegraded CE S3
  ▼ The admission webhook of admission-policy-engine has unavailable replicas.

  The `gatekeeper-controller-manager` Deployment in the `d8-admission-policy-engine` namespace has unavailable replicas, and the remaining ones still serve admission requests.

  The webhook has no redundancy left. Losing the last replica makes the API server reject every request the webhook intercepts, because the webhook has `failurePolicy: Fail`.

  A rollout of the Deployment raises this alert for a short time and needs no action. If the alert holds, find out why the replica does not start:

  ```
  d8 k -n d8-admission-policy-engine get pods -l app=gatekeeper,control-plane=controller-manager -o
  wide
  d8 k -n d8-admission-policy-engine describe pods -l app=gatekeeper,control-plane=controller-
  manager
  d8 k -n d8-admission-policy-engine get events --sort-by=.lastTimestamp | tail -30
  ```

- D8AdmissionPolicyEngineWebhookNotServing CE S2
  ▼ The API server cannot call the admission webhook of admission-policy-engine.

  The API server is rejecting requests because it fails to call a webhook of the `admission-policy-engine` module. The webhook has `failurePolicy: Fail`, so the cluster is blocked for everything the webhook intercepts.

  The alert is independent of the replica counters: it fires while the pods are `Ready` as well. A replica that is running but unreachable to the API server produces the same outage, and only this alert reports it. Typical causes are a `gatekeeper-webhook-server-cert` that no longer matches the `caBundle` of the ValidatingWebhookConfiguration, an empty `gatekeeper-webhook-service` endpoint list, and a network policy that blocks the API server.

  The API server counts a webhook that exceeds its `timeoutSeconds` of 15 the same way it counts one it cannot reach, so a few slow evaluations of a large object raise the metric as well. They do not raise the alert: `for: 15m` requires the failures to continue, while a burst leaves the rate

elevated for little more than its own duration plus the five-minute window.

Read the reason the API server reports, then check the certificate and the endpoints:

```
d8 k -n d8-admission-policy-engine logs deploy/gatekeeper-controller-manager -c manager --all-pods=true --tail=200
d8 k -n d8-admission-policy-engine get endpoints gatekeeper-webhook-service
d8 k get validatingwebhookconfiguration d8-admission-policy-engine-config -o jsonpath='{.webhooks[0].clientConfig.caBundle}' | base64 -d | openssl x509 -noout -subject -dates
d8 k -n d8-admission-policy-engine get secret gatekeeper-webhook-server-cert -o jsonpath='{.data.ca\.crt}' | base64 -d | openssl x509 -noout -subject -dates
```

The two certificates must match. Deckhouse Platform reissues them through the module’s hook, so deleting the secret makes it regenerate the pair.

- D8AdmissionPolicyEngineWebhookUnavailable CE S2
  ▾ The admission webhook of admission-policy-engine has no available replicas.

  The `gatekeeper-controller-manager` Deployment in the `d8-admission-policy-engine` namespace has no available replicas.

  The Deployment serves the admission webhook of the module, and the webhook has `failurePolicy: Fail`. While no replica is available, the API server rejects every request the webhook intercepts, cluster-wide:

  - Pods and the controllers that create them are not created or updated.
  - Deletion of those resources is rejected as well.
  - Roles, RoleBindings and Gatekeeper constraints are not applied.
  - The `d8 k exec`, `d8 k attach` and `d8 k debug` requests intercepted by the webhooks are rejected. This includes `d8 k exec` and `d8 k attach` in the `d8-*` and `kube-*` namespaces.

  Find out why the replicas are gone:

  ```
  d8 k -n d8-admission-policy-engine get deploy gatekeeper-controller-manager
  d8 k -n d8-admission-policy-engine get pods -l app=gatekeeper,control-plane=controller-manager -o wide
  d8 k -n d8-admission-policy-engine describe pods -l app=gatekeeper,control-plane=controller-manager
  d8 k -n d8-admission-policy-engine logs deploy/gatekeeper-controller-manager -c manager --all-pods=true --tail=200
  ```

  If a pod stays `Pending`, look at the events of the namespace and at the nodes the replicas can run on:

  ```
  d8 k -n d8-admission-policy-engine get events --sort-by=.lastTimestamp | tail -30
  d8 k get nodes -l node-role.deckhouse.io/system
  d8 k get nodes -l node-role.kubernetes.io/control-plane
  ```

- OperationPolicyViolation CE S3
  ▾ XXXObjects in the XXX namespaceXXXCluster-scoped objectsXXX violate the XXX OperationPolicy.

  Existing objects XXXin the `XXX` namespace XXXof cluster-scoped kinds XXXviolate the `XXX` OperationPolicy. An object is checked when it is created or updated, so these objects were created before the policy applied to them or before its rules changed.

  Objects that violate the policy: VALUE.

  To list the violating objects and the rules they break, run the following Prometheus query:

```
count by (violating_kind, violating_name, kind, violation_msg) (
  d8_gatekeeper_exporter_constraint_violations{
    source_type="OperationPolicy",
    name="XXX",
    violation_enforcement="deny",
    violating_namespace="XXX"
  }
)
```

Bring the objects in line with the policy. You can also check the admission-policy-engine reports in the Deckhouse web interface.

- PodSecurityStandardsViolation CE S3
  ▼ Pods in the XXX namespace violate the XXX Pod Security Standard.

  Running Pods in the `XXX` namespace violate the Pod Security Standard published as the `XXX` SecurityPolicy. A Pod is checked when it is created, so these Pods were created before the standard applied to them or before its rules changed. They keep running until they are restarted, and are denied then.

  Pods that violate the standard in the namespace: VALUE.

  To list the violating Pods and the rules they break, run the following Prometheus query:

  ```
  count by (violating_name, kind, violation_msg) (
    d8_gatekeeper_exporter_constraint_violations{
      source_type="PSS",
      name=~"XXX-.+",
      violation_enforcement="deny",
      violating_kind="Pod",
      violating_namespace="XXX"
    }
  )
  ```

  Bring the workloads in line with the standard, or exempt them with a SecurityPolicyException. You can also check the admission-policy-engine reports in the Deckhouse web interface.

- SecurityPolicyViolation CE S3
  ▼ XXXObjects in the XXX namespaceXXXCluster-scoped objectsXXX violate the XXX SecurityPolicy.

  Existing objects XXXin the `XXX` namespace XXXof cluster-scoped kinds XXXviolate the `XXX` SecurityPolicy. An object is checked when it is created or updated, so these objects were created before the policy applied to them or before its rules changed.

  Objects that violate the policy: VALUE.

  To list the violating objects and the rules they break, run the following Prometheus query:

  ```
  count by (violating_kind, violating_name, kind, violation_msg) (
    d8_gatekeeper_exporter_constraint_violations{
      source_type="SecurityPolicy",
      name="XXX",
      violation_enforcement="deny",
      violating_namespace="XXX"
    }
  )
  ```

  Bring the objects in line with the policy, or exempt them with a SecurityPolicyException. You can also check the admission-policy-engine reports in the Deckhouse web interface.

Module cert-manager

- CertmanagerCertificateChallengePending CE S4
  ▼ ACME Challenge for domain "XXX" is pending for more than 1 hour.

  The ACME Challenge `NAMESPACE/NAME` for domain `XXX` has been in `pending` state for more than

1 hour and requires investigation.

Common causes:

- DNS misconfiguration (for DNS-01 challenges).
- Ingress or firewall issues blocking HTTP-01 validation.
- ACME provider rate limiting.
- Network connectivity issues.

Resolution steps:

1. Check the Challenge status and reason:

```
d8 k -n NAMESPACE describe challenge NAME
```

2. Check `cert-manager` logs for errors:

```
d8 k -n d8-cert-manager logs -l app=cert-manager -c cert-manager --tail=100
```

3. If the challenge is stuck, delete the Order to trigger a retry:

```
d8 k -n NAMESPACE get orders
d8 k -n NAMESPACE delete order ORDER_NAME
```

- CertmanagerCertificateChallengePending CE S6
  ▾ ACME Challenge for domain "XXX" is pending for more than 10 minutes.

  The ACME Challenge `NAMESPACE/NAME` for domain `XXX` has been in `pending` state for more than 10 minutes.

  This may indicate issues with the ACME challenge validation process.

  Common causes:

  - DNS propagation delays (for DNS-01 challenges).
  - Ingress or firewall issues blocking HTTP-01 validation.
  - ACME provider rate limiting or temporary unavailability.

  Diagnostic steps:

  1. Check the Challenge status:

```
d8 k -n NAMESPACE describe challenge NAME
```

  2. Check `cert-manager` logs for errors:

```
d8 k -n d8-cert-manager logs -l app=cert-manager -c cert-manager --tail=100
```

- CertmanagerCertificateChallengeStuck CE S4
  ▾ ACME Challenge for domain "XXX" is stuck in "STATUS_REFERENCE" state.

  The ACME Challenge `NAMESPACE/NAME` for domain `XXX` is in `STATUS_REFERENCE` state and requires manual intervention.

  Reason: XXX

  The certificate will not be issued or renewed until the issue is resolved.

  Common causes:

  - DNS misconfiguration (for DNS-01 challenges).
  - Ingress or firewall issues (for HTTP-01 challenges).
  - Rate limiting by the ACME provider.
  - Authorization expired before challenge completion.

  Resolution steps:

  1. Check the Challenge status and reason:

```
d8 k -n NAMESPACE describe challenge NAME
```

  2. Delete the failed Order to trigger a new certificate request:

```
d8 k -n NAMESPACE get orders
d8 k -n NAMESPACE delete order ORDER_NAME
```

- CertmanagerCertificateExpired CE S4
  ▼ Certificate NAMESPACE/NAME is not provided.

  Certificate is not provided.

  To check the certificate details, run the following command:

  ```
  d8 k -n NAMESPACE describe certificate NAME
  ```

- CertmanagerCertificateExpiredSoon CE S4
  ▼ Certificate will expire soon.

  The certificate `NAMESPACE/NAME` will expire in less than two weeks.

  To check the certificate details, run the following command:

  ```
  d8 k -n NAMESPACE describe certificate CERTIFICATE-NAME
  ```

- CertmanagerCertificateOrderErrors CE S5
  ▼ Cert-manager couldn't order a certificate.

  Cert-manager received responses with the status code `STATUS_REFERENCE` when requesting `SCHEME://HOST_NAMEPATH`.

  This can affect certificate ordering and prolongation in the future. For details, check the cert-manager logs using the following command:

  ```
  d8 k -n d8-cert-manager logs -l app=cert-manager -c cert-manager
  ```

Module chrony

- NodeTimeNotSynchronizedAtBoot CE S5
  ▼ Master node NODE_NAME started kubelet before its clock was synchronized.

  During the last boot of the master node `NODE_NAME`, the clock was not synchronized from NTP before kubelet started. Either no NTP server answered within the waiting time, the servers that answered disagreed with each other, nodelet could not run the synchronization, or the synchronization hung and systemd stopped it. kubelet and the control plane started with a clock taken from the RTC or the hypervisor. If that clock was wrong, the control plane could issue tokens and certificates with incorrect timestamps.

  To resolve the issue:

  1. Check the synchronization log on the node. On a node managed by bashible, run:

     ```
     journalctl -u nodelet.service -b
     ```

     A Deckhouse Engine node has no SSH access. Read the log from a debug pod, where `IMAGE` is any image available to the cluster that has the `chroot` utility:

     ```
     d8 k -n kube-system debug node/NODE_NAME -i --profile=sysadmin --image=IMAGE -- chroot
     /host journalctl --no-pager -u nodelet.service -b | grep -E 'clock|NTP'
     ```

  2. On a node managed by bashible, check that the installed `nodelet.service` has `Type=notify` and that nodelet started. If the package is missing or outdated, bashible installs it on its next run. To start that run sooner, run the following command on the node:

     ```
     rm -f /var/lib/bashible/configuration_checksum
     ```

  3. Otherwise, ensure the NTP servers defined in the chrony configuration are reachable through the node network and their names are resolvable by the node DNS settings, without Kubernetes DNS. If the log reports `the NTP servers disagree` or `the addresses of SERVER disagree`, use servers whose answers agree with each other.

  4. The alert stays active until the node boots again and the synchronization succeeds. On a

node managed by bashible, disabling boot-time synchronization also clears it. After you have checked the clock on the node, you can clear the alert without a reboot. On a node managed by bashible, run on the node:

```
systemctl reset-failed nodelet.service
rm -f /var/run/node-exporter-textfile/d8_early_time_sync.prom
```

If `nodelet.service` is in the `failed` state, `systemctl reset-failed` keeps bashible from writing the failure metric again.

On a Deckhouse Engine node, remove the file from a debug pod, as in step 1:

```
d8 k -n kube-system debug node/NODE_NAME -i --profile=sysadmin --image=IMAGE -- chroot
/host rm -f /var/run/node-exporter-textfile/d8_early_time_sync.prom
```

Each debug command leaves a `node-debugger-*` pod in the `kube-system` namespace. Delete it with `d8 k -n kube-system delete pod POD_NAME`, using the name the command printed.

The alert resolves about 10 minutes after the file is removed.

- NodeTimeOutOfSync CE S5
  ▾ **Clock on the node NODE_NAME is drifting.**

  Time on the node `NODE_NAME` is out of sync and drifts apart from the NTP server clock by VALUE seconds.

  To resolve the time synchronization issues:

  - Fix network errors:
    - Ensure the upstream time synchronization servers defined in the chrony configuration are available.
    - Eliminate large packet loss and excessive latency to upstream time synchronization servers.
  - Modify the NTP servers list defined in the chrony configuration.
- NTPDaemonOnNodeDoesNotSynchronizeTime CE S5
  ▾ **NTP daemon on the node NODE_NAME haven't synchronized time for too long.**

  Steps to troubleshoot:

  1. Check if the chrony pod is running on the node by executing the following command:

     ```
     d8 k -n d8-chrony --field-selector spec.nodeName="NODE_NAME" get pods
     ```

  2. Verify the chrony daemon’s status by executing the following command:

     ```
     d8 k -n d8-chrony exec POD_NAME -- /opt/chrony-static/bin/chronyc sources
     ```

  3. Resolve the time synchronization issues:

     - Fix network errors:
       - Ensure the upstream time synchronization servers defined in the chrony configuration are available.
       - Eliminate large packet loss and excessive latency to upstream time synchronization servers.
     - Modify the NTP servers list defined in the chrony configuration.

Module cloud-provider-aws

- D8CloudProviderAWSIMDSv2NotConverged CE S6
  ▾ **Some EC2 instances of the cluster still allow IMDSv1.**

  `imdsv2: true` is set in `AWSClusterConfiguration`, but VALUE EC2 instances of the cluster still accept metadata requests without a session token, which leaves them more exposed to unauthorized metadata access, including through SSRF attacks.

  Existing instances are not reconfigured by the setting alone:

  1. Master, static and bastion instances are updated by a converge run. Start the DKP installer and run `dhctl converge`.
  2. Ephemeral instances are re-created when their nodes are rolled, which happens on its own.

Check that the nodes of every `CloudEphemeral` NodeGroup are being replaced: `d8 k get nodegroups`.

The instance state is re-read once per discovery period of the cloud data discoverer (one hour by default), so the alert can lag behind the last node being replaced.

Module cloud-provider-huaweicloud

- D8HuaweiCloudMachineStuckInDeleting EE S6
  ▼ HuaweiCloudMachine NAME is stuck in Deleting for more than 24h.

  The HuaweiCloudMachine `NAME` in namespace `NAMESPACE` has been stuck in Deleting state for more than 24 hours.

  This usually means the deletion job in HuaweiCloud is failing or the API is unavailable.

  To inspect the machine status, run:

  ```
  d8 k get huaweicloudmachine -n NAMESPACE NAME -o yaml
  ```

  Check the controller logs for errors:

  ```
  d8 k logs -n d8-cloud-provider-huaweicloud -l app=caphc-controller-manager
  ```

Module cloud-provider-openstack

- OpenStackPreemptibleUnsupported EE S8
  ▼ NodeGroup NODE_GROUP_NAME requests preemptible instances, but this cluster cannot deliver them (reason: XXX).

  The OpenStackInstanceClass referenced by NodeGroup `NODE_GROUP_NAME` has `spec.preemptible: true`, but the raw Nova `preemptible` tag will not reach the virtual machines: nodes are created as regular (non-preemptible) VMs, and Selectel-side preemption never kicks in.

  XXX **Reason:** the NodeGroup runs on the **MCM engine**, which has no way to emit raw Nova tags — `machine-controller-manager`'s OpenStackMachineClass CRD does not expose the field. Only the CAPI engine (`capi-controller-manager` + `capo-controller-manager`) renders raw Nova tags via `OpenStackMachineTemplate.spec.template.spec.tags`.

  How to fix:

  1. Confirm the current engine and offending InstanceClass:

     ```
     d8 k get ng NODE_GROUP_NAME -o jsonpath='{.status.engine}{"\n"}'
     d8 k get ng NODE_GROUP_NAME -o jsonpath='{.spec.cloudInstances.classReference}
     {"\n"}'
     ```

  2. Choose one of the following actions:

     - **Recommended.** Remove the `node.deckhouse.io/use-mcm` annotation from the NodeGroup so it migrates to CAPI. Nodes will be recreated on the CAPI engine, this time carrying the `preemptible` tag:

       ```
       d8 k annotate ng NODE_GROUP_NAME node.deckhouse.io/use-mcm-
       ```

     - Alternatively, if this NodeGroup must stay on MCM, set `spec.preemptible: false` on the OpenStackInstanceClass (nodes stay regular, the alert clears):

       ```
       d8 k patch openstackinstanceclass CLASS_NAME --type=merge -p '{"spec":
       {"preemptible":false}}'
       ```

       Note: a single OpenStackInstanceClass shared between a CAPI NodeGroup (where the field works) and an MCM one (where it doesn't) will keep firing this alert on the MCM side. Use separate InstanceClasses per engine when the classes differ in `preemptible`.

  XXX **Reason:** the cluster's `connection.authURL` does not point at Selectel (`selcloud.ru` / `selectel`). The raw Nova `preemptible` tag is a **Selectel-specific mechanism**; on other OpenStack providers Nova accepts the tag but ignores it, so instances are billed and behave as

regular non-preemptible VMs.

How to fix:

1. Confirm the offending InstanceClass and the cluster's authURL:

   ```
   d8 k get ng NODE_GROUP_NAME -o jsonpath='{.spec.cloudInstances.classReference}
   {"\n"}'
   d8 k -n kube-system get secret d8-node-manager-cloud-provider -o
   jsonpath='{.data.openstack}' | base64 -d | jq -r '.connection.authURL'
   ```

2. Set `spec.preemptible: false` on the OpenStackInstanceClass — the field only makes sense on Selectel-hosted clusters:

   ```
   d8 k patch openstackinstanceclass CLASS_NAME --type=merge -p '{"spec":
   {"preemptible":false}}'
   ```

   The alert clears on the next scrape after the change; existing nodes stay running (they are already regular VMs — the tag was never emitted).

XXX **Reason:** unknown (`XXX`). This alert should surface only two well-known cases (`mcm`, `non-selectel`). A new reason implies node-controller has been extended without this runbook — check the release notes for `cloud-provider-openstack` before deciding what to do. XXX

Module cloud-provider-yandex

- D8CloudProviderYandexCloudMigrationPending CE S6
  ▼ **The cloud-provider-yandex module is waiting for migration resources to be applied.**

  The `cloud-provider-yandex` module has detected the legacy `YandexProviderClusterConfiguration` secret in the cluster and is waiting for the new migration resources (ModuleConfig v2, CredentialSecret, NodeGroups, InstanceClasses) to be applied before completing the migration.

  To complete the migration, apply the resources from the `d8-migration-resources` Secret:

  ```
  d8 k -n d8-cloud-provider-yandex get secret d8-migration-resources -o
  jsonpath='{.data.resources\.yaml}' | base64 -d | d8 k apply -f -
  ```

  After applying the resources, the alert will disappear automatically once the module detects that all required resources are in place.

  After the migration is complete, the legacy `YandexProviderClusterConfiguration` secret is no longer needed and can be deleted manually:

  1. Make sure the cloud discovery data is stored outside the legacy secret. The module reads it from the `d8-candi-cloud-provider-discovery-data` Secret first and uses the legacy secret only as a fallback, so the following command must print a non-empty value:

     ```
     d8 k -n d8-cloud-provider-yandex get secret d8-candi-cloud-provider-discovery-data -o
     jsonpath='{.data.cloud-provider-discovery-data\.json}'
     ```

     If it prints nothing, the discovery data exists only in the legacy secret, and deleting that secret would lose it. Copy the payload over — the key holds exactly the same discovery data dhctl recorded from the infrastructure run:

     ```
     d8 k -n kube-system get secret d8-provider-cluster-configuration \
       -o jsonpath='{.data.cloud-provider-discovery-data\.json}' | base64 -d >
     /tmp/yandex-discovery.json

     d8 k -n d8-cloud-provider-yandex create secret generic d8-candi-cloud-provider-discovery-data
     \
       --from-file=cloud-provider-discovery-data.json=/tmp/yandex-discovery.json \
       --dry-run=client -o yaml | d8 k apply -f -
     ```

  2. Back up the secret. It contains cloud credentials and discovery data, so store the file securely:

```
d8 k -n kube-system get secret d8-provider-cluster-configuration -o yaml > d8-provider-cluster-configuration-backup.yaml
```

3. Allow the deletion. The secret is protected by an admission webhook and cannot be deleted without the annotation:

```
d8 k -n kube-system annotate secret d8-provider-cluster-configuration deckhouse.io/allow-delete=true
```

4. Delete the secret:

```
d8 k -n kube-system delete secret d8-provider-cluster-configuration
```

- D8YandexNatInstanceConnectionsQuotaUtilization CE S4
  ▼ **Connection quota utilization of the Yandex NAT instance exceeds 85% over the last 5 minutes.**

  The connection quota for the Yandex NAT instance has exceeded 85% utilization over the past 5 minutes.

  To prevent potential issues, contact Yandex technical support and request an increase in the connection quota.

- NATInstanceWithDeprecatedAvailabilityZone CE S9
  ▼ **NAT instance NAME is in a deprecated availability zone.**

  The NAT instance `NAME` is located in the availability zone `ru-central1-c`, which has been deprecated by Yandex Cloud. To resolve this issue, migrate the NAT instance to either `ru-central1-a` or `ru-central1-b` by following the instructions below.

  > **i** The migration process involves irreversible changes and may result in a significant downtime. The duration typically depends on Yandex Cloud's response time and can last several tens of minutes.

  1. Migrate the NAT instance. To get `providerClusterConfiguration.withNATInstance`, run the following command:

     ```
     d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller module values -g cloud-provider-yandex -o json | jq -c | jq '.cloudProviderYandex.internal.providerClusterConfiguration.withNATInstance'
     ```

     - If you specified `withNATInstance.natInstanceInternalAddress` and/or `withNATInstance.internalSubnetID` in `providerClusterConfiguration`, remove them using the following command:

       ```
       d8 system edit provider-cluster-configuration
       ```

     - If you specified `withNATInstance.externalSubnetID` and/or `withNATInstance.natInstanceExternalAddress` in `providerClusterConfiguration`, change them to the appropriate values.

       To get the address and subnet ID, use the Yandex Cloud Console or CLI.

       To change `withNATInstance.externalSubnetID` and `withNATInstance.natInstanceExternalAddress`, run the following command:

       ```
       d8 system edit provider-cluster-configuration
       ```

  2. Run the appropriate edition and version of the Deckhouse installer container on the **local** machine. You may have to change the container registry address to do that. After that, perform the converge.

     - Get the appropriate edition and version of Deckhouse:

```
DH_VERSION=$(d8 k -n d8-system get deployment deckhouse -o
jsonpath='{.metadata.annotations.core\.deckhouse\.io\/version}')
DH_EDITION=$(d8 k -n d8-system get deployment deckhouse -o
jsonpath='{.metadata.annotations.core\.deckhouse\.io\/edition}' | tr
'[:upper:]' '[:lower:]')
echo "DH_VERSION=$DH_VERSION DH_EDITION=$DH_EDITION"
```

- Run the installer:

```
docker run --pull=always -it -v "$HOME/.ssh/:/tmp/.ssh/"
registry.deckhouse.io/deckhouse/${DH_EDITION}/install:${DH_VERSION} bash
```

- Perform the converge:

```
dhctl converge --ssh-agent-private-keys=/tmp/.ssh/SSH_KEY_FILENAME --ssh-
user=USERNAME --ssh-host MASTER-NODE-0-HOST
```

3. Update the route table.
   - Get the route table name:

```
d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller
module values -g cloud-provider-yandex -o json | jq -c | jq '.global.prefix //
.global.clusterConfiguration.cloud.prefix'
```

   - Get the NAT instance name:

```
d8 k -n d8-system exec -ti svc/deckhouse-leader -c deckhouse -- deckhouse-controller
module values -g cloud-provider-yandex -o json | jq -c | jq
'.cloudProviderYandex.internal.providerDiscoveryData.natInstanceName'
```

   - Get the NAT instance internal IP address:

```
yc compute instance list | grep -e "INTERNAL IP" -e
NAT_INSTANCE_NAME_FROM_PREVIOUS_STEP
```

   - Update the route:

```
yc vpc route-table update --name ROUTE_TABLE_NAME_FROM_PREVIOUS_STEP --route
"destination=0.0.0.0/0,next-
hop=NAT_INSTANCE_INTERNAL_IP_FROM_PREVIOUS_STEP"
```

- NodeGroupNodeWithDeprecatedAvailabilityZone CE S9
  ▼ **NodeGroup NODE_GROUP_NAME contains nodes in a deprecated availability zone.**

  Certain nodes in the node group `NODE_GROUP_NAME` are located in the availability zone `ru-central1-c`, which has been deprecated by Yandex Cloud.

  Steps to troubleshoot:

  1. Identify the nodes that need to be migrated by running the following command:

```
d8 k get node -l "topology.kubernetes.io/zone=ru-central1-c"
```

  2. Migrate your nodes, disks, and load balancers to one of the supported zones: `ru-central1-a`, `ru-central1-b`, or `ru-central1-d`. Refer to the Yandex migration guide for detailed instructions.

> **i** You can’t migrate public IP addresses between zones. For details, refer to the migration guide.

Module cloud-provider-zvirt

- D8CloudProviderZvirtMigrationPending SE-PLUS S6
  ▼ **The cloud-provider-zvirt module is waiting for migration resources to be applied.**

  The `cloud-provider-zvirt` module has detected the legacy `ZvirtClusterConfiguration` secret in the cluster and is waiting for the new migration resources (ModuleConfig v2, CredentialSecret, NodeGroups, InstanceClasses) to be applied before completing the migration.

  To complete the migration, apply the resources from the `d8-migration-resources` Secret:

  ```
  d8 k -n d8-cloud-provider-zvirt get secret d8-migration-resources -o
  jsonpath='{.data.resources\.yaml}' | base64 -d | d8 k apply -f -
  ```

  After applying the resources, the alert will disappear automatically once the module detects that all required resources are in place.

  After the migration is complete, the legacy `ZvirtProviderClusterConfiguration` secret is no longer needed and can be deleted manually:

  1. Make sure the cloud discovery data is stored outside the legacy secret. The module reads it from the `d8-candi-cloud-provider-discovery-data` Secret first and uses the legacy secret only as a fallback, so the following command must print a non-empty value:

     ```
     d8 k -n d8-cloud-provider-zvirt get secret d8-candi-cloud-provider-discovery-data -o
     jsonpath='{.data.cloud-provider-discovery-data\.json}'
     ```

     If it prints nothing, the discovery data exists only in the legacy secret, and deleting that secret would lose it. Copy the payload over — the key holds exactly the same discovery data dhctl recorded from the infrastructure run:

     ```
     d8 k -n kube-system get secret d8-provider-cluster-configuration \
       -o jsonpath='{.data.cloud-provider-discovery-data\.json}' | base64 -d >
     /tmp/zvirt-discovery.json

     d8 k -n d8-cloud-provider-zvirt create secret generic d8-candi-cloud-provider-discovery-data
     \
       --from-file=cloud-provider-discovery-data.json=/tmp/zvirt-discovery.json \
       --dry-run=client -o yaml | d8 k apply -f -
     ```

  2. Back up the secret. It contains cloud credentials and discovery data, so store the file securely:

     ```
     d8 k -n kube-system get secret d8-provider-cluster-configuration -o yaml > d8-provider-
     cluster-configuration-backup.yaml
     ```

  3. Allow the deletion. The secret is protected by an admission webhook and cannot be deleted without the annotation:

     ```
     d8 k -n kube-system annotate secret d8-provider-cluster-configuration deckhouse.io/allow-
     delete=true
     ```

  4. Delete the secret:

     ```
     d8 k -n kube-system delete secret d8-provider-cluster-configuration
     ```

Module cni-cilium

- CiliumAgentEndpointsNotReady CE S4
  ▼ **Over 50% of all known endpoints aren't ready in agent NAMESPACE/POD_NAME.**

  For details, refer to the logs of the agent:

  ```
  d8 k -n NAMESPACE logs POD_NAME
  ```

- CiliumAgentMapPressureCritical CE S4
  ▾ **eBPF map MAP_NAME exceeds 90% utilization in agent NAMESPACE/POD_NAME.**

  The eBPF map resource utilization limit has almost been reached.

  Check with the vendor for potential remediation steps.

- CiliumAgentMetricNotFound CE S4
  ▾ **Agent NAMESPACE/POD_NAME isn't sending some metrics.**

  Steps to troubleshoot:

  1. Check the logs of the agent:

     ```
     d8 k -n NAMESPACE logs POD_NAME
     ```

  2. Verify the agent's health status:

     ```
     d8 k -n NAMESPACE exec -ti POD_NAME cilium-health status
     ```

  3. Compare the metrics with those of a neighboring agent.

  > **i** Note that the absence of metrics can indirectly indicate that new pods can't be created on the node due to connectivity issues with the agent.

- CiliumAgentPolicyImportErrors CE S4
  ▾ **Agent NAMESPACE/POD_NAME fails to import policies.**

  For details, refer to the logs of the agent:

  ```
  d8 k -n NAMESPACE logs POD_NAME
  ```

- CiliumAgentUnreachableHealthEndpoints CE S4
  ▾ **Agent NAMESPACE/POD_NAME can't reach some of the node health endpoints.**

  For details, query Cilium health status API:

  ```
  d8 k -n NAMESPACE exec POD_NAME -- cilium-health status
  ```

  You can also refer to the agent logs:

  ```
  d8 k -n NAMESPACE logs POD_NAME
  ```

- CniCiliumNetworkPeeringWithoutPeeringModule EE S4
  ▾ **NetworkPeering is enabled, but the peering module is disabled.**

  NetworkPeering connects the clusters peered by the `peering` module. With the module disabled, no new mesh with a peer comes up, and the meshes already configured are not updated.

  To resolve this issue, enable the `peering` module, or set `networkPeering.enabled: false` in the `cni-cilium` ModuleConfig.

- CniCiliumNonStandardVXLANPortFound CE S4
  ▾ **Cilium configuration uses a non-standard VXLAN port.**

  The Cilium configuration specifies a non-standard VXLAN port `XXX`. The recommended port number is `XXX`.

  To resolve this issue, update the `tunnel-port` parameter in the `cilium-configmap` ConfigMap located in the `d8-cni-cilium` namespace to match the recommended port.

  If you configured the non-standard port on purpose, ignore this alert.

- CniCiliumOrphanEgressGatewayPolicyFound SE-PLUS S4
  ▾ **Orphaned EgressGatewayPolicy with an irrelevant EgressGateway name has been found.**

  The cluster contains an orphaned EgressGatewayPolicy named `NAME` with an irrelevant EgressGateway name.

To resolve this issue, verify the EgressGateway name specified in the EgressGatewayPolicy resource `EGRESSGATEWAY` and update it as needed.

- CNICiliumPolicyWithRequiresFieldsFound CE S4
  ▼ The XXX XXXNAMESPACE/XXXNAME uses the fromRequires or toRequires fields.

  The XXX `NAME` XXX in the `NAMESPACE` namespaceXXX uses the `fromRequires` or `toRequires` fields.

  Cilium 1.19 and later doesn't support these fields. The Cilium agent of these versions can't read such policies and fails on all nodes. Deckhouse won't deploy a release with such a Cilium version until all these policies are rewritten.

  To resolve this issue, rewrite each `fromRequires` constraint as an `ingressDeny` rule with an inverted selector. Don't move the selector into the deny rule as is: this inverts the policy. A deny rule wins over allow rules of any policy, so it keeps the original scope: `fromRequires` applied to all policies selecting the endpoint.

  For example, `fromRequires` with `matchLabels: {env: prod}` becomes:

  ```
  ingressDeny:
  - fromEndpoints:
    - matchExpressions:
      - {key: env, operator: NotIn, values: [prod]}
  XXX
    - matchExpressions:
      - {key: k8s:io.kubernetes.pod.namespace, operator: Exists}
      - {key: k8s:io.kubernetes.pod.namespace, operator: NotIn, values: [NAMESPACE]}
  XXX
  ```

  - Add a separate `NotIn` selector for each label of the constraint. XXX
  - Keep the second selector: in a CiliumNetworkPolicy, `fromRequires` also implied the policy namespace, so sources from other namespaces were rejected. The `Exists` condition is required, otherwise the rule also blocks the host, the world, and other sources without a namespace. XXX
  - Rewrite `toRequires` the same way, as an `egressDeny` rule with `toEndpoints`.
  - Add the deny rule first, check the traffic, and only then remove `fromRequires` and `toRequires`.

  To list all affected policies, use the `d8_cni_cilium_policy_with_requires_fields == 1` expression in Prometheus.

- D8IPv4OptionsGuardAuditMode CE S9
  ▼ The CVE-2026-98432 filter only counts packets on VALUE nodes of the cluster.

  The `ipv4OptionsGuard.mode` of the CNI module is `Audit` on VALUE nodes: packets with IP options are only counted, not dropped, and MPTCP stays enabled. The nodes remain exposed to CVE-2026-98432.

  Clusters that existed before the mitigation get `Audit` by default. Once the `D8IPv4OptionsGuardMatchedTraffic` alert shows that no workload relies on IP options, switch to `Enforce` in the ModuleConfig of the CNI module (`cni-cilium`, `cni-flannel` or `cni-simple-bridge`):

  ```
  spec:
    settings:
      ipv4OptionsGuard:
        mode: Enforce
  ```

- D8IPv4OptionsGuardBackendMismatch CE S6
  ▼ The CVE-2026-98432 filter on the node NODE_NAME uses a different iptables mode than iptables-wrapper selected.

  The node `NODE_NAME` is protected, but the filter uses `XXX`: the kernel modules of the mode selected by iptables-wrapper are not loaded, while those of the other mode are.

  The details are in the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

  The filter and the other Deckhouse components use different packet filtering frameworks on this node. Such a security configuration is harder to audit and troubleshoot.

Possible actions:

- Find out why the kernel modules of the mode selected by iptables-wrapper are not loaded on the node.
- If loading these kernel modules is acceptable, set `ipv4OptionsGuard.allowKernelModuleLoad: true` in the CNI module settings.

- D8IPv4OptionsGuardFilterBypassed CE S6
  ▼ **Packets can skip the CVE-2026-98432 filter in VALUE network namespaces on the node NODE_NAME.**

  The node `NODE_NAME` uses legacy iptables. In VALUE network namespaces, a rule in the `PREROUTING` chain of the `raw` table ahead of the jump to `D8-IPV4OPT-GUARD` can end the traversal of the table (for example, `-j ACCEPT`). Packets accepted by that rule never reach the filter.

  The guard puts its jump first when it installs the filter, but does not move it later, so as not to fight with other software on the node that manages its own rules. The affected network namespaces are named in the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

  Possible actions:

  - Find the software that inserted the rule (`iptables-legacy -t raw -S PREROUTING` in the network namespace) and make it append the rule instead, or use a target that does not end the traversal.
  - Or put the jump first by hand: `iptables-legacy -t raw -I PREROUTING 1 -j D8-IPV4OPT-GUARD`. The guard removes the old jump on its next pass.
- D8IPv4OptionsGuardMatchedTraffic CE S7
  ▼ **IPv4 packets with IP options were seen on the node NODE_NAME in the Audit mode.**

  Over the last hour, the ipv4-options-guard sidecar matched VALUE IPv4 packets with IP options (rule `XXX`) on the node `NODE_NAME`.

  In the `Audit` mode they are only counted. In the `Enforce` mode they would be dropped, and this alert is not raised.

  Legitimate TCP traffic almost never carries IP options. If a workload relies on them (for example, CIPSO labeled networking), exclude the node with the `ipv4-options-guard.deckhouse.io/disabled: "true"` label before switching `ipv4OptionsGuard.mode` to `Enforce`. Otherwise, this may be an attempt to exploit CVE-2026-98432.

- D8IPv4OptionsGuardMetricsAbsent CE S4
  ▼ **The CVE-2026-98432 filter state is unknown on the node NODE_NAME.**

  The CNI agent pod runs on the node `NODE_NAME`, but Prometheus gets no metrics from its `ipv4-options-guard` container.

  Without these metrics, the other `D8IPv4OptionsGuard*` alerts cannot fire for this node, so it may be unprotected unnoticed.

  Check the `ipv4-options-guard` container of the CNI agent pod on that node and the scraping of its metrics.

- D8IPv4OptionsGuardNodeUnprotected CE S4
  ▼ **The CVE-2026-98432 filter cannot be installed on the node NODE_NAME.**

  The ipv4-options-guard sidecar of the CNI agent could not protect the node `NODE_NAME` (reason: `XXX`).

  - `iptables_wrapper_failed` — iptables-wrapper could not determine the iptables mode of the node.
  - `kernel_modules_not_loaded` — the kernel modules of the mode selected by iptables-wrapper are not loaded, and loading them is not allowed.

  The details are in the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

  The node remains exposed to CVE-2026-98432 until its kernel is updated.

  Possible actions:

  - Update the node kernel to a version with the fix and reboot the node.
  - If the node uses legacy iptables and loading the kernel modules named in the reason is acceptable, set `ipv4OptionsGuard.allowKernelModuleLoad: true` in the CNI module settings.
- D8IPv4OptionsGuardReconcileFailed CE S6
  ▼ **The CVE-2026-98432 filter failed in VALUE network namespaces on the node**

NODE_NAME.

Some network namespaces on the node `NODE_NAME` are not protected.

Check the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

- D8NodeHasUnmetKernelRequirements CE S4
  ▼ Nodes have unmet kernel requirements.

  Deckhouse has detected that some nodes don’t meet the required kernel constraints. As a result, certain modules can’t run on these nodes.

  Kernel requirements for each module:

  - **Cilium module**: Kernel version must be **>= 5.8**.

  To list all affected nodes, use the `d8_node_kernel_does_not_satisfy_requirements == 1` expression in Prometheus.

Module cni-flannel

- D8IPv4OptionsGuardAuditMode CE S9
  ▼ The CVE-2026-98432 filter only counts packets on VALUE nodes of the cluster.

  The `ipv4OptionsGuard.mode` of the CNI module is `Audit` on VALUE nodes: packets with IP options are only counted, not dropped, and MPTCP stays enabled. The nodes remain exposed to CVE-2026-98432.

  Clusters that existed before the mitigation get `Audit` by default. Once the `D8IPv4OptionsGuardMatchedTraffic` alert shows that no workload relies on IP options, switch to `Enforce` in the ModuleConfig of the CNI module (`cni-cilium`, `cni-flannel` or `cni-simple-bridge`):

  ```
  spec:
    settings:
      ipv4OptionsGuard:
        mode: Enforce
  ```

- D8IPv4OptionsGuardBackendMismatch CE S6
  ▼ The CVE-2026-98432 filter on the node NODE_NAME uses a different iptables mode than iptables-wrapper selected.

  The node `NODE_NAME` is protected, but the filter uses `XXX`: the kernel modules of the mode selected by iptables-wrapper are not loaded, while those of the other mode are.

  The details are in the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

  The filter and the other Deckhouse components use different packet filtering frameworks on this node. Such a security configuration is harder to audit and troubleshoot.

  Possible actions:

  - Find out why the kernel modules of the mode selected by iptables-wrapper are not loaded on the node.
  - If loading these kernel modules is acceptable, set `ipv4OptionsGuard.allowKernelModuleLoad: true` in the CNI module settings.
- D8IPv4OptionsGuardFilterBypassed CE S6
  ▼ Packets can skip the CVE-2026-98432 filter in VALUE network namespaces on the node NODE_NAME.

  The node `NODE_NAME` uses legacy iptables. In VALUE network namespaces, a rule in the `PREROUTING` chain of the `raw` table ahead of the jump to `D8-IPV4OPT-GUARD` can end the traversal of the table (for example, `-j ACCEPT`). Packets accepted by that rule never reach the filter.

  The guard puts its jump first when it installs the filter, but does not move it later, so as not to fight with other software on the node that manages its own rules. The affected network namespaces are named in the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

  Possible actions:

  - Find the software that inserted the rule (`iptables-legacy -t raw -S PREROUTING` in the network namespace) and make it append the rule instead, or use a target that does not end the traversal.

    - Or put the jump first by hand: `iptables-legacy -t raw -I PREROUTING 1 -j D8-IPV4OPT-GUARD`. The guard removes the old jump on its next pass.
- D8IPv4OptionsGuardMatchedTraffic CE S7
  ▾ IPv4 packets with IP options were seen on the node NODE_NAME in the Audit mode.

  Over the last hour, the ipv4-options-guard sidecar matched VALUE IPv4 packets with IP options (rule `XXX`) on the node `NODE_NAME`.

  In the `Audit` mode they are only counted. In the `Enforce` mode they would be dropped, and this alert is not raised.

  Legitimate TCP traffic almost never carries IP options. If a workload relies on them (for example, CIPSO labeled networking), exclude the node with the `ipv4-options-guard.deckhouse.io/disabled: "true"` label before switching `ipv4OptionsGuard.mode` to `Enforce`. Otherwise, this may be an attempt to exploit CVE-2026-98432.

- D8IPv4OptionsGuardMetricsAbsent CE S4
  ▾ The CVE-2026-98432 filter state is unknown on the node NODE_NAME.

  The CNI agent pod runs on the node `NODE_NAME`, but Prometheus gets no metrics from its `ipv4-options-guard` container.

  Without these metrics, the other `D8IPv4OptionsGuard*` alerts cannot fire for this node, so it may be unprotected unnoticed.

  Check the `ipv4-options-guard` container of the CNI agent pod on that node and the scraping of its metrics.

- D8IPv4OptionsGuardNodeUnprotected CE S4
  ▾ The CVE-2026-98432 filter cannot be installed on the node NODE_NAME.

  The ipv4-options-guard sidecar of the CNI agent could not protect the node `NODE_NAME` (reason: `XXX`).

    - `iptables_wrapper_failed` — iptables-wrapper could not determine the iptables mode of the node.
    - `kernel_modules_not_loaded` — the kernel modules of the mode selected by iptables-wrapper are not loaded, and loading them is not allowed.

  The details are in the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

  The node remains exposed to CVE-2026-98432 until its kernel is updated.

  Possible actions:

    - Update the node kernel to a version with the fix and reboot the node.
    - If the node uses legacy iptables and loading the kernel modules named in the reason is acceptable, set `ipv4OptionsGuard.allowKernelModuleLoad: true` in the CNI module settings.
- D8IPv4OptionsGuardReconcileFailed CE S6
  ▾ The CVE-2026-98432 filter failed in VALUE network namespaces on the node NODE_NAME.

  Some network namespaces on the node `NODE_NAME` are not protected.

  Check the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

Module cni-simple-bridge

- D8IPv4OptionsGuardAuditMode CE S9
  ▾ The CVE-2026-98432 filter only counts packets on VALUE nodes of the cluster.

  The `ipv4OptionsGuard.mode` of the CNI module is `Audit` on VALUE nodes: packets with IP options are only counted, not dropped, and MPTCP stays enabled. The nodes remain exposed to CVE-2026-98432.

  Clusters that existed before the mitigation get `Audit` by default. Once the `D8IPv4OptionsGuardMatchedTraffic` alert shows that no workload relies on IP options, switch to `Enforce` in the ModuleConfig of the CNI module (`cni-cilium`, `cni-flannel` or `cni-simple-bridge`):

- D8IPv4OptionsGuardReconcileFailed CE S6
  ▾ **The CVE-2026-98432 filter failed in VALUE network namespaces on the node NODE_NAME.**

  Some network namespaces on the node `NODE_NAME` are not protected.

  Check the logs of the `ipv4-options-guard` container of the CNI agent pod on that node.

Module control-plane-manager

- D8ControlPlaneComponentsResourcesInsufficientCapacity CE S5
  ▾ **Automatic control-plane resource tuning cannot increase XXX requests due to lack of available capacity.**

  Automatic control-plane resource tuning attempted to increase `XXX` requests for one or more control-plane components (kube-apiserver, etcd, kube-controller-manager, kube-scheduler), but the calculated requests exceed the available capacity of at least one master node after accounting for the kubelet reservation and resource requests of other (non-control-plane) pods already scheduled on the node.

  XXX Additional memory required: `XXXB`. XXX Additional CPU required: `VALUEm` CPU. XXX

  To resolve this, free up resources on master nodes by moving or reducing other workloads or increase the CPU or RAM available on the nodes.

  To disable automatic tuning for this resource and manage requests manually, set `spec.settings.resourcesRequests.XXX` in the ModuleConfig of `control-plane-manager`.

- D8ControlPlaneDefaultVersionDrift CE S5
  ▾ **Control plane Kubernetes version rollback is blocked (Default soft-guard freeze).**

  The cluster tracks the Deckhouse default Kubernetes version (`kubernetesVersion: Default` in ModuleConfig `control-plane-manager`, or unset ModuleConfig with no ClusterConfiguration pin). That default is now more than 1 minor below the highest version this cluster has ever run (`maxUsed`).

  Rollback blocked: Deckhouse freezes the published target (holds it at the current control-plane version, or at the last desired version when the current one is not published yet) and does not roll Default down toward the lower default. Control plane and kubelet stay on the frozen target until the Deckhouse default catches up within the `maxUsed−1` window.

  Check the `frozen` label on the metric: `frozen="true"` means the digit is held as described above. `frozen="false"` means the window is violated but nothing was left to hold the digit at (for example the `d8-cluster-kubernetes` ConfigMap was deleted), so the published target **has** moved down to the Deckhouse default — pin the intended version explicitly.

  To resolve this alert:

    - Do nothing and wait, if you are happy staying on the version the cluster runs now. This is a valid resolution only while `frozen="true"`: the cluster is not degraded, the version is held, and the alert clears by itself once the Deckhouse default rises back into the `maxUsed−1` window. How long that takes depends on why the default dropped — after a Deckhouse rollback, until you upgrade Deckhouse again; when the release default is simply older than the version this cluster runs, until a Deckhouse release ships a high enough default, which may be several releases away.
    - To keep the current (higher) version and stop the alert now, pin it explicitly:

```
d8 k patch mc control-plane-manager --type merge -p '{"spec":{"settings":
{"kubernetesVersion":"current version"}}}'
```

  - To downgrade deliberately, pin one minor at a time (more than 1 minor below `maxUsed` is rejected):

```
d8 k patch mc control-plane-manager --type merge -p '{"spec":{"settings":
{"kubernetesVersion":"current version - 1 minor"}}}'
```

- D8ControlPlaneManagerObsoleteMonitoringKubernetesControlPlaneModuleConfig CE S9
  ▼ Obsolete monitoring-kubernetes-control-plane ModuleConfig should be removed.

  The `monitoring-kubernetes-control-plane` module was merged into the `control-plane-manager` module, but its ModuleConfig still exists in the cluster and is no longer used.

  Remove it manually:

```
d8 k delete moduleconfig monitoring-kubernetes-control-plane
```

  If the ModuleConfig is deployed from an external source (e.g. a Git repository), make sure it is removed from there so it is not created again.

- D8ControlPlaneManagerPodNotRunning CE S6
  ▼ Controller pod isn't running on node NODE_NAME.

  The `d8-control-plane-manager` pod is either failing or hasn’t been scheduled on node `NODE_NAME`.

  To resolve this issue, check the status of the `kube-system/d8-control-plane-manager` DaemonSet and its pods by running the following command:

```
d8 k -n kube-system get daemonset,pod --selector=app=d8-control-plane-manager
```

- D8ControlPlaneNodeMaintenanceModeEnabled CE S4
  ▼ Maintenance mode is enabled for control-plane node NODE_NAME.

  Control-plane node `NODE NAME` has maintenance mode enabled with label `control-plane-manager.deckhouse.io/maintenance`. While this label is present, the control plane is not managed by `control-plane-manager`.

  If maintenance is complete, remove the label:

```
d8 k label cpn NODE_NAME control-plane-manager.deckhouse.io/maintenance-
```

- D8ControlPlaneOperationRunningTooLong CE S4
  ▼ Control-plane operation XXX for COMPONENT_NAME on node NODE_NAME runs or retries longer than 10 minutes.

  Control-plane operation `XXX` for component `COMPONENT_NAME` on node `NODE_NAME` has been running or retrying for more than 10 minutes.

  Check the corresponding ControlPlaneOperation and logs of the `d8-control-plane-manager` Pod on that node:

```
d8 k get cpo XXX -o yaml
d8 k -n kube-system logs -l app=d8-control-plane-manager --field-selector
spec.nodeName=NODE_NAME
```

- D8EtcdDatabaseHighFragmentationRatio CE S7
  ▼ etcd database size in use is less than 50% of the allocated storage.

  The etcd database size in use on instance `INSTANCE_NAME` is less than 50% of the allocated disk space, indicating potential fragmentation. Additionally, the total storage size exceeds 75% of the configured quota.

  To resolve this issue, defragment the etcd database by running the following command:

```
d8 k -n kube-system exec -ti etcd-NODE_NAME -- /usr/bin/etcdctl \
  --cacert /etc/kubernetes/pki/etcd/ca.crt \
  --cert /etc/kubernetes/pki/etcd/ca.crt \
  --key /etc/kubernetes/pki/etcd/ca.key \
  --endpoints https://127.0.0.1:2379/ defrag --command-timeout=30s
```

- D8EtcdExcessiveDatabaseGrowth CE S4
  ▼ **etcd cluster database is growing rapidly.**

  Based on the growth rate observed over the last six hours, Deckhouse predicts that the etcd database will run out of disk space within one day on instance `INSTANCE_NAME`.

  To prevent disruptions, investigate the cause and take necessary action.

- D8EtcdHighRequestsLatency CE S5
  ▼ **Etcd request latency (p99) has exceeded 800 ms multiple times in the past hour.**

  The 99th percentile of etcd request duration on `INSTANCE_NAME` has exceeded 800 ms more than twice in the last hour.

  High etcd latency can cause API server timeouts, slow admission webhooks, and general cluster instability.

  Investigate the following:

  - **Node disk I/O**: Etcd is extremely sensitive to disk performance. Check disk utilization and I/O wait on the control plane node.
  - **Network-attached storage**: If the etcd data directory resides on NFS, Ceph, or another network storage, check connectivity and latency to the storage backend. Etcd requires a consistently low-latency local disk (SSD recommended).
  - **Control plane summary**: Review the **Kubernetes Cluster → Control Plane Status** Grafana dashboard for an overall picture of API server and etcd health, request rates, and error rates.
  - **Node base performance**: Check node CPU and RAM utilization and load average. If the node is CPU-bound (load average significantly exceeds the number of CPU cores), consider scaling up the control plane node.

- D8InvalidEtcdDefragCronSchedule CE S6
  ▼ **Invalid etcd defragmentation cron schedule in ModuleConfig.**

  The `controlPlaneManager.etcd.defrag.cronSchedule` value `XXX` is not a valid cron expression.

  Deckhouse has fallen back to the default schedule (`0 1 * * *`) to keep defragmentation running.

  To fix this, set a valid 5-field cron expression:

  ```
  d8 k patch moduleconfig control-plane-manager --type merge \
    -p '{"spec":{"settings":{"etcd":{"defrag":{"cronSchedule":"0 1 * * *"}}}}}'
  ```

  Valid examples:

  - `0 1 * * *` — daily at 01:00 UTC
  - `0 */6 * * *` — every 6 hours
  - `30 2 * * 0` — weekly on Sunday at 02:30 UTC

- D8KubeEtcdDatabaseSizeCloseToTheLimit CE S3
  ▼ **etcd database size is approaching the limit.**

  The etcd database size on `NODE_NAME` is nearing its size limit. This may be caused by a high number of events, such as pod evictions or the recent creation of numerous resources in the cluster.

  Possible solutions:

  - Defragment the etcd database by running the following command:

    ```
    d8 k -n kube-system exec -ti etcd-NODE_NAME -- /usr/bin/etcdctl \
      --cacert /etc/kubernetes/pki/etcd/ca.crt \
      --cert /etc/kubernetes/pki/etcd/ca.crt \
      --key /etc/kubernetes/pki/etcd/ca.key \
      --endpoints https://127.0.0.1:2379/ defrag --command-timeout=30s
    ```

  - Increase node memory. Starting from 24 GB, `quota-backend-bytes` will increase by 1 GB for every extra 8 GB of memory.

    Example:

Node memory	quota-backend-bytes
16 GB	2147483648 (2 GB)
24 GB	3221225472 (3 GB)
32 GB	4294967296 (4 GB)
40 GB	5368709120 (5 GB)
48 GB	6442450944 (6 GB)
56 GB	7516192768 (7 GB)
64 GB	8589934592 (8 GB)
72 GB	8589934592 (8 GB)
…	…

- D8KubernetesStaleTokensDetected CE S8
  ▼ Stale service account tokens detected for XXX/XXX.

  Service account `XXX/XXX` is using a stale token. This issue may occur if an application reads the token only at startup and does not reload it periodically. As a result, an outdated token might be used, leading to security breach and authentication failures.

  Recommended actions:

  - Ensure your application is configured to periodically reload the token from the file system.
  - Verify that you are using an up-to-date client library that supports automatic token rotation.

  Note that currently these tokens are not blocked because the `--service-account-extend-token-expiration` flag is enabled by default (`Default: true`). With this flag enabled, admission-injected tokens are extended up to 1 year during token generation to facilitate a safe transition from legacy tokens to the bound service account token feature, ignoring the value of `service-account-max-token-expiration`.

  For further investigation: You can find the problematic pods using the following command:

```
d8 k get pods -A -o json | jq -r '.items[] | select(.spec.serviceAccountName=="XXX"
and .metadata.namespace=="XXX") | .metadata.name'
```

- D8KubernetesVersionIsDeprecated CE S7
  ▼ Kubernetes version VERSION_NUMBER is deprecated.

  The current Kubernetes version `VERSION_NUMBER` has been deprecated, and support for it will be removed in upcoming releases.

  Please migrate to the next kubernetes version (at least 1.34)

  Read documentation about how to update the Kubernetes version in the cluster.

- D8NeedDecreaseEtcdQuotaBackendBytes CE S6
  ▼ Deckhouse suggests reducing quota-backend-bytes.

  When the control plane node memory is reduced, Deckhouse may suggest reducing `quota-backend-bytes`. While Deckhouse is capable of automatically increasing this value, reducing it must be done manually.

  To modify `quota-backend-bytes`, set the `controlPlaneManager.etcd.maxDbSize` parameter. Before setting a new value, check the current database usage on every control plane node by running:

```
for pod in $(d8 k get pod -n kube-system -l component=etcd,tier=control-plane -o name); do
  d8 k -n kube-system exec -ti "$pod" -- /usr/bin/etcdctl \
    --cacert /etc/kubernetes/pki/etcd/ca.crt \
    --cert /etc/kubernetes/pki/etcd/ca.crt \
    --key /etc/kubernetes/pki/etcd/ca.key \
    endpoint status -w json | jq --arg a "$pod" -r \
    '.[0].Status.dbSize / 1024 / 1024 | tostring | $a + ": " + . + " MB"';
done
```

Things to note:

- The maximum value for `controlPlaneManager.etcd.maxDbSize` is 8 GB.
- If control plane nodes have less than 24 GB, set `controlPlaneManager.etcd.maxDbSize` to 2 GB.
- Starting from 24 GB, `quota-backend-bytes` will increase by 1 GB for every extra 8 GB of memory.

  Example:

Node memory	quota-backend-bytes
16 GB	2147483648 (2 GB)
24 GB	3221225472 (3 GB)
32 GB	4294967296 (4 GB)
40 GB	5368709120 (5 GB)
48 GB	6442450944 (6 GB)
56 GB	7516192768 (7 GB)
64 GB	8589934592 (8 GB)
72 GB	8589934592 (8 GB)
…	…

- D8ObsoleteClusterDomainInClusterConfiguration CE S6
  ▼ The obsolete clusterDomain field is still present in ClusterConfiguration.

  `ClusterConfiguration` still carries the obsolete `clusterDomain` field. The place to manage the cluster domain is ModuleConfig `control-plane-manager`.

  This fires simply because the field is present, even if ModuleConfig `control-plane-manager` already overrides it - the goal is to remove the deprecated field, not just override it.

  To resolve this alert:

  1. If ModuleConfig `control-plane-manager` does not exist, create it:

     ```
     d8 s module enable control-plane-manager
     ```

  2. Migrate the value straight from the Secret into ModuleConfig:

     ```
     DOMAIN=$(d8 k -n kube-system get secret d8-cluster-configuration \
       -o jsonpath='{.data.cluster-configuration\.yaml}' | base64 -d \
       | sed -n 's/^clusterDomain:[[:space:]]*//p' | tr -d "\"'")

     d8 k patch moduleconfig control-plane-manager --type merge \
       -p "{\"spec\":{\"version\":3,\"settings\":{\"network\":
     {\"clusterDomain\":\"$DOMAIN\"}}}}"
     ```

     The value must match the one the cluster currently runs with; admission rejects a mismatch.

  3. Remove the field from ClusterConfiguration:

     ```
     d8 system edit cluster-configuration
     ```

     Delete `clusterDomain`, then save.

  Once the field is removed from `ClusterConfiguration`, this alert is resolved.

- D8ObsoleteEncryptionAlgorithmInClusterConfiguration CE S6
  ▼ Obsolete encryptionAlgorithm in ClusterConfiguration needs to be migrated to control-plane-manager ModuleConfig.

  The `encryptionAlgorithm` field is set to a non-default value in ClusterConfiguration but has not been migrated to ModuleConfig `control-plane-manager` yet.

  Until the migration is complete, the value from ClusterConfiguration is used to avoid unintended

certificate rotation.

To resolve this alert, migrate the setting:

1. If ModuleConfig `control-plane-manager` does not exist, create it first:

   ```
   d8 s module enable control-plane-manager
   ```

2. Migrate the value from ClusterConfiguration to ModuleConfig in one command:

   ```
   d8 k patch moduleconfig control-plane-manager --type merge -p "$(cat <<EOF
   {"spec": {"version": 3, "settings": {"encryptionAlgorithm": "$(d8 k -n kube-system get secret d8-cluster-configuration -o jsonpath='{.data.cluster-configuration\.yaml}' | base64 -d | grep encryptionAlgorithm | awk '{print $2}')"}}}
   EOF
   )"
   ```

Once ModuleConfig is updated, this alert will be resolved automatically.

1. Remove `encryptionAlgorithm` from ClusterConfiguration:

   ```
   d8 system edit cluster-configuration
   ```

   Delete the `encryptionAlgorithm` field and save.

- D8ObsoleteGlobalControlPlaneResourcesRequests CE S6
  ▼ **Obsolete global control-plane resource requests need to be migrated.**

  Control-plane resource requests are being migrated from global settings to `moduleconfig control-plane-manager`.

  The obsolete settings are still used as a fallback, but they should be moved to the `control-plane-manager` module settings. The migration does not change the meaning of the values: `cpu` and `memory` remain the total resource requests for control-plane components on each master node.

  To complete the migration, follow the steps below:

  1. Review the current obsolete settings in `moduleconfig global`:

     ```
     d8 k get mc global -o jsonpath='{.spec.settings.modules.resourcesRequests.controlPlane}'; echo
     ```

     Example of obsolete settings:

     ```
     spec:
       settings:
         modules:
           resourcesRequests:
             controlPlane:
               cpu: 1000m
               memory: 500Mi
     ```

  2. Make sure the `moduleconfig control-plane-manager` resource exists and uses settings version `3`.

     If the resource does not exist, create it:

     ```
     d8 s module enable control-plane-manager
     ```

     Set the settings version:

     ```
     d8 k patch mc control-plane-manager --type merge \
       -p '{"spec":{"version":3}}'
     ```

3. Copy the obsolete values from `moduleconfig global` to `moduleconfig control-plane-manager`.

   The following command preserves the original JSON value types, including numeric CPU values:

   ```
   d8 k patch mc control-plane-manager --type merge -p "$(
     d8 k get mc global -o json | jq -c \
       '{"spec":{"version":3,"settings":{"resourcesRequests":
   .spec.settings.modules.resourcesRequests.controlPlane}}}'
   )"
   ```

   After migration, the `moduleconfig control-plane-manager` resource should contain:

   ```
   spec:
     version: 3
     settings:
       resourcesRequests:
         cpu: 1000m
         memory: 500Mi
   ```

4. Check that the values were applied:

   ```
   d8 k get mc control-plane-manager -o
   jsonpath='{.spec.settings.resourcesRequests}'; echo
   ```

5. Remove the obsolete settings from `moduleconfig global`:

   ```
   d8 k patch mc global --type merge \
     -p '{"spec":{"settings":{"modules":{"resourcesRequests":null}}}}'
   ```

- D8ObsoleteKubernetesVersionFieldInClusterConfiguration CE S6
  ▾ **The obsolete kubernetesVersion field is still present in ClusterConfiguration.**

  `ClusterConfiguration` still carries the obsolete `kubernetesVersion` field. The place to manage the cluster Kubernetes version is `settings.kubernetesVersion` in ModuleConfig `control-plane-manager`.

  To resolve this alert:

  1. If ModuleConfig `control-plane-manager` does not exist, create it:

     ```
     d8 s module enable control-plane-manager
     ```

  2. Read what the obsolete field currently holds:

     ```
     d8 k -n kube-system get secret d8-cluster-configuration -o jsonpath='{.data.cluster-
     configuration\.yaml}' | base64 -d | grep '^kubernetesVersion:'
     ```

  3. If ModuleConfig has no `kubernetesVersion` yet, set that same value there, so the cluster keeps the version it runs today (replace `1.34` with what you saw; if you saw `Automatic`, use `Default`):

     ```
     d8 k patch moduleconfig control-plane-manager --type merge -p '{"spec":
     {"version":3,"settings":{"kubernetesVersion":"1.34"}}}'
     ```

     Set `Default` instead if you want Deckhouse to choose the version. Note that this starts an upgrade whenever the release default is higher than the pinned version:

     ```
     d8 k patch moduleconfig control-plane-manager --type merge -p '{"spec":
     {"version":3,"settings":{"kubernetesVersion":"Default"}}}'
     ```

  4. Remove `kubernetesVersion` from ClusterConfiguration:

```
d8 system edit cluster-configuration
```

Delete the `kubernetesVersion` field and save.

Once the `kubernetesVersion` field is removed from `ClusterConfiguration`, this alert is resolved.

- D8ObsoleteNetworkFieldsInClusterConfiguration CE S6
  ▼ **Obsolete network fields are still present in ClusterConfiguration.**

  `ClusterConfiguration` still carries one or more of the obsolete `podSubnetCIDR`, `serviceSubnetCIDR`, `podSubnetNodeCIDRPrefix` fields. The place to manage the cluster's network is the `network` section of ModuleConfig `control-plane-manager`.

  This fires simply because a field is present, even if ModuleConfig `control-plane-manager` already overrides it - the goal is to remove the deprecated field, not just override it.

  To resolve this alert:

  1. If ModuleConfig `control-plane-manager` does not exist, create it:

     ```
     d8 s module enable control-plane-manager
     ```

  2. Migrate the values straight from the Secret into ModuleConfig using the following command:

     ```
     d8 k patch moduleconfig control-plane-manager --type merge -p "$(
       d8 k -n kube-system get secret d8-cluster-configuration -o jsonpath='{.data.cluster-configuration\.yaml}' | base64 -d \
         | yq -o=json '{"podSubnetCIDR": .podSubnetCIDR, "serviceSubnetCIDR": .serviceSubnetCIDR, "podSubnetNodeCIDRPrefix": .podSubnetNodeCIDRPrefix}' \
         | jq -c '{spec: {version: 3, settings: {network: with_entries(select(.value != null))}}}'
     )"
     ```

     Once a field is set in ModuleConfig this way, it cannot be migrated again: the network group is immutable once set.

  3. Remove all three fields from ClusterConfiguration:

     ```
     d8 system edit cluster-configuration
     ```

     Delete `podSubnetCIDR`, `serviceSubnetCIDR` and `podSubnetNodeCIDRPrefix`, then save.

  Once all three fields are removed from `ClusterConfiguration`, this alert is resolved.

- D8ObsoletePublishAPIinUserAuthn CE S6
  ▼ **Obsolete Publish API settings in user-authn need to be migrated.**

  Publish API ingress settings are being migrated from `mc user-authn` to `mc control-plane-manager`.

  To complete the migration, follow the steps below:

  1. Review current settings for `publishAPI` in the `moduleconfig user-authn` resource.

     Note that legacy `user-authn` `spec.version: 1` uses `publishAPI.enable` instead of `publishAPI.enabled`. No manual rewrite is required: the command in step 4 uses the normalized payload from the temporary ConfigMap.

  2. If the `moduleconfig control-plane-manager` resource exists, update its spec to `spec.version: 3`. If `settings.apiserver.loadBalancer` is set, migrate it to `settings.apiserver.publishAPI.loadBalancer`. If the resource does not exist, proceed to step 3.

  3. If `moduleconfig control-plane-manager` does not exist, create it via `d8`:

     ```
     d8 s module enable control-plane-manager
     ```

     And set the settings version:

```
d8 k patch moduleconfig control-plane-manager --type merge \
-p '{"spec":{"version":3}}'
```

4. Apply the migrated settings into `moduleconfig control-plane-manager` from temporary configMap by executing the following script:

```
d8 k patch moduleconfig control-plane-manager --type merge -p "$(cat <<EOF
{"spec": {"settings": {"apiserver": {"publishAPI": {"ingress": \
$(d8 k -n kube-system get cm d8-publishapi-config-migration -
ojsonpath='{.data.config}')
   }}}}}
EOF
)"
```

5. Remove obsolete `spec.settings.publishAPI` section from `moduleconfig user-authn`.

- D8ProblematicFeatureGateInUse CE S9
  ▼ Feature gate XXX is STATUS_REFERENCE in current Kubernetes version XXX and should be removed from the configuration. Is not using in the cluster control-plane.

  The feature gate `XXX` is currently enabled in the control-plane-manager ModuleConfig, but it is STATUS_REFERENCE in the current Kubernetes version `XXX`.

  XXX This feature gate does not exist in any component (apiserver, kube-controller-manager, kube-scheduler, kubelet) and is not being applied to the cluster. XXX

  Recommended actions:

  1. Remove `XXX` from the `spec.settings.enabledFeatureGates` list in the control-plane-manager ModuleConfig:

```
d8 k edit mc control-plane-manager
```

  For more information about Kubernetes feature gates, refer to the official documentation.

- D8UsingFeatureGateWillBeDeprecated CE S9
  ▼ Feature gate XXX will be deprecated in Kubernetes version XXX.

  The feature gate `XXX` is currently enabled in the control-plane-manager ModuleConfig, but it will be deprecated in Kubernetes version `XXX`.

  Current Kubernetes version: `XXX`

  Recommended actions:

  1. Review the usage of this feature gate in your cluster.
  2. Plan migration away from this feature gate before upgrading to version `XXX`.
  3. Remove `XXX` from the `spec.settings.enabledFeatureGates` list in the control-plane-manager ModuleConfig:

```
d8 k edit mc control-plane-manager
```

  For more information about Kubernetes feature gates, refer to the official documentation.

- HelmReleasesHasResourcesWithDeprecatedVersions CE S5
  ▼ At least one Helm release contains resources with deprecated apiVersion, which will be removed in Kubernetes version VERSION_NUMBER.

  To list all affected resources, run the following Prometheus query:

```
max by (helm_release_namespace, helm_release_name, helm_version,
resource_namespace, resource_name, api_version, kind, k8s_version)
(resource_versions_compatibility) == 1
```

  For more details on upgrading deprecated resources, refer to the Kubernetes deprecation guide available at `https://kubernetes.io/docs/reference/using-api/deprecation-guide/#vXXX`.

  Note that the check runs once per hour, so this alert should resolve within an hour after migrating deprecated resources.

- HelmReleasesHasResourcesWithUnsupportedVersions CE S4

▾ At least one Helm release contains resources with unsupported apiVersion for Kubernetes version VERSION_NUMBER.

To list all affected resources, run the following Prometheus query:

```
max by (helm_release_namespace, helm_release_name, helm_version,
resource_namespace, resource_name, api_version, kind, k8s_version)
(resource_versions_compatibility) == 2
```

For more details on migrating deprecated resources, refer to the Kubernetes deprecation guide available at `https://kubernetes.io/docs/reference/using-api/deprecation-guide/#vXXX`.

Note that the check runs once per hour, so this alert should resolve within an hour after migrating deprecated resources.

- K8SApiserverDown CE S3
  ▾ API servers can't be reached.

  No API servers are reachable, or they have all disappeared from service discovery.

- K8sCertificateExpiration CE S5
  ▾ Kubernetes has API clients with soon-to-expire certificates.

  Some clients are connecting to COMPONENT_NAME with certificates that will expire in less than a day on node `COMPONENT_NAME`.

  To check control plane certificates, use kubeadm:

  1. Install kubeadm using the following command:

     ```
     apt install kubeadm=1.24.*
     ```

  2. Check certificates:

     ```
     kubeadm alpha certs check-expiration
     ```

  To check kubelet certificates, do the following on each node:

  1. Check kubelet configuration:

     ```
     ps aux \
       | grep "/usr/bin/kubelet" \
       | grep -o -e "--kubeconfig=\S*" \
       | cut -f2 -d"=" \
       | xargs cat
     ```

  2. Locate the `client-certificate` or `client-certificate-data` field.
  3. Check certificate expiration using OpenSSL.

  Note that there are no tools to find other stale kubeconfig files. Consider enabling the `control-plane-manager` module for advanced debugging.

- K8sCertificateExpiration CE S6
  ▾ Kubernetes has API clients with soon-to-expire certificates.

  Some clients are connecting to COMPONENT_NAME with certificates that will expire in less than 7 days on node `NODE_NAME`.

  To check control plane certificates, use kubeadm:

  1. Install kubeadm using the following command:

     ```
     apt install kubeadm=1.24.*
     ```

  2. Check certificates:

     ```
     kubeadm alpha certs check-expiration
     ```

  To check kubelet certificates, do the following on each node:

1. Check kubelet configuration:

   ```
   ps aux \
     | grep "/usr/bin/kubelet" \
     | grep -o -e "--kubeconfig=\S*" \
     | cut -f2 -d"=" \
     | xargs cat
   ```

2. Locate the `client-certificate` or `client-certificate-data` field.
3. Check certificate expiration using OpenSSL.

Note that there are no tools to find other stale kubeconfig files. Consider enabling the `control-plane-manager` module for advanced debugging.

- K8SControllerManagerTargetDown CE S3
  ▼ **Controller manager is down.**

  There is no running kube-controller-manager. As a result, deployments and replication controllers are not progressing.

- K8SSchedulerTargetDown CE S3
  ▼ **Scheduler is down.**

  The Kubernetes scheduler is not running. As a result, new pods are not being assigned to nodes.

- KubeEtcdHighFsyncDurations CE S7
  ▼ **Syncing (fsync) WAL files to disk is slow.**

  In the last 15 minutes, the 99th percentile of the fsync duration for WAL files exceeded 0.5 seconds: VALUE.

  Possible causes:

  - High disk latency where etcd data is stored.
  - High CPU usage on the node.

- KubeEtcdHighNumberOfLeaderChanges CE S5
  ▼ **The etcd cluster is re-electing the leader too frequently.**

  There have been VALUE leader re-elections for the etcd cluster member running on node `NODE_NAME` in the last 10 minutes.

  Possible causes:

  - High disk latency where etcd data is stored.
  - High CPU usage on the node.
  - Degradation of network connectivity between cluster members in the multi-master mode.

- KubeEtcdInsufficientMembers CE S4
  ▼ **Insufficient members in the etcd cluster.**

  The etcd cluster has too few members, increasing the risk of failure if another member becomes unavailable. To resolve this issue, check the status of etcd Pods: `bash d8 k -n kube-system get pod -l component=etcd`

- KubeEtcdNoLeader CE S4
  ▼ **The etcd cluster member running on node NODE_NAME has lost the leader.**

  To resolve this issue, check the status of the etcd Pods: `bash d8 k -n kube-system get pod -l component=etcd | grep NODE_NAME`

- KubeEtcdTargetAbsent CE S5
  ▼ **There is no etcd target in Prometheus.**

  Steps to troubleshoot:

  1. Check the status of the etcd Pods:

     ```
     d8 k -n kube-system get pod -l component=etcd
     ```

  2. Review Prometheus logs:

     ```
     d8 k -n d8-monitoring logs -l app.kubernetes.io/name=prometheus -c prometheus
     ```

- KubeEtcdTargetDown CE S5

▼ **Prometheus is unable to scrape etcd metrics.**

Steps to troubleshoot:

1. Check the status of the etcd Pods:

   ```
   d8 k -n kube-system get pod -l component=etcd
   ```

2. Review Prometheus logs:

   ```
   d8 k -n d8-monitoring logs -l app.kubernetes.io/name=prometheus -c prometheus
   ```

- KubernetesServiceExternalIPsDeprecated CE S6
  ▼ **The cluster has Services that use the deprecated spec.externalIPs field.**

  There are `VALUE` Service(s) in user namespaces that use the `spec.externalIPs` field. Services in the `d8-*` and `kube-system` namespaces are not checked.

  The `spec.externalIPs` field is officially deprecated in Kubernetes because of the CVE-2020-8554 security vulnerability. Starting with Kubernetes 1.36, the API server returns a warning for every request that sets this field. Support for the field will be removed in future Kubernetes versions.

  Plan the migration of the affected Services to a supported way of exposing them, for example:

  - A Service of the `LoadBalancer` type. In bare-metal clusters, use the `metallb` module to assign addresses.
  - A Service of the `NodePort` type.
  - An Ingress or Gateway API resource for HTTP(S) traffic.

  For details, refer to the Kubernetes announcement.

  To list the affected Services with their namespaces and external IP addresses, run:

  ```
  d8 k get services -A -o json | jq -r '["NAMESPACE", "NAME", "TYPE", "EXTERNAL-IPS"],
  (.items[] | select(.spec.externalIPs) | select(.metadata.namespace |
  test("^(d8-.*|kube-system)$") | not) | [.metadata.namespace, .metadata.name,
  .spec.type, (.spec.externalIPs | join(","))]) | @tsv' | column -t
  ```

  Alternatively, run the following Prometheus query:

  ```
  max by (namespace, service, external_ip)
  (kube_service_spec_external_ip{namespace!~"d8-.*|kube-system"})
  ```

Module deckhouse

- ApplicationHorizontalPodAutoscalerMissing CE S5
  ▼ **Application NAME in namespace XXX has no HorizontalPodAutoscaler for XXX XXX.**

  The `spec.resourceRequests` parameter of Application `NAME` in namespace `XXX` sets a replicas range (`minReplicas` and `maxReplicas`) for XXX `XXX`, but the application deploys no HorizontalPodAutoscaler for this workload. Deckhouse Platform runs the workload with `minReplicas` replicas instead.

  To fix the issue, do one of the following:

  - Check the application settings: a package can deploy HorizontalPodAutoscaler only when a setting enables it.
  - Replace the range with a fixed number of replicas: set `replicas` instead of `minReplicas` and `maxReplicas`.

  To view the resource settings of the application, run the following command:

  ```
  d8 k get application NAME -n XXX -o jsonpath='{.spec.resourceRequests}'
  ```

- ApplicationHorizontalPodAutoscalerPinned CE S5
  ▼ **HorizontalPodAutoscaler of XXX XXX of Application NAME in namespace XXX doesn't scale the workload.**

  The `spec.resourceRequests` parameter of Application `NAME` in namespace `XXX` sets a fixed number of replicas (`replicas`) for XXX `XXX`, which a HorizontalPodAutoscaler of the application

scales. Deckhouse Platform sets both bounds of the HorizontalPodAutoscaler to this number, so it doesn’t scale the workload.

To let HorizontalPodAutoscaler scale the workload, replace `replicas` with a range: set `minReplicas` and `maxReplicas`.

To view the resource settings of the application, run the following command:

```
d8 k get application NAME -n XXX -o jsonpath='{.spec.resourceRequests}'
```

- ApplicationIsInMaintenanceMode CE S6
  ▼ Application NAME in namespace XXX is running in maintenance mode.

  Application `NAME` in namespace `XXX` is running in maintenance mode. In this mode, its state is not reconciled, which prevents configuration or hook changes from being applied automatically.

  To switch the application back to normal mode, edit the corresponding Application resource with the following command:

  ```
  d8 k patch application NAME -n XXX --type=json -p='[{"op": "remove", "path": "/spec/maintenance"}]'
  ```

- ApplicationVerticalPodAutoscalerMissing CE S5
  ▼ VerticalPodAutoscaler does not manage at least one resource range of container CONTAINER_NAME of XXX XXX of Application NAME in namespace XXX.

  The `spec.resourceRequests` parameter of Application `NAME` in namespace `XXX` sets a resource range (`min` and `max`) for container `CONTAINER_NAME` of `XXX XXX`, but at least one resource in the range is not managed by a VerticalPodAutoscaler of the application. Deckhouse Platform applies the range for each such resource as fixed values instead: the container gets `min` as the request and `max` as the limit.

  To fix the issue, do one of the following:

  - Check that the `vertical-pod-autoscaler` module is enabled: an application deploys VerticalPodAutoscaler only when the module is enabled.
  - Check the VerticalPodAutoscaler of the workload: it doesn’t set the resources in the `Off` update mode, for a container whose policy mode is `Off`, for a resource missing from `controlledResources` of the policy, and for init containers.
  - Replace the range with fixed resources: set `requests` and `limits` instead of `min` and `max`.

  To view the resource settings of the application, run the following command:

  ```
  d8 k get application NAME -n XXX -o jsonpath='{.spec.resourceRequests}'
  ```

- ApplicationVerticalPodAutoscalerPinned CE S5
  ▼ Fixed resource settings limit VerticalPodAutoscaler for container CONTAINER_NAME of XXX XXX of Application NAME in namespace XXX.

  The `spec.resourceRequests` parameter of Application `NAME` in namespace `XXX` sets fixed `cpu` or `memory` requests or limits for container `CONTAINER_NAME` of `XXX XXX`. If a request is set for a resource managed by VerticalPodAutoscaler, Deckhouse Platform sets both VPA bounds to that request. If a limit is set, Deckhouse Platform sets `controlledValues: RequestsOnly`: VPA can change requests that are not fixed by the Application, but does not change limits.

  To let VerticalPodAutoscaler manage the requests within a range, replace the fixed `cpu` and `memory` requests and limits with `min` and `max`.

  To view the resource settings of the application, run the following command:

  ```
  d8 k get application NAME -n XXX -o jsonpath='{.spec.resourceRequests}'
  ```

- D8CNIEnabledMoreThanOne CE S2
  ▼ More than one CNI is enabled in the cluster.

  Deckhouse has detected that multiple CNIs are enabled in the cluster. For the cluster to work correctly, exactly one CNI must be enabled.

  To resolve this issue, follow these steps:

  1. List the CNI modules and their enabled state:

```
d8 k get moduleconfig -o custom-
columns='NAME:.metadata.name,ENABLED:.spec.enabled' | grep -E 'NAME|cni-'
```

2. Decide which CNI the cluster must keep. Check which one actually serves the nodes before disabling anything:

```
d8 k -n d8-cni-cilium get pods 2>/dev/null; d8 k -n d8-cni-flannel get pods 2>/dev/null; d8
k -n d8-cni-simple-bridge get pods 2>/dev/null
```

3. Disable every other CNI module, one at a time:

```
d8 k patch moduleconfig CNI_MODULE_NAME --type=merge -p '{"spec":{"enabled":false}}'
```

Changing the CNI of a running cluster disrupts pod networking. If you are unsure which CNI to keep, contact support before disabling anything.

- D8CNIMisconfigured CE S5
  ▼ The parameters specified in ModuleConfig of CNI_NAME do not match the ones that are actually being used in the cluster.

  This happened because there were several sources for configuring CNI parameters in the cluster, and ModuleConfig did not have the highest priority previously.

  To resolve this issue, the following steps should be taken:

  1. Find the ConfigMap `d8-system/desired-cni-moduleconfig` in the cluster, which contains the actual ModuleConfig settings.

     ```
     d8 k -n d8-system get configmap desired-cni-moduleconfig -o yaml
     ```

  2. Apply this prepared ModuleConfig to the cluster. This will not cause any actual reconfigurations in the cluster and is completely safe.
  3. Once the parameters in “ModuleConfig” match those used in the cluster:
     - this alert will be resolved,
     - and the priority of the sources for configuring CNI will change, and ModuleConfig will become the main source of truth.
  4. After that, you can add the desired parameters to the ModuleConfig CNI and they will be applied immediately.
- D8DeckhouseConfigInvalid CE S5
  ▼ Deckhouse rejected the cluster configuration: one of the ModuleConfig resources is invalid.

  Deckhouse has detected errors in the cluster configuration. The usual causes are `spec.settings` that do not match the module’s settings schema, and a failed conversion of `spec.settings` to the latest schema version.

  This alert does not name the module, because the underlying metric has no labels. Deckhouse puts the exact error into the `status.message` field of the ModuleConfig that caused it, prefixed with `Error:`.

  To resolve this issue, follow these steps:

  1. Find the affected configuration. The `MESSAGE` column holds the error and the `VERSION` column holds the settings schema version currently in use:

     ```
     d8 k get moduleconfig
     ```

  2. Read the full error for the ModuleConfig that reports one (`global` is a valid value for `MODULE_NAME`):

     ```
     d8 k get moduleconfig MODULE_NAME -o jsonpath='{.status.message}{"\n"}'
     ```

  3. Fix `spec.settings`, or `spec.version` if the error mentions a settings version or a conversion:

     ```
     d8 k edit moduleconfig MODULE_NAME
     ```

4. If no ModuleConfig reports an error, check the Deckhouse logs:

   ```
   d8 k -n d8-system logs -f -l app=deckhouse
   ```

- D8DeckhouseCouldNotDeleteModule CE S4
  ▼ **Deckhouse is unable to delete the MODULE_NAME module.**

  To investigate the issue, check the logs by running the following command:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- D8DeckhouseCouldNotDiscoverModules CE S4
  ▼ **Deckhouse is unable to discover modules.**

  To investigate the issue, check the logs by running the following command:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- D8DeckhouseCouldNotRunGlobalHook CE S5
  ▼ **Deckhouse is unable to run the HOOK_NAME global hook.**

  To investigate the issue, check the logs by running the following command:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- D8DeckhouseCouldNotRunModule CE S4
  ▼ **Deckhouse is unable to start the MODULE_NAME module.**

  To investigate the issue, check the logs by running the following command:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- D8DeckhouseCouldNotRunModuleHook CE S7
  ▼ **Deckhouse is unable to run the MODULE_NAME/HOOK_NAME module hook.**

  To investigate the issue, check the logs by running the following command:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- D8DeckhouseCustomTargetDown CE S4
  ▼ **Prometheus is unable to scrape custom metrics generated by Deckhouse hooks.**

  Prometheus cannot reach the endpoint that serves metrics exported by Deckhouse hooks. Deckhouse core metrics may still be scraped, so this usually points at the hook metrics endpoint rather than at Deckhouse being down.

  To investigate the issue, follow these steps:

  1. Check that the pod is up:

     ```
     d8 k -n d8-system get pods -l app=deckhouse -o wide
     ```

  2. Look for hook failures in the logs, since a hook that never completes exports no metrics:

     ```
     d8 k -n d8-system logs -l app=deckhouse --tail=100 | grep -i error
     ```

  3. Check that the scrape configuration for hook metrics is still present:

     ```
     d8 k -n d8-monitoring get podmonitor deckhouse -o jsonpath='{range
     .spec.podMetricsEndpoints[*]}{.path}{"\n"}{end}'
     ```

- D8DeckhouseDeprecatedConfigmapManagedByArgoCD CE S4
  ▼ **Deprecated Deckhouse ConfigMap managed by Argo CD.**

  The Deckhouse ConfigMap is no longer used.

  To resolve this issue, remove the `d8-system/deckhouse` ConfigMap from Argo CD.

- D8DeckhouseGlobalHookFailsTooOften CE S9
  ▼ **The HOOK_NAME Deckhouse global hook is crashing too frequently.**

  The `HOOK_NAME` hook has failed multiple times in the last `__SCRAPE_INTERVAL_X_4__`.

  To investigate the issue, check the logs by running the following command:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- D8DeckhouseHasNoAccessToRegistry CE S7
  ▼ **Deckhouse is unable to connect to the registry.**

  Deckhouse can’t connect to the registry to check for new releases. With a release channel set, it checks the channel every 3 minutes; without one, it checks the digest of its own image every 15 seconds. Without access to the registry, automatic updates are unavailable.

  Module images come from the same registry, so pods that need a new image fail to start as well, sometimes with errors that do not mention the registry. The usual causes are expired or changed credentials, a registry certificate that has expired or was replaced with one signed by an unknown authority, and a network or proxy change.

  To investigate the issue, follow these steps:

  1. Read the registry error in the logs. `UNAUTHORIZED` points at the credentials, `x509` at the certificate, and a timeout or a refused connection at the network:

     ```
     d8 k -n d8-system logs -l app=deckhouse --tail=500 | grep -iE 'check deckhouse release|registry'
     ```

  2. Check which registry address the cluster is configured to use:

     ```
     d8 k -n d8-system get secret deckhouse-registry -o jsonpath='{.data.address}' | base64 -d
     ```

  3. If the address is correct, the credentials are the next suspect. Check when the secret was last updated:

     ```
     d8 k -n d8-system get secret deckhouse-registry
     ```

  4. If the error mentions `x509`, check who issued the registry certificate and when it expires. Run the command on a master node and substitute the host from the registry address, and its port if it is not 443:

     ```
     openssl s_client -connect REGISTRY_HOST:443 -servername REGISTRY_HOST </dev/null 2>/dev/null | openssl x509 -noout -issuer -enddate
     ```

  5. Check that the node running Deckhouse can reach the registry at all, for example through a proxy or a firewall rule that changed.

- D8DeckhouseIsHung CE S4
  ▼ **Deckhouse is down.**

  Deckhouse is probably down, since the `deckhouse_live_ticks` metric in Prometheus has stopped increasing. This metric is expected to increment every 10 seconds.

  To investigate the issue, follow these steps:

  1. Check the pod state and its restart count:

     ```
     d8 k -n d8-system get pods -l app=deckhouse -o wide
     ```

  2. Read the logs. A deadlock or a hook that never returns stops the ticks while the pod still looks healthy:

     ```
     d8 k -n d8-system logs -l app=deckhouse --tail=200
     ```

  3. Check whether a queue stopped moving at the same time:

```
d8 system queue list
```

4. If the pod is alive but stuck, restart it:

```
d8 k -n d8-system rollout restart deploy/deckhouse
```

- D8DeckhouseIsNotOnReleaseChannel CE S9
  ▼ **Deckhouse isn't subscribed to any regular release channels.**

  Deckhouse in this cluster isn’t subscribed to any of the regular release channels: `Alpha`, `Beta`, `EarlyAccess`, `Stable`, or `RockSolid`.

  To resolve this issue, follow these steps:

  1. Check the current release channel used in the cluster:

```
d8 k -n d8-system  get deploy deckhouse -o json | jq
'.spec.template.spec.containers[0].image' -r
```

  2. Subscribe to one of the regular release channels by adjusting the `deckhouse` module configuration.

- D8DeckhouseModuleHookFailsTooOften CE S9
  ▼ **The MODULE_NAME/HOOK_NAME Deckhouse hook is crashing too frequently.**

  The `HOOK NAME` hook of the `MODULE_NAME` module has failed multiple times in the last `__SCRAPE_INTERVAL_X_4__`.

  To investigate the issue, check the logs by running the following command:

```
d8 k -n d8-system logs -f -l app=deckhouse
```

- D8DeckhouseModuleImageDownloadInterrupted CE S4
  ▼ **Download of the MODULE_NAME module image was interrupted.**

  Deckhouse Platform was downloading the image of the `MODULE_NAME` module, version `VERSION_NUMBER`, from the container registry to build its erofs image, and the download was interrupted. The module version isn’t put on the node running Deckhouse Platform until a download completes.

  The download is interrupted when it doesn’t finish within the registry request timeout, 2 minutes by default, or when the connection to the container registry drops. A slow connection to the container registry is the usual cause.

  To investigate the issue, follow these steps:

  1. Find the reason in the logs. A timeout reads as `context deadline exceeded`, a dropped connection as `unexpected EOF` or `connection reset by peer`:

```
d8 k -n d8-system logs -l app=deckhouse --tail=1000 | grep 'download image layers'
```

  2. Find the ModuleSource the module is downloaded from and the address of its container registry:

```
d8 k get module MODULE_NAME -o jsonpath='{.properties.source}'
d8 k get modulesource SOURCE_NAME -o jsonpath='{.spec.registry.repo}'
```

  3. Check that the image of version `VERSION_NUMBER` is in the container registry:

```
d8 cr ls REGISTRY_ADDRESS/MODULE_NAME
```

     For a private registry, pass the credentials from the ModuleSource:

```
d8 cr ls -u USERNAME -p PASSWORD REGISTRY_ADDRESS/MODULE_NAME
```

  4. Check that the node running Deckhouse Platform reaches the container registry and downloads from it fast enough, for example, through a proxy or a firewall rule that changed.

- D8DeckhouseModuleUpdatePolicyNotFound CE S5
  ▼ **Module update policy not found for MODULE_RELEASE.**

  The module update policy for MODULE_RELEASE is missing.

  To resolve this issue, remove the label from the module release using the following command:

  ```
  d8 k label mr MODULE_RELEASE modules.deckhouse.io/update-policy-
  ```

  A new suitable policy will be detected automatically.

- D8DeckhouseModuleValidationError CE S5
  ▼ **Module configuration failed for module MODULE_NAME.**

  Initial config for module MODULE_NAME is not valid.

  You can get more details via

  ```
  d8 k get mr -l module=MODULE_NAME
  ```

  Provided error: XXX

- D8DeckhouseObsoleteMonitoringDeckhouseModuleConfig CE S9
  ▼ **Obsolete monitoring-deckhouse ModuleConfig should be removed.**

  The `monitoring-deckhouse` module was merged into the `deckhouse` module, but its ModuleConfig still exists in the cluster and is no longer used.

  Remove it manually:

  ```
  d8 k delete moduleconfig monitoring-deckhouse
  ```

  If the ModuleConfig is deployed from an external source (e.g. a Git repository), make sure it is removed from there so it is not created again.

- D8DeckhousePodIsNotReady CE S4
  ▼ **The Deckhouse Pod is NOT Ready.**

  The Deckhouse pod is running but has not become Ready. While this lasts, Deckhouse is not converging the cluster: module updates and configuration changes are not applied.

  To investigate the issue, follow these steps:

  1. Check the pod state and its restart count:

     ```
     d8 k -n d8-system get pods -l app=deckhouse -o wide
     ```

  2. Read the events and probe failures at the bottom of the pod description:

     ```
     d8 k -n d8-system describe pod -l app=deckhouse
     ```

  3. Check the logs. A readiness probe that never succeeds is most often a startup hook that fails or hangs:

     ```
     d8 k -n d8-system logs -l app=deckhouse --tail=200
     ```

  4. Check whether a queue is stuck, which keeps Deckhouse from reporting Ready:

     ```
     d8 system queue list
     ```

- D8DeckhousePodIsNotRunning CE S4
  ▼ **The Deckhouse Pod is NOT Running.**

  There is no running Deckhouse pod in the `d8-system` namespace. Nothing is reconciling the cluster: no module updates, no configuration changes, and no Deckhouse releases are applied.

  To investigate the issue, follow these steps:

  1. Check the pod state. `Pending` points at scheduling, `ImagePullBackOff` at the registry, and `CrashLoopBackOff` at Deckhouse failing to start:

```
d8 k -n d8-system get pods -l app=deckhouse -o wide
```

2. Read the events to find out why the pod is not running:

```
d8 k -n d8-system describe pod -l app=deckhouse
```

3. If the pod is restarting, read the logs of the previous run:

```
d8 k -n d8-system logs -l app=deckhouse --previous --tail=200
```

4. Check that the Deployment itself is present and has the replicas it expects:

```
d8 k -n d8-system get deploy deckhouse
```

- D8DeckhousePodIsRestartingTooOften CE S9
  ▼ Excessive Deckhouse restarts detected.

  Number of restarts in the last hour: VALUE.

  Excessive Deckhouse restarts indicate a potential issue. Normally, Deckhouse should be up and running continuously.

  To investigate the issue, check the logs by running the following command:

```
d8 k -n d8-system logs -f -l app=deckhouse
```

- D8DeckhouseQueueIsHung CE S6
  ▼ Module queue MODULE_NAME (type XXX, hook HOOK_NAME) is hung.

  The module queue head has remained unchanged for more than 10 minutes.

  Affected queue:

  - Module: `MODULE_NAME`
  - Task type: `XXX`
  - Hook: `HOOK_NAME`

  To investigate the issue, check the logs of the `deckhouse` controller pods:

```
d8 k -n d8-system logs -f -l app=deckhouse
```

- D8DeckhouseQueueIsHungCritical CE S4
  ▼ Critical module queue MODULE_NAME (type XXX, hook HOOK_NAME) is hung.

  The critical module queue head has remained unchanged for more than 10 minutes.

  Affected queue:

  - Module: `MODULE_NAME`
  - Task type: `XXX`
  - Hook: `HOOK_NAME`

  To investigate the issue, check the logs of the `deckhouse` controller pods:

```
d8 k -n d8-system logs -f -l app=deckhouse
```

- D8DeckhouseQueueIsHungGlobal CE S4
  ▼ Global/Parallel task XXX (hook HOOK_NAME) is hung.

  The global/parallel task head has remained unchanged for more than 10 minutes.

  Affected task:

  - Task type: `XXX`
  - Hook: `HOOK_NAME`

  To investigate the issue, check the logs of the `deckhouse` controller pods:

```
d8 k -n d8-system logs -f -l app=deckhouse
```

- D8DeckhouseRegistryModeUnsupported CE S9
  ▼ **The deckhouse ModuleConfig stores the unsupported registry mode XXX.**

  The `deckhouse` ModuleConfig has `spec.settings.registry.mode: XXX`. `Proxy` and `Local` are modes of the v1 implementation of the `registry` module, and they have no effect in Deckhouse Platform 1.78: the registry is managed by the `registry` module and configured in the `registry` ModuleConfig. These values are removed in Deckhouse Platform 1.79, and a `deckhouse` ModuleConfig that still stores one will not pass validation there.

  To resolve this issue, do the following before updating to Deckhouse Platform 1.79:

  1. Check the stored value:

     ```
     d8 k get moduleconfig deckhouse -o jsonpath='{.spec.settings.registry}'
     ```

  2. Remove the `spec.settings.registry` section:

     ```
     d8 k patch moduleconfig deckhouse --type json -p '[{"op": "remove", "path":
     "/spec/settings/registry"}]'
     ```

     Alternatively, set the mode to `Unmanaged` and drop the `proxy` section, which is allowed only in `Proxy` mode:

     ```
     d8 k patch moduleconfig deckhouse --type merge -p '{"spec": {"settings":
     {"registry": {"mode": "Unmanaged", "proxy": null}}}}'
     ```

     Both edits are accepted. Switching the mode to `Proxy` or `Local` is refused.

  3. If the cluster needs what the stored mode was set for, an in-cluster registry or cache, configure it in the `registry` ModuleConfig: `mode: Managed` with `primary.upstream`, and `storage.cache` for an in-cluster cache. Removing the stored mode does not change where the cluster pulls images from, so this step is not required to resolve the alert.

  If the `deckhouse` ModuleConfig is deployed from an external source (e.g. a Git repository), make the same change there so the value is not applied again.

- D8DeckhouseSelfTargetAbsent CE S4
  ▼ **There is no Deckhouse target in Prometheus.**

  Prometheus has no `deckhouse` target at all. Unlike a target that is down, this means the target was never discovered, so the problem is usually with the Service, its endpoints, or the monitoring configuration rather than with Deckhouse itself.

  To investigate the issue, follow these steps:

  1. Check that the Deckhouse pod exists and is running:

     ```
     d8 k -n d8-system get pods -l app=deckhouse -o wide
     ```

  2. Check that the Service has endpoints. An empty `ENDPOINTS` column means nothing matches the selector:

     ```
     d8 k -n d8-system get endpoints deckhouse
     ```

  3. Check that the scrape configuration for Deckhouse exists:

     ```
     d8 k -n d8-system get servicemonitor,podmonitor -l app=deckhouse
     ```

  4. Check that the monitoring stack itself is healthy:

     ```
     d8 k -n d8-monitoring get pods
     ```

- D8DeckhouseSelfTargetDown CE S4
  ▼ **Prometheus is unable to scrape Deckhouse metrics.**

  Prometheus cannot reach the `deckhouse` metrics endpoint. Deckhouse itself may still be working, but its own metrics are missing, so most other Deckhouse alerts are blind while this lasts.

To investigate the issue, follow these steps:

1. Check that the pod is up and how long it has been running:

   ```
   d8 k -n d8-system get pods -l app=deckhouse -o wide
   ```

2. Look for scrape errors, such as a connection refused or a TLS failure:

   ```
   d8 k -n d8-system logs -l app=deckhouse --tail=100
   ```

3. Check that the pod still exposes the `self` metrics port:

   ```
   d8 k -n d8-system get pod -l app=deckhouse -o jsonpath='{range
   .items[*].spec.containers[*].ports[*]}{.name}{"="}{.containerPort}{"\n"}
   {end}'
   ```

- D8DeckhouseWatchErrorOccurred CE S5
  ▼ **Possible API server connection error in the client-go informer.**

  Deckhouse has detected an error in the client-go informer, possibly due to connection issues with the API server.

  Steps to investigate:

  1. Check Deckhouse logs for more information by running:

     ```
     d8 k -n d8-system logs deploy/deckhouse | grep error | grep -i watch
     ```

  2. This alert attempts to detect a correlation between the faulty snapshot invalidation and API server connection errors, specifically for the `handle-node-template` hook in the `node-manager` module.

     To compare the snapshot with the actual node objects for this hook, run the following command:

     ```
     diff -u <(d8 k get nodes -o jsonpath='{range .items[*]}{.metadata.name}{"\n"}
     {end}'|sort) <(d8 k -n d8-system exec svc/deckhouse-leader -c deckhouse -- deckhouse-
     controller module snapshots node-manager -o json | jq '."040-node-
     manager/hooks/handle_node_templates.go"' | jq '.nodes.snapshot[] |
     .filterResult.Name' -r | sort)
     ```

- D8HasModuleConfigAllowedToDisable CE S4
  ▼ **The ModuleConfig annotation for allowing module disabling is set.**

  The ModuleConfig is pending module disabling.

  It is recommended that you keep your module configurations clean by removing unnecessary approval annotations.

  If you ignore this alert and do not clear the annotation, the module may be accidentally removed from the cluster, potentially leading to irreversible consequences.

  To resolve this issue and stop the alert, run the following command:

  ```
  d8 k annotate moduleconfig MODULE_NAME modules.deckhouse.io/allow-disabling-
  ```

  With Module v2 enabled, remove the `packages.deckhouse.io/allow-disabling` annotation instead:

  ```
  d8 k annotate moduleconfig MODULE_NAME packages.deckhouse.io/allow-disabling-
  ```

- D8LicenseClusterKeyInvalid BE S4
  ▼ **The cluster licensing key is damaged.**

  The Secret `d8-system/cluster-key` does not hold a valid cluster key. Deckhouse Platform keeps computing the license state, but it cannot sign the cluster data file for the customer portal, and license records bound to the cluster key are not accepted.

  Deckhouse Platform does not replace a damaged key on its own: a new key is a new cluster

identity, and the license keys issued for the old one may stop applying. Apart from Deckhouse Platform, only `system:sudouser` may change the Secret.

If a backup of the Secret is available, restore it as described in the documentation. Otherwise delete the Secret, and Deckhouse Platform creates a new cluster key:

```
d8 k --as=system:sudouser -n d8-system delete secret cluster-key
```

After a new key is created:

1. Download the cluster data in the Deckhouse web UI section “Licensing”.
2. Upload the file to the customer portal (https://lk.deckhouse.ru) and issue a new key there.
3. Upload the key in the same Deckhouse web UI section.

- D8LicenseComplianceGrace BE S5
  ▼ The cluster license is in the grace period.

  The license keys of the cluster have expired, and the grace period is running. When it ends, the license state becomes `Violation`.

  To check the number of remaining grace days in the period, run the following command:

  ```
  d8 k get effectivelicense deckhouse-platform -o jsonpath='{.status.key.graceDays}{"\n"}'
  ```

  To renew the license:

  1. Download the cluster data in the Deckhouse web UI section “Licensing”.
  2. Upload the file to the customer portal (https://lk.deckhouse.ru) and issue a new key there.
  3. Upload the key in the same Deckhouse web UI section.
- D8LicenseComplianceViolation BE S4
  ▼ The cluster license is violated.

  The cluster license has been violated: the license keys expired, and the grace period ended (if the key had one).

  Uncovered nodes are reported by the `D8LicenseUnlicensedNodes` alert.

  Deckhouse Platform and the workloads keep running.

  To restore the license, get a new license key:

  1. Download the cluster data in the Deckhouse web UI section “Licensing”.
  2. Upload the file to the customer portal (https://lk.deckhouse.ru) and issue a new key there.
  3. Upload the key in the same Deckhouse web UI section.
- D8LicenseKeyExpiresSoon BE S7
  ▼ The cluster license expires soon.

  The license key of the cluster expires within 7 days.

  To renew the license:

  1. Download the cluster data in the Deckhouse web UI section “Licensing”.
  2. Upload the file to the customer portal (https://lk.deckhouse.ru) and issue a new key there.
  3. Upload the key in the same Deckhouse web UI section.

  To check the expiry date of a key, run the following command:

  ```
  d8 k get effectivelicense deckhouse-platform -o jsonpath='{.status.key.validUntil}{"\n"}'
  ```

- D8LicenseRejectedRecords BE S6
  ▼ There are rejected license records or keys.

  A record of an installed license key, or a whole key, was rejected. It grants nothing until it is fixed. Possible causes:

  - The key has been damaged, it is not a Deckhouse Platform license key or was not signed by Deckhouse Platform.
  - The key requires a newer Deckhouse Platform version.
  - The key was issued for another cluster.
  - The same record has already been installed with another key.
  - The record does not match the key format.

  Replaced, expired and future records, and records of a type this Deckhouse Platform version does not know, are counted separately and do not fire the alert.

The Deckhouse web UI section “Licensing” shows the cause next to each key in the “License keys” table. To obtain the cause via the command line, run the following command:

```
d8 k get clusterlicenses -o jsonpath='{range .items[*]}{.metadata.name}{"\n"}{range
.status.records[?(@.reason)]}  {.id}: {.reason} {.message}{"\n"}{end}{end}'
```

To replace the key, issue a new one in the customer portal (https://lk.deckhouse.ru).

- D8LicenseUnlicensedNodes BE S4
  ▼ **The cluster license is violated because of unlicensed nodes.**

  The cluster has nodes that the installed license keys do not cover, and the license state is `Violation`.

  The state changes only after nodes have stayed uncovered for an hour without a break. During a node replacement the new node joins before the old one leaves, and for that short time one node is uncovered. The delay keeps such a replacement silent.

  Removing the extra nodes ends the violation at once. If nodes go over the limit again within 24 hours after that, the violation ends only after every node has stayed covered for 8 hours, and after 24 hours for every further repeat. While every node is covered and a repeat still goes on, `status.overLimitEndsAt` names the moment it ends.

  To identify the moment the over-limit episode began:

  ```
  d8 k get effectivelicense deckhouse-platform -o jsonpath='{.status.overLimitSince}{"\n"}'
  ```

  The Deckhouse web UI section “Licensing” lists the uncovered nodes in the “License required” group and shows what to add to the license.

  To cover the nodes, get a license key for the current cluster size:

  1. Download the cluster data in the Deckhouse web UI section “Licensing”.
  2. Upload the file to the customer portal (https://lk.deckhouse.ru) and issue a new key there.
  3. Upload the key in the same Deckhouse web UI section.
- D8ModuleOutdatedByMajorVersion CE S9
  ▼ **Module MODULE_NAME is running XXX major versions behind.**

  Module `MODULE_NAME` is running XXX major versions behind on major version releases. Major version updates may contain breaking changes and require immediate attention and careful planning.

  To check the module releases status, run the following command:

  ```
  d8 k get mr -l module=MODULE_NAME
  ```XXXXXX

  This major release has from-to version constraints that must be met before applying the update.
  To check the update instructions (from-to versions), run the following command:

  ```bash
  d8 k get mr NAME -o jsonpath='{.spec.update.versions[*]}'
  ```

  This will show you the update paths including the from-to versions defined in the release.XXX

  To approve the module major release update, run the following command:

  `bash d8 k annotate mr NAME modules.deckhouse.io/approved="true" XXX`
- D8NodeHasDeprecatedOSVersion CE S4
  ▼ **Nodes with deprecated OS versions detected.**

  Deckhouse has detected nodes running deprecated OS versions.

  Steps to troubleshoot:

  1. Get a list of affected nodes by running the following Prometheus query:

     ```
     kube_node_info{os_image=~"Ubuntu 18.04.*|Debian GNU/Linux 10.*|CentOS Linux
     7.*"}
     ```

2. Update the affected nodes to a supported OS version.

- DeckhouseEditionNotFound CE S6
  ▼ **Incorrect Deckhouse Platform edition.**

  Specify a Deckhouse Platform edition in `MODULE_NAME` ModuleConfig.

  ```
  d8 k patch moduleconfig MODULE_NAME --type merge --patch '{"spec": {"settings":
  {"license": {"edition": "DKP_EDITION"}}}}'
  ```

  Where `DKP_EDITION` is the edition you want to use: `CE`, `BE`, `EE`, `SE`, or `SE-plus`.

- DeckhouseHighMemoryUsage CE S3
  ▼ **Deckhouse memory usage is too high.**

  Deckhouse pod `POD_NAME` on node `NODE_NAME` has high memory usage.

  Please, if possible, get the dumps for debugging purposes (it will take around 30 seconds):

  ```
  curl -s "http://$(d8 k -n d8-system get pod POD_NAME -o
  jsonpath='{.status.hostIP}'):4222/debug/pprof/heap" -o /tmp/heap.pprof
  curl -s "http://$(d8 k -n d8-system get pod POD_NAME -o
  jsonpath='{.status.hostIP}'):4222/debug/pprof/goroutine" -o /tmp/goroutine.pprof
  curl -s "http://$(d8 k -n d8-system get pod POD_NAME -o
  jsonpath='{.status.hostIP}'):4222/debug/pprof/profile?seconds=30" -o /tmp/cpu.pprof
  ```

  and send these files (/tmp/heap.pprof, /tmp/cpu.pprof and /tmp/goroutine.pprof) to the support team.

- DeckhouseMigratedModuleNotDownloaded CE S6
  ▼ **Migrated module MODULE_NAME has not been downloaded yet.**

  Module `MODULE_NAME` specified in DeckhouseRelease was moved to an external source and is available in a ModuleSource registry, but it has not been downloaded yet (no deployed ModuleRelease exists). DeckhouseRelease will be locked until the module is downloaded.

  This alert is usually temporary while the module source controller downloads the module from the registry. If the alert persists, this may indicate:

  - The module's update policy or ModuleSource is misconfigured, preventing the module from being downloaded.
  - A network issue is preventing the module from being downloaded.

  To investigate the issue, do the following:

  - Check the ModuleRelease objects for the module:

    ```
    d8 k get mr -l module=MODULE_NAME
    ```

  - Check the configured ModuleSources:

    ```
    d8 k get modulesources
    ```

  - Check the `deckhouse` logs for more details:

    ```
    d8 k -n d8-system logs -f -l app=deckhouse
    ```

- DeckhouseMigratedModuleNotFound CE S6
  ▼ **Migrated module MODULE_NAME was not found in any ModuleSource registry.**

  Module `MODULE_NAME` specified in DeckhouseRelease was moved to an external source and was not found in any available ModuleSource registry. DeckhouseRelease will be locked until the module becomes available in one of the configured ModuleSource registries.

  This may indicate:

  - A ModuleSource registry is misconfigured.
  - The module has not been published to the registry yet.
  - A network issue is preventing access to the registry.

To investigate the issue, do the following:

- Check the configured ModuleSources:

  ```
  d8 k get modulesources
  ```

- List the available module sources:

  ```
  d8 k -n d8-system exec -it deployment/deckhouse -c deckhouse -- deckhouse-controller
  registry get sources
  ```

- List the modules available in a specific source:

  ```
  d8 k -n d8-system exec -it deployment/deckhouse -c deckhouse -- deckhouse-controller
  registry get modules source_name
  ```

- Check the `deckhouse` logs for more details:

  ```
  d8 k -n d8-system logs -f -l app=deckhouse
  ```

- DeckhouseModuleUpdatingFailedBrokenSequence CE S4
  ▼ **Module update has failed. Updating sequence is broken.**

  The ‘MODULE_NAME’ module update has failed.

  Current version: XXX. Desired version: VERSION_NUMBER.

  Attempt to download interim releases failed. Deckhouse updates modules one minor version at a time, so every intermediate version must exist in the registry.

  Possible reasons:

  - Some of the necessary versions of the module image are not available in the registry.
  - The registry is unreachable.

  To resolve this issue, follow these steps:

  1. Check which module releases exist and where the sequence stopped:

     ```
     d8 k get modulereleases -l module=MODULE_NAME
     ```

  2. Read the reason recorded on the release that is not deployed:

     ```
     d8 k get modulereleases -l module=MODULE_NAME -o custom-
     columns='NAME:.metadata.name,VERSION:.spec.version,PHASE:.status.phase,MESSA
     GE:.status.message'
     ```

  3. Find the module source that serves this repo. The `registry` label above is a repo URL, not a source name:

     ```
     d8 k get modulesource -o custom-
     columns='NAME:.metadata.name,REPO:.spec.registry.repo'
     ```

  4. Ensure that every minor version of the ‘MODULE_NAME’ module image between XXX and VERSION_NUMBER is available in the registry ‘XXX’. If the cluster uses a mirror, the missing versions have to be pulled into it first.

- DeckhouseModuleUpdatingFailedModuleIsNotValid CE S4
  ▼ **Module update has failed. Module is not valid.**

  The ‘MODULE_NAME’ module update has failed.

  Desired version: VERSION_NUMBER.

  Possible reasons:

  - The module image is corrupted.

  To resolve this issue, ensure that the VERSION_NUMBER image in the registry ‘XXX’ is valid.

Check which versions of the ‘MODULE_NAME’ module are available in the registry:

```
d8 cr ls XXX/MODULE_NAME/release
```

For a private registry, pass the credentials from the corresponding ModuleSource:

```
d8 cr ls -u USERNAME -p PASSWORD XXX/MODULE_NAME/release
```

To get the exact error, check Deckhouse logs: `d8 k -n d8-system logs deploy/deckhouse | grep "failed to download module"`

- DeckhouseReleaseDisruptionApprovalRequired CE S4
  ▼ **Deckhouse release disruption approval required.**

  The new Deckhouse release includes a disruptive update that requires manual approval.

  To check the details, run the following command:

  ```
  d8 k describe DeckhouseRelease NAME
  ```

  To approve the disruptive update, run the following command:

  ```
  d8 k annotate DeckhouseRelease NAME release.deckhouse.io/disruption-approved=true
  ```

- DeckhouseReleaseIsBlocked CE S5
  ▼ **Deckhouse release requirements haven't been met.**

  The requirements for the Deckhouse release haven’t been met.

  To check the details, run the following command:

  ```
  d8 k describe DeckhouseRelease NAME
  ```

- DeckhouseReleaseIsWaitingManualApproval CE S3
  ▼ **A new Deckhouse release is awaiting manual approval.**

  A new Deckhouse release is available but requires manual approval before it can be applied.

  To approve the release, run the following command:

  ```
  d8 k patch DeckhouseRelease NAME --type=merge -p='{"approved": true}'
  ```

- DeckhouseReleaseIsWaitingManualApproval CE S6
  ▼ **A new Deckhouse release is awaiting manual approval.**

  A new Deckhouse release is available but requires manual approval before it can be applied.

  To approve the release, run the following command:

  ```
  d8 k patch DeckhouseRelease NAME --type=merge -p='{"approved": true}'
  ```

- DeckhouseReleaseIsWaitingManualApproval CE S9
  ▼ **A new Deckhouse release is awaiting manual approval.**

  A new Deckhouse release is available but requires manual approval before it can be applied.

  To approve the release, run the following command:

  ```
  d8 k patch DeckhouseRelease NAME --type=merge -p='{"approved": true}'
  ```

- DeckhouseReleaseNotificationNotSent CE S4
  ▼ **Deckhouse release notification webhook hasn't been sent.**

  The Deckhouse release notification webhook failed to send.

  To check the notification webhook address, run the following command:

  ```
  d8 k get mc deckhouse -o yaml
  ```

- DeckhouseUpdating CE S4

  Deckhouse is being updated to XXX.

- DeckhouseUpdatingFailed CE S4
  ▼ **Deckhouse update has failed.**

  The Deckhouse update to version VERSION_NUMBER has failed.

  Possible reasons:

  - The next minor or patch version of the Deckhouse image is not available in the registry.
  - The Deckhouse image is corrupted.
  - Deckhouse cannot reach the registry.

  To resolve this issue, follow these steps:

  1. Check the state of the releases. The one stuck in `Pending` is the one that failed:

     ```
     d8 k get deckhousereleases
     ```

  2. Read the reason recorded on that release:

     ```
     d8 k get deckhousereleases -o custom-
     columns='NAME:.metadata.name,PHASE:.status.phase,MESSAGE:.status.message'
     ```

  3. Read the corresponding error in the logs:

     ```
     d8 k -n d8-system logs -l app=deckhouse --tail=200 | grep -i release
     ```

  4. Ensure that version VERSION_NUMBER of the Deckhouse image is present in the registry. If the cluster uses a mirror, the missing version has to be pulled into it first.

- ModuleAtConflict CE S4
  ▼ **Conflict detected for module MODULE_NAME.**

  Deckhouse has detected conflicting sources for the MODULE_NAME module: it is available from more than one ModuleSource and no source is selected, so the module is not deployed.

  To resolve this issue, follow these steps:

  1. List the sources that provide the module:

     ```
     d8 k get module MODULE_NAME -o jsonpath='{.properties.availableSources}{"\n"}'
     ```

  2. Compare what each source offers, so you pick the one you actually want:

     ```
     d8 k get modulerelease -l module=MODULE_NAME
     ```

  3. Select the source in the module configuration:

     ```
     d8 k patch moduleconfig MODULE_NAME --type=merge -p '{"spec":
     {"source":"SOURCE_NAME"}}'
     ```

  4. Verify that the module has left the `Conflict` phase. The `SOURCE` and `PHASE` columns show the result:

     ```
     d8 k get module MODULE_NAME
     ```

- ModuleConfigObsoleteVersion CE S4
  ▼ **ModuleConfig NAME uses obsolete settings version VERSION_NUMBER, the latest one is XXX.**

  Deckhouse has detected that ModuleConfig `NAME` has `spec.version: VERSION_NUMBER`, while the latest settings schema version of the `NAME` module is XXX.

  Deckhouse converts `spec.settings` from version VERSION_NUMBER to version XXX on the fly, so the module keeps working, but the stored configuration remains outdated. Support for version VERSION_NUMBER may be dropped in a future release.

To resolve this issue, follow these steps:

1. Review the migration notes for the `NAME` module settings, one line per conversion step:

   ```
   d8 k get modulesettingsdefinition NAME -o jsonpath='{range
   .spec.versions[*].conversions[*]}{.descriptions.en}{"\n"}{end}'
   ```

2. Migrate `spec.settings` accordingly and set `spec.version` to XXX:

   ```
   d8 k edit moduleconfig NAME
   ```

3. Verify that the version has been updated and no warnings are left:

   ```
   d8 k get moduleconfig NAME -o jsonpath='{.spec.version}{"\t"}{.status.message}
   {"\n"}'
   ```

- ModuleHasDeprecatedUpdatePolicy CE S4
  ▼ Module MODULE_NAME is matched by the deprecated update policy UPDATE_POLICY_NAME.

  Deckhouse has detected that the module `MODULE_NAME` is using the deprecated update policy `UPDATE_POLICY_NAME`. The `v1alpha1` policy has a selector that no longer functions.

  To specify the update policy in the module configuration, run the following command:

  ```
  d8 k patch moduleconfig MODULE_NAME --type='json' -p='[{"op": "add", "path":
  "/spec/updatePolicy", "value": "UPDATE_POLICY_NAME"}]'
  ```

  After resolving all alerts related to the update policy `UPDATE_POLICY_NAME`, clear the selector by running the following command:

  ```
  d8 k patch moduleupdatepolicies.v1alpha1.deckhouse.io UPDATE_POLICY_NAME --type='json' -
  p='[{"op": "replace", "path":
  "/spec/moduleReleaseSelector/labelSelector/matchLabels", "value": {"": ""}}]'
  ```

- ModuleIsDeprecated CE S9
  ▼ Module MODULE_NAME is deprecated.

  The module `MODULE_NAME` is deprecated and will not receive new updates. The module may be removed in a future release, so disable it in a controlled manner rather than waiting for it to disappear.

  To resolve this issue, follow these steps:

  1. Check the module state before changing anything. The `STAGE` column reads `Deprecated`, and the conditions show whether anything still runs:

     ```
     d8 k get module MODULE_NAME
     ```

  2. Find out whether other modules declare a dependency on it:

     ```
     d8 k get modules -o json | jq -r '.items[] |
     select(.properties.requirements.modules | has("MODULE_NAME")) |
     .metadata.name'
     ```

  3. Once nothing depends on it and its workloads are no longer needed, disable the module:

     ```
     d8 k patch moduleconfig MODULE_NAME --type=merge -p '{"spec":{"enabled":false}}'
     ```

- ModuleIsInMaintenanceMode CE S6
  ▼ Module MODULE_NAME is running in maintenance mode.

  Module `MODULE_NAME` is running in maintenance mode. In this mode, its state is not reconciled, which prevents configuration or hook changes from being applied automatically.

  To switch the module back to normal mode, edit the corresponding ModuleConfig resource with the following command:

```
d8 k patch moduleconfig MODULE_NAME --type=json -p='[{"op": "remove", "path":
"/spec/maintenance"}]'
```

- ModuleReleaseIsBlockedByRequirements CE S6
  ▼ A new release for module MODULE_NAME has been blocked due to unmet requirements.

  A new release for module `MODULE_NAME` has been blocked because it doesn’t meet the required conditions.

  To check the requirements, run the following command:

  ```
  d8 k  get mr NAME -o json | jq .spec.requirements
  ```

- ModuleReleaseIsOutdated CE S5
  ▼ Module MODULE_NAME is XXX or more minor versions behind the latest available release.

  Module `MODULE_NAME` is running XXX or more minor versions behind the latest available release. This module is significantly outdated and may have compatibility issues.

  To approve the module release update, run the following command:

  ```
  d8 k annotate mr NAME modules.deckhouse.io/approved="true"
  ```

- ModuleReleaseIsOutdated CE S7
  ▼ Module MODULE_NAME is 2 minor versions behind the latest available release.

  Module `MODULE_NAME` is running 2 minor versions behind the latest available release. Updating is recommended to maintain compatibility and access to latest features.

  To approve the module release update, run the following command:

  ```
  d8 k annotate mr NAME modules.deckhouse.io/approved="true"
  ```

- ModuleReleaseIsOutdated CE S9
  ▼ Module MODULE_NAME is 1 minor version behind the latest available release.

  Module `MODULE_NAME` is running 1 minor version behind the latest available release. Consider updating to maintain compatibility and security.

  To approve the module release update, run the following command:

  ```
  d8 k annotate mr NAME modules.deckhouse.io/approved="true"
  ```

- ModuleReleaseIsWaitingManualApproval CE S6
  ▼ A new release for module MODULE_NAME is awaiting manual approval.

  A new release for module `MODULE_NAME` is available but requires manual approval before it can be applied.

  To approve the module release, run the following command:

  ```
  d8 k annotate mr NAME modules.deckhouse.io/approved="true"
  ```

Module descheduler

Module documentation

- D8DocumentationModulesListNotBuilt CE S8
  ▼ The page of the list of modules in the documentation is not updated.

  docs-builder could not build the page of the list of modules for 30 minutes. The page shows the list as it was built before, or says that the list is being prepared.

  Check the logs of docs-builder:

```
d8 k -n d8-system logs -l app=documentation -c builder --tail=-1 | grep "write the list
of modules"
```

- D8DocumentationModuleVersionsNotUpdated CE S8
  ▼ **The versions of modules in the documentation search were not updated for an hour.**

  docs-builder updates the versions of modules the search and the AI export use every 15 minutes; the last update finished more than an hour ago, or none has finished in the hour since docs-builder started reading the registry.

  Check the logs of docs-builder:

  ```
  d8 k -n d8-system logs -l app=documentation -c builder --tail=-1 | grep -i -E
  "resolve|render pinned"
  ```

- D8DocumentationNoLeader CE S7
  ▼ **No documentation replica reads the registry.**

  No replica of the documentation holds the `docs-builder-ondemand-leader` Lease in `d8-system`. The versions of modules the search uses are not updated; versions users open are still prepared.

  Check the Lease and the logs of docs-builder:

  ```
  d8 k -n d8-system get lease docs-builder-ondemand-leader -o yaml
  d8 k -n d8-system logs -l app=documentation -c builder --tail=-1 | grep -i lead
  ```

- D8DocumentationPinnedVersionsTooLarge CE S8
  ▼ **The module versions the documentation keeps at all times take more space than planned.**

  docs-builder keeps the versions of modules the search uses on the cache volume of the pod and never evicts them. They take XXXB, more than the space set aside for them.

  Versions users open are evicted sooner and prepared again more often. If the volume fills up, Kubernetes evicts the documentation pod, and the versions are prepared again unless they are kept in S3.

  The size is in the `docs builder ondemand cache pinned_bytes` metric, the space set aside in `docs_builder_ondemand_cache_pinned_budget_bytes`: the cache volume of the pod less 2 GiB of versions users open. The space is not configurable: report the alert to the Deckhouse technical support with the number of modules enabled in the cluster.

- D8DocumentationReplicaReadsRegistry CE S8
  ▼ **A documentation replica can not read S3 and reads the registry itself.**

  A replica of the documentation could not read the versions of the leader from S3 for 10 minutes and prepares them from the registry itself until S3 answers again.

  Check the S3 storage of the documentation (`moduleStorage.s3` of the `documentation` ModuleConfig) and the logs of docs-builder:

  ```
  d8 k -n d8-system logs -l app=documentation -c builder --tail=-1 | grep -i s3
  ```

- D8DocumentationS3NotReady CE S9
  ▼ **Module versions documentation is not kept in S3, the S3 storage is not ready.**

  The `documentation` ModuleConfig keeps the prepared documentation of module versions in S3 (`moduleStorage.s3.type`), but the S3 storage has not been usable for 15 minutes. Until it is, the documentation is kept in the documentation pod only and is prepared again after a restart of the pod.

  With `type: External`, check that the Secret from `moduleStorage.s3.external.secretRef` exists and holds the keys listed on the usage page of the module. The reason is in the log of the `builder` container:

  ```
  d8 k -n d8-system logs deploy/documentation -c builder | grep -i s3
  ```

- D8DocumentationSystemS3Disabled CE S9
  ▼ **Module versions documentation is not kept in S3, the system-s3 module is disabled.**

  `moduleStorage.s3.type: System` is set in the `documentation` ModuleConfig, but the `system-`

`s3` module is disabled. Until it is enabled, the prepared documentation of module versions is kept in the documentation pod only and is prepared again after a restart of the pod.

Enable the `system-s3` module, or set `moduleStorage.s3.type` to `Disabled` in the `documentation` ModuleConfig.

- D8DocumentationVersionNotRenderedAnew CE S9
  ▼ **Some module versions in S3 can not be prepared with the current look of the documentation.**

  After an update of the documentation look, VALUE module versions kept in S3 could not be prepared again. They open as they were prepared before the update.

  Find them in the logs of docs-builder:

  ```
  d8 k -n d8-system logs -l app=documentation -c builder --tail=-1 | grep "the template can not render the version"
  ```

- ModuleConfigDeprecated CE S9
  ▼ **Deprecated deckhouse-web ModuleConfig detected.**

  The `deckhouse-web` module has been renamed to `documentation`, and a new `documentation` ModuleConfig is generated automatically.

  Steps to troubleshoot:

  1. Remove the deprecated `deckhouse-web` ModuleConfig from the CI deployment process.
  2. Delete it using the following command:

     ```
     d8 k delete mc deckhouse-web
     ```

Module istio

- D8IstioActiveWaypointsWithAmbientDisabled EE S6
  ▼ **Active Istio waypoint exists while ambient mesh is disabled.**

  Deckhouse has detected an active waypoint Deployment `DEPLOYMENT_NAME` in namespace `NAMESPACE`, created for WaypointInstance `XXX`, while ambient mesh is disabled.

  This usually happens if ambient mesh was enabled, a WaypointInstance was created, and then ambient mesh was disabled. In this state the waypoint-controller is not running, so it cannot reconcile or clean up WaypointInstance resources.

  To inspect affected resources, run:

  ```
  d8 k -n NAMESPACE get waypointinstance XXX -o yaml
  d8 k -n NAMESPACE get deploy,svc,sa,gateway,pdb,hpa,vpa -l istio.deckhouse.io/waypoint-instance=XXX
  ```

  Recommended remediation:

  1. Temporarily enable ambient mesh.
  2. Wait until waypoint-controller starts.
  3. Delete the affected WaypointInstance or change configuration as needed.
  4. Wait until managed waypoint resources are reconciled as needed or removed.
  5. Disable ambient mesh again.

  If ambient mesh cannot be re-enabled, manually remove the managed waypoint resources and then remove the WaypointInstance finalizer only after verifying that no managed resources remain.

- D8IstioActualDataPlaneVersionNotEqualDesired EE S8
  ▼ **There are pods with Istio data plane version VERSION_NUMBER, but desired version is XXX.**

  There are pods in the `NAMESPACE` namespace with Istio data plane version `VERSION_NUMBER`, while the desired version is `XXX`. As a result, the Istio version will be changed after the pod is restarted.

  To resolve the issue, use the following cheat sheet:

```
### Namespace-wide configuration
# `istio.io/rev=vXYZ`: Use a specific revision.
# `istio-injection=enabled`: Use the global revision.
d8 k get ns NAMESPACE --show-labels

### Pod-wide configuration
d8 k -n NAMESPACE get pods -l istio.io/rev=DESIRED_VISION
```

- D8IstioActualVersionIsNotInstalled EE S4
  ▼ **The control plane version for pods with injected sidecars isn't installed.**

  There are pods in the `NAMESPACE` namespace with injected sidecars of version `VERSION_NUMBER` (revision `REVISION_NUMBER`), but the corresponding control plane version is not installed. As a result, these pods have lost synchronization with the state in Kubernetes.

  To resolve this issue, install the required control plane version. Alternatively, update the namespace or pod configuration to match an installed control plane version.

  To identify orphaned pods, run the following command:

  ```
  d8 k -n NAMESPACE get pods -l 'service.istio.io/canonical-name' -o json | jq --arg revision REVISION_NUMBER '.items[] |
  select(.metadata.annotations."sidecar.istio.io/status" // "{}" | fromjson |
  .revision == $revision) | .metadata.name'
  ```

- D8IstioAdditionalControlplaneDoesntWork CE S4
  ▼ **Additional control plane isn't working.**

  Deckhouse has detected that the additional Istio control plane `ISTIO_REVISION_LABEL` isn’t working.

  As a result, sidecar injection for pods with `ISTIO_REVISION_LABEL` isn’t working as well.

  To check the status of the control plane pods, run the following command:

  ```
  d8 k get pods -n d8-istio -l istio.io/rev=ISTIO_REVISION_LABEL
  ```

- D8IstioAllianceAmbientGatewayAddressUnusable EE S6
  ▼ **The ambient east-west gateway has no address peers can dial.**

  The ambient east-west gateway is deployed in this cluster, but publishes no address peer clusters can dial: its Service is missing, it has no external address, no node is running a gateway pod, or every address it has is neither an IP address nor a usable DNS name. The `metadata-exporter` pod logs in `d8-istio` say which.

  Peer clusters keep using the addresses they fetched last, if any. Those that have none cannot reach ambient-mode workloads here.

  To fix, set `alliance.ambientGateway.advertise` to the IP address or DNS name peers should dial. Or make the load balancer assign an address (`alliance.ambientGateway.loadBalancerClass`, `.serviceAnnotations`). Or switch `alliance.ambientGateway.inlet` to `NodePort` and check that gateway pods are scheduled (`.nodeSelector`, `.tolerations`). Or, if ambient multicluster is not needed, switch all multicluster members back to sidecar mode.

- D8IstioAllianceDataPlaneNotConnected EE S4
  ▼ **Data-plane connectivity check failed for XXX NAME.**

  The data-plane health check of XXX `NAME` with uuid `XXX` has been failing for more than 5 minutes.

  This means that actual service mesh traffic between clusters is not flowing properly, even though the control plane metadata exchange may be working.

  Possible causes:

  - The remote cluster’s `alliance-healthcheck` pod is not running.
  - Istio sidecar injection is not working properly on the healthcheck pods.
  - The ingress gateway between clusters is misconfigured or unreachable.
  - mTLS or trust domain configuration issues between clusters.

  To check the status:

```
d8 k get XXX NAME -o json | jq '.status.conditions[] |
select(.type=="DataplaneConnectionReady")'
```

- D8IstioAllianceDiscoveryMetadataEndpointRequestedViaDeprecatedSubdomain EE S5
  ▼ **A peer cluster requests private metadata using a deprecated subdomain.**

  Remote XXX `NAME`, (UUID: `XXX`) requests private metadata from hostname `XXX`, that hostname uses the deprecated `istio` subdomain.

  Update the remote cluster XXX resource: set `spec.metadataEndpoint` to `(publicDomainTemplate + istio-metadata)/metadata/`.

  Migration steps on the remote cluster:

  1. Ensure DNS resolves the new target `(publicDomainTemplate + istio-metadata)`.
  2. Update `spec.metadataEndpoint` to use the new domain name. Keep the path `/metadata/` unchanged.
  3. Verify remote metadata fetch and alliance health after the change.
- D8IstioAllianceIngressGatewayAddressUnusable EE S6
  ▼ **The ingress gateway for federation and multicluster has no address peers can dial.**

  The ingress gateway that peer clusters reach this cluster through is deployed, but publishes no address they can dial: its Service is missing, it has no external address, or no node is running a gateway pod. The `metadata-exporter` pod logs in `d8-istio` say which.

  Peer clusters keep using the addresses they fetched last, if any. Those that have none cannot reach federated services or, over multicluster, sidecar-mode workloads here.

  To fix, set `alliance.ingressGateway.advertise` to the addresses peers should dial. Or make the load balancer assign an address (`alliance.ingressGateway.loadBalancerClass`, `.serviceAnnotations`). Or switch `alliance.ingressGateway.inlet` to `NodePort` and check that gateway pods are scheduled (`.nodeSelector`, `.tolerations`).

- D8IstioConfigAnalysisConflictingGateways EE S5
  ▼ **Conflicting Istio Gateways detected (IST0145).**

  The Istio configuration analyzer found conflicting Gateways in revision `REVISION_NUMBER`.

  Code: `XXX` (`ConflictingGateways`) Namespace: `NAMESPACE` Resource: `XXX`

  Two or more Gateways share the same selector, port, and host match. Ingress traffic may be routed unpredictably or return 404.

  Steps to resolve:

  1. List Gateways and compare `spec.selector`, server ports, and hosts for overlaps involving `XXX`.
  2. Deduplicate or narrow hosts/ports so each combination is unique.
  3. See https://istio.io/latest/docs/reference/config/analysis/ist0145/

  List matching issues in Prometheus (Grafana → Explore):

  ```
  d8_istio_config_analysis_issue{type="ConflictingGateways",revision="REVISION_NUMBER"}
  ```

  Check analyzer logs:

  ```
  d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
  ```

- D8IstioConfigAnalysisError EE S5
  ▼ **Istio configuration analysis detected an error-level issue.**

  The Istio configuration analyzer found an error in revision `REVISION_NUMBER`.

  Type: `ERROR_TYPE` (`XXX`) Namespace: `NAMESPACE` Resource: `XXX`

  Inspect the reported resource in namespace `NAMESPACE`.

  Documentation for analysis codes: https://istio.io/latest/docs/reference/config/analysis/

  List analysis issues in Prometheus (Grafana → Explore):

  ```
  d8_istio_config_analysis_issue{revision="REVISION_NUMBER",severity="Error"}
  ```

Check analyzer pods and logs:

```
d8 k -n d8-istio get pods -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER
d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
```

- D8IstioConfigAnalysisImageAutoWithoutInjection EE S5
  ▼ **Pod uses image auto without Istio injection (IST0147).**

  The Istio configuration analyzer found pods with `image: auto` that are not targeted for sidecar injection in revision `REVISION_NUMBER`.

  Code: `XXX` (`ImageAutoWithoutInjectionError`) Namespace: `NAMESPACE` Resource: `XXX`

  `image: auto` is rewritten only when the Istio injector mutates the pod. Without injection the container image stays literally `auto` and the pod will not run correctly.

  Steps to resolve:

  1. Enable sidecar injection for the namespace or workload (`istio-injection=enabled` / `istio.io/rev=REVISION_NUMBER`, or a matching RevisionTag).
  2. Restart / recreate the affected pods after injection is enabled.
  3. See https://istio.io/latest/docs/reference/config/analysis/ist0147/

  List matching issues in Prometheus (Grafana → Explore):

  ```
  d8_istio_config_analysis_issue{type="ImageAutoWithoutInjectionError",revision="REVISION_NUMBER"}
  ```

  Check analyzer logs:

  ```
  d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
  ```

- D8IstioConfigAnalysisInvalidGatewayCredential EE S5
  ▼ **Gateway TLS credential is invalid (IST0161).**

  The Istio configuration analyzer found an invalid Gateway credential in revision `REVISION_NUMBER`.

  Code: `XXX` (`InvalidGatewayCredential`) Namespace: `NAMESPACE` Resource: `XXX`

  The Secret referenced by the Gateway for TLS is missing or does not contain a usable certificate/key. HTTPS listeners on that Gateway will fail.

  Steps to resolve:

  1. Open the Gateway `XXX` in namespace `NAMESPACE` and note `credentialName` / TLS secret references.
  2. Verify the Secret exists in the same namespace as the ingress Gateway workload and has valid `tls.crt` / `tls.key` (or the expected keys).
  3. See https://istio.io/latest/docs/reference/config/analysis/ist0161/

  List matching issues in Prometheus (Grafana → Explore):

  ```
  d8_istio_config_analysis_issue{type="InvalidGatewayCredential",revision="REVISION_NUMBER"}
  ```

  Check analyzer logs:

  ```
  d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
  ```

- D8IstioConfigAnalysisReferencedResourceNotFound EE S5
  ▼ **Istio resource references a missing dependency (IST0101).**

  The Istio configuration analyzer found a missing reference in revision `REVISION_NUMBER`.

  Code: `XXX` (`ReferencedResourceNotFound`) Namespace: `NAMESPACE` Resource: `XXX`

  An Istio object points to a Gateway, Service, ServiceEntry, or another dependency that does not exist (typo, wrong namespace, or resource not created yet). Traffic to that route may fail.

  Steps to resolve:

  1. Inspect the reported resource in namespace `NAMESPACE` and fix the broken reference (use FQDN for cross-namespace hosts, e.g. `reviews.backend.svc.cluster.local`).
  2. Confirm the target object exists.

3. See https://istio.io/latest/docs/reference/config/analysis/ist0101/

List matching issues in Prometheus (Grafana → Explore):

```
d8_istio_config_analysis_issue{type="ReferencedResourceNotFound",revision="REVISION_NUMBER"}
```

Check analyzer logs:

```
d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
```

- D8IstioConfigAnalysisSchemaValidationError EE S5
  ▼ Istio resource failed schema validation (IST0106).

  The Istio configuration analyzer found a schema validation error in revision `REVISION_NUMBER`.

  Code: `XXX` (`SchemaValidationError`) Namespace: `NAMESPACE` Resource: `XXX`

  The resource does not match the Istio API schema and may be ignored or rejected by the control plane.

  Steps to resolve:

  1. Inspect `XXX` in namespace `NAMESPACE` and compare fields with the Istio API for your control plane version.
  2. Fix invalid or unknown fields, then re-apply the manifest.
  3. See https://istio.io/latest/docs/reference/config/analysis/ist0106/

  List matching issues in Prometheus (Grafana → Explore):

  ```
  d8_istio_config_analysis_issue{type="SchemaValidationError",revision="REVISION_NUMBER"}
  ```

  Check analyzer logs:

  ```
  d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
  ```

- D8IstioConfigAnalysisWarning EE S4
  ▼ Istio configuration analysis detected a warning-level issue.

  The Istio configuration analyzer found a warning in revision `REVISION_NUMBER`.

  Type: `ERROR_TYPE` (`XXX`) Namespace: `NAMESPACE` Resource: `XXX`

  Inspect the reported resource in namespace `NAMESPACE`.

  Documentation for analysis codes: https://istio.io/latest/docs/reference/config/analysis/

  List analysis warnings in Prometheus (Grafana → Explore):

  ```
  d8_istio_config_analysis_issue{revision="REVISION_NUMBER",severity="Warning"}
  ```

  Check analyzer pods and logs:

  ```
  d8 k -n d8-istio get pods -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER
  d8 k -n d8-istio logs -l app=istio-config-analyzer,istio.io/rev=REVISION_NUMBER --tail=100
  ```

- D8IstioCustomCAMaterialInvalid CE S4
  ▼ The Istio custom CA material is invalid but is being served to istiod.

  The Istio module is publishing CA material (`XXX`) that failed validation to istiod.

  The module never hard-blocks on module-owned or last-good material (doing so would rotate the mesh root and break mTLS cluster-wide), so it keeps serving this material with only a warning. However, istiod may reject it, which can prevent it from issuing or renewing workload certificates.

  Depending on the `source`:

  - `cacerts` — the `d8-istio/cacerts` Secret (or the CA reused from it) is not a valid CA. Inspect the Secret and restore valid `ca-cert.pem`/`ca-key.pem` (and `root-cert.pem`/`cert-chain.pem` if used).
  - `secretRef:namespace/name` — the last-good CA that was previously resolved from this `ca.secretRef` has become invalid (for example, its chain expired). Fix the referenced Secret so the next re-resolution (every 5 minutes) succeeds.

Refer to the custom CA documentation.

- D8IstioCustomCASecretRefUnresolved CE S5
  ▼ **The Istio custom CA ca.secretRef cannot be resolved.**

  The Istio module could not re-resolve the configured `ca.secretRef` (`XXX`) and is keeping the last successfully-resolved CA.

  The mesh is not regressed — istiod keeps running on the exact CA material it already had — but any change made to the source Secret is not being picked up. Common causes:

  - the referenced Secret was deleted or renamed;
  - the referenced Secret was made malformed (not valid PEM, not a CA certificate, or a mismatched key pair);
  - a transient Kubernetes API problem.

  The module re-resolves the Secret every 5 minutes; this alert clears automatically once resolution succeeds. Inspect the referenced Secret and restore valid CA material.

  Refer to the custom CA documentation.

- D8IstioDataPlaneVersionMismatch EE S8
  ▼ **There are pods with data plane version different from the control plane version.**

  There are pods in the `NAMESPACE` namespace with Istio data plane version `VERSION_NUMBER`, which is different from the control plane version `DESIRED_VERSION`.

  Steps to resolve the issue:

  1. Restart affected pods and use the following PromQL query to get a full list:

     ```
     max by (namespace, dataplane_pod)
     (d8_istio_dataplane_metadata{full_version="VERSION_NUMBER"})
     ```

  2. Use the automatic Istio data plane upgrade.

- D8IstioDataPlaneWithoutIstioInjectionConfigured EE S4
  ▼ **Detected pods with Istio sidecars but istio-injection isn't configured.**

  There are pods in the `NAMESPACE` namespace with Istio sidecars, but istio-injection isn’t configured. As a result, these pods will lose their Istio sidecars after being recreated.

  To identify the affected pods, run the following command:

  ```
  d8 k -n NAMESPACE get pods -o json | jq -r --arg revision REVISION_NUMBER '.items[] |
  select(.metadata.annotations."sidecar.istio.io/status" // "{}" | fromjson |
  .revision == $revision) | .metadata.name'
  ```

- D8IstioDeprecatedIstioVersionInstalled CE
  ▼ **The installed Istio version has been deprecated.**

  Deckhouse has detected that a deprecated Istio version `VERSION_NUMBER` is installed.

  Support for this version will be removed in upcoming Deckhouse releases. The higher the alert severity, the greater the probability of support being discontinued.

  To learn how to upgrade Istio, refer to the upgrade guide.

- D8IstioDesiredVersionIsNotInstalled EE S6
  ▼ **Desired control plane version isn't installed.**

  There is a desired Istio control plane version `XXX` (revision `REVISION_NUMBER`) configured for pods in the `NAMESPACE` namespace, but that version isn’t installed. As a result, pods can’t be recreated in the `NAMESPACE` namespace.

  To resolve this issue, install the desired control plane version. Alternatively, update the namespace or pod configuration to match an installed control plane version.

  Use the following cheat sheet:

```
### Namespace-wide configuration
# `istio.io/rev=vXYZ`: Use a specific revision.
# `istio-injection=enabled`: Use the global revision.
d8 k get ns NAMESPACE --show-labels

### Pod-wide configuration
d8 k -n NAMESPACE get pods -l istio.io/rev=REVISION_NUMBER
```

- D8IstioFederationMetadataEndpointDoesntWork EE S6
  ▼ **IstioFederation FEDERATION_NAME gets no usable metadata from the remote cluster.**

  The Deckhouse hook could not get usable metadata from the endpoint `ENDPOINT_NAME` for IstioFederation `FEDERATION_NAME`.

  The reason and the details are in the `PublicMetadataExchangeReady` and `PrivateMetadataExchangeReady` conditions of the IstioFederation. The endpoint may respond normally while the metadata is still unusable, for example, when the ingress gateway of the remote cluster has no address yet.

  To view the conditions, run the following command:

  ```
  d8 k get istiofederation FEDERATION_NAME -o jsonpath='{range .status.conditions[*]}
  {.type}: {.status}: {.reason}: {.message}{"\n"}{end}'
  ```

  To reproduce the request to the public endpoint, run the following command:

  ```
  curl ENDPOINT_NAME
  ```

  To reproduce the request to private endpoints (run from the Deckhouse pod), run the following:

  ```
  KEY="$(deckhouse-controller module values istio -o json | jq -r
  .internal.remoteAuthnKeypair.priv)"
  LOCAL_CLUSTER_UUID="$(deckhouse-controller module values -g istio -o json | jq -r
  .global.discovery.clusterUUID)"
  REMOTE_CLUSTER_UUID="$(d8 k get istiofederation FEDERATION_NAME -o json | jq -r
  .status.metadataCache.public.clusterUUID)"
  TOKEN="$(deckhouse-controller helper gen-jwt --private-key-path <(echo "$KEY") --claim
  iss=d8-istio --claim sub=$LOCAL_CLUSTER_UUID --claim aud=$REMOTE_CLUSTER_UUID --
  claim scope=private-federation --ttl 1h)"
  curl -H "Authorization: Bearer $TOKEN" ENDPOINT_NAME
  ```

- D8IstioFederationRemoteClusterUUIDMismatch EE S4
  ▼ **IstioFederation peer cluster UUID changed.**

  Public metadata from `ENDPOINT_NAME` for IstioFederation `FEDERATION_NAME` reports cluster UUID `XXX`, but the previously pinned UUID is `XXX`.

  Deckhouse stops private metadata exchange and does not send a federation JWT until the peer identity is confirmed again.

  Check whether `spec.metadataEndpoint` was pointed to another cluster or the remote endpoint was replaced.

  To inspect the resource:

  ```
  d8 k get istiofederation FEDERATION_NAME -o yaml
  curl ENDPOINT_NAME
  ```

  If the peer change is intentional, recreate the IstioFederation resource so a new UUID can be pinned.

- D8IstioGlobalControlplaneDoesntWork CE S4
  ▼ **Global control plane isn't working.**

  Deckhouse has detected that the global Istio control plane `ISTIO_REVISION_LABEL` isn’t working.

  As a result, sidecar injection for pods with global revision isn’t working as well, and the validating webhook for Istio resources is absent.

  To check the status of the control plane pods, run the following command:

```
d8 k get pods -n d8-istio -l istio.io/rev=ISTIO_REVISION_LABEL
```

- D8IstioMulticlusterMetadataEndpointDoesntWork EE S6
  ▼ IstioMulticluster MULTICLUSTER_NAME gets no usable metadata from the remote cluster.

  The Deckhouse hook could not get usable metadata from the endpoint `ENDPOINT_NAME` for IstioMulticluster `MULTICLUSTER_NAME`.

  The reason and the details are in the `PublicMetadataExchangeReady` and `PrivateMetadataExchangeReady` conditions of the IstioMulticluster. The endpoint may respond normally while the metadata is still unusable, for example, when the remote cluster does not deploy the gateway this cluster reaches it through.

  To view the conditions, run the following command:

  ```
  d8 k get istiomulticluster MULTICLUSTER_NAME -o jsonpath='{range .status.conditions[*]}
  {.type}: {.status}: {.reason}: {.message}{"\n"}{end}'
  ```

  To reproduce the request to the public endpoint, run the following command:

  ```
  curl ENDPOINT_NAME
  ```

  To reproduce the request to private endpoints (run from the `d8-system/deckhouse` pod), run the following:

  ```
  KEY="$(deckhouse-controller module values istio -o json | jq -r
  .internal.remoteAuthnKeypair.priv)"
  LOCAL_CLUSTER_UUID="$(deckhouse-controller module values -g istio -o json | jq -r
  .global.discovery.clusterUUID)"
  REMOTE_CLUSTER_UUID="$(d8 k get istiomulticluster MULTICLUSTER_NAME -o json | jq -r
  .status.metadataCache.public.clusterUUID)"
  TOKEN="$(deckhouse-controller helper gen-jwt --private-key-path <(echo "$KEY") --claim
  iss=d8-istio --claim sub=$LOCAL_CLUSTER_UUID --claim aud=$REMOTE_CLUSTER_UUID --
  claim scope=private-multicluster --ttl 1h)"
  curl -H "Authorization: Bearer $TOKEN" ENDPOINT_NAME
  ```

- D8IstioMulticlusterRemoteAPIHostDoesntWork EE S6
  ▼ Multicluster remote API host health check failed.

  The remote API host `API_HOST` for IstioMulticluster `MULTICLUSTER_NAME` has failed the health check performed by the Deckhouse monitoring hook.

  To reproduce the request (run from the `d8-system/deckhouse` pod), run the following:

  ```
  TOKEN="$(deckhouse-controller module values istio -o json | jq -r --arg ah API_HOST
  '.internal.multiclusters[]| select(.apiHost == $ah)| .apiJWT ')"
  curl -H "Authorization: Bearer $TOKEN" https://API_HOST/version
  ```

- D8IstioMulticlusterRemoteClusterUUIDMismatch EE S4
  ▼ IstioMulticluster peer cluster UUID changed.

  Public metadata from `ENDPOINT_NAME` for IstioMulticluster `MULTICLUSTER_NAME` reports cluster UUID `XXX`, but the previously pinned UUID is `XXX`.

  Deckhouse stops private metadata exchange and does not send a multicluster JWT until the peer identity is confirmed again.

  Check whether `spec.metadataEndpoint` was pointed to another cluster or the remote endpoint was replaced.

  To inspect the resource:

  ```
  d8 k get istiomulticluster MULTICLUSTER_NAME -o yaml
  curl ENDPOINT_NAME
  ```

  If the peer change is intentional, recreate the IstioMulticluster resource so a new UUID can be pinned.

- D8IstioNetworkNameIsNotLabelValue CE S6
  ▼ **The Istio network name is not a valid Kubernetes label value.**

  The Istio network name `XXX` of this cluster is not a valid Kubernetes label value. Because of this, the name is left out of every place where a label value is required.

  Contact Deckhouse technical support to resolve the issue.

- D8IstioOperatorReconcileError CE S5
  ▼ **The istio-operator is unable to reconcile Istio control plane setup.**

  Deckhouse has detected an error in the `istio-operator` reconciliation loop.

  To investigate the issue, check the operator logs:

  ```
  d8 k -n d8-istio logs -l app=operator,revision=REVISION_NUMBER
  ```

- D8IstioPodsWithoutIstioSidecar EE S4
  ▼ **Detected pods without Istio sidecars but with istio-injection configured.**

  There is a pod `POD_NAME` in the `NAMESPACE` namespace without Istio sidecars, but with istio-injection configured.

  To identify the affected pods, run the following command:

  ```
  d8 k -n NAMESPACE get pods -l '!service.istio.io/canonical-name' -o json | jq -r
  '.items[] | select(.metadata.annotations."sidecar.istio.io/inject" != "false")
  | .metadata.name'
  ```

- D8IstioRemoteClusterNotSynced EE S4
  ▼ **XXXIstioMulticluster MULTICLUSTER_NAME is not synchronized.XXXIstio remote cluster CLUSTER_ID is not synchronized.XXX**

  XXXThe Istio control plane instance `INSTANCE NAME` cannot synchronize with the remote cluster described by IstioMulticluster `MULTICLUSTER_NAME` (cluster ID `CLUSTER_ID`).XXXThe Istio control plane instance `INSTANCE_NAME` cannot synchronize with the remote cluster `CLUSTER_ID`.XXX

  Possible causes:

  - The remote cluster is offline.
  - The remote API endpoint is not reachable.
  - The remote ServiceAccount token is invalid or expired.
  - There is a TLS or certificate issue between the clusters.
  - Remote and local Istio versions mismatch.

  XXXCheck the conditions of the IstioMulticluster:

  ```
  d8 k get istiomulticluster MULTICLUSTER_NAME -o jsonpath='{range .status.conditions[*]}
  {.type}: {.status}: {.reason}: {.message}{"\n"}{end}'
  ```

  All conditions must be `True`. If a condition is not `True`, its `reason` and `message` say what is wrong. Access to the remote API is reported by the `RemoteAPIServerReady` condition.

  If there is no such resource, this cluster was registered by the secret `XXX` alone — check the API address and the token in the kubeconfig it stores. XXXNo IstioMulticluster resource registered this cluster, so check the API address and the token in the kubeconfig stored in the secret `XXX`. XXX

- D8IstioReservedUIDConflict CE S4
  ▼ **Application container is running as UID 1337 (reserved by Istio).**

  Container `CONTAINER_NAME` in pod `POD_NAME` in namespace `NAMESPACE` is running as UID `1337`.

  UID `1337` is reserved by Istio for the `istio-proxy` sidecar container. When application containers run with this UID, their traffic bypasses Istio completely — no routing rules, mTLS, or telemetry will be applied.

  To fix the issue, change the `runAsUser` in the container's or pod's `securityContext` to a different UID.

- D8IstioVersionIsIncompatibleWithK8sVersion CE S3
  ▼ **The installed Istio version is incompatible with the Kubernetes version.**

  The installed Istio version `VERSION_NUMBER` may not work properly with the current Kubernetes

version `VERSION_NUMBER` because it’s not supported officially.

To resolve the issue, upgrade Istio following the guide.

- IstioIrrelevantExternalServiceFound CE S5
  ▼ **External service found with irrelevant ports specifications.**

  A service `NAME` in the `NAMESPACE` namespace has an irrelevant port specification.

  The `.spec.ports[]` field isn’t applicable for services of the `ExternalName` type. However, Istio renders port listeners for external services as `0.0.0.0:port`, which captures all traffic to the specified port. This can cause problems for services that aren’t registered in the Istio registry.

  To resolve the issue, remove the `.spec.ports` section from the service configuration. It is safe.

Module kube-dns

- KubernetesCoreDNSHasCriticalErrors CE S5
  ▼ **Critical errors found in CoreDNS.**

  Deckhouse has detected at least one critical error in the CoreDNS pod POD_NAME.

  To resolve the issue, review the container logs:

  ```
  d8 k -n kube-system logs POD_NAME
  ```

Module metallb

- D8MetallbBGPSessionDown EE S4
  ▼ **MetalLB BGP session is down.**

  JOB_NAME, MetalLB CONTAINER_NAME on POD_NAME has BGP session PEER down.

  Check the logs for details:

  ```
  d8 k -n d8-metallb logs daemonset/speaker -c speaker
  ```

- D8MetallbConfigNotLoaded EE S4
  ▼ **The MetalLB configuration hasn't been loaded.**

  JOB_NAME, MetalLB CONTAINER_NAME on POD_NAME hasn’t been loaded.

  To find the cause of the issue, review the controller logs:

  ```
  d8 k -n d8-metallb logs deploy/controller -c controller
  ```

- D8MetallbConfigStale EE S4
  ▼ **MetalLB is running on a stale configuration.**

  JOB_NAME, MetalLB CONTAINER_NAME on POD_NAME is running on a stale configuration because the latest configuration failed to load.

  To find the cause of the issue, review the controller logs:

  ```
  d8 k -n d8-metallb logs deploy/controller -c controller
  ```

- D8MetallbNotSupportedServiceAnnotationsDetected SE S4
  ▼ **The annotation 'ANNOTATION_NAME' has been deprecated for the service 'NAME' in the 'NAMESPACE' namespace.**

  The annotation ‘ANNOTATION_NAME’ has been deprecated for the service ‘NAME’ in the ‘NAMESPACE’ namespace.

  The following service annotations are no longer effective:

  - `metallb.universe.tf/ip-allocated-from-pool`: Remove this annotation.
  - `metallb.universe.tf/address-pool`: Replace it with the `.spec.loadBalancerClass` parameter or use the `network.deckhouse.io/metal-load-balancer-class` annotation, referencing the appropriate MetalLoadBalancerClass.
  - `metallb.universe.tf/loadBalancerIPs`: Replace it with `network.deckhouse.io/load-balancer-ips: IP`.
  - `metallb.universe.tf/allow-shared-ip`: Replace it with `network.deckhouse.io/load-`

`balancer-shared-ip-key`.
  - `metallb.io/ip-allocated-from-pool`: Remove this annotation.
  - `metallb.io/address-pool`: Replace it with the `.spec.loadBalancerClass` parameter or use the `network.deckhouse.io/metal-load-balancer-class` annotation, referencing the appropriate MetalLoadBalancerClass.
  - `metallb.io/loadBalancerIPs`: Replace it with `network.deckhouse.io/load-balancer-ips: IP`.
  - `metallb.io/allow-shared-ip`: Replace it with `network.deckhouse.io/load-balancer-shared-ip-key`.

Please note. Existing LoadBalancer services of Deckhouse have been migrated automatically, but the new ones will not be.

- D8MetallbObsoleteLayer2PoolsAreUsed SE S7
  ▼ **The metallb module has obsolete layer2 pools configured.**

  In ModuleConfig version 2, addressPool ‘NAME’ of type “layer2” are ignored. They should be removed from the configuration.

- D8MetallbUpdateMCVersionRequired SE S5
  ▼ **The metallb ModuleConfig settings are outdated.**

  D8 MetalLB settings are outdated.

  To resolve this issue, increase version in the ModuleConfig `metallb`.

- L2LoadBalancerOrphanServiceFound SE S4
  ▼ **Orphaned service with an irrelevant L2LoadBalancer name has been found.**

  The cluster contains an orphaned service `NAME` in the `NAMESPACE` namespace with an irrelevant L2LoadBalancer name.

  To resolve this issue, verify the L2LoadBalancer name specified in the annotation `network.deckhouse.io/l2-load-balancer-name`.

Module multitenancy-manager

- ClusterResourceGrantPolicyViolation CE S6
  ▼ **Objects in namespace XXX use cluster-wide resources that are not available to its project.**

  Objects in namespace `XXX` reference cluster-wide resources (for example, a StorageClass or a ClusterRole) that the current ClusterResourceGrantPolicy objects do not make available to the project of this namespace. The `project` label of the metric holds the namespace, not the project name. Such an object was created before the policy changed. It keeps working, and when it is updated, only new values are checked.

  Steps to troubleshoot:

  1. Find the objects, their fields and the resources on the “Security” → “Cluster Resource Grant Violations” Grafana dashboard, or in the `d8 cluster objects grant violated{project="XXX"}` metric (labels `violating_object_name`, `violating_field`, `violating_resource` and `grant`).
  2. Check which resources are available to the project:

     ```
     d8 k get available RESOURCE_NAME -n XXX -o yaml
     ```

  3. Make the resource available to the project in a ClusterResourceGrantPolicy, or change the field of the object to an available value.
- D8NamespaceNotAdopted CE S6
  ▼ **Namespace XXX belongs to no project.**

  Namespace `XXX` was created directly more than 10 minutes ago and is still not a project. The multitenancy-manager controller turns every namespace outside the system ones into a project of its own within seconds, whatever the `allowNamespacesWithoutProjects` parameter says. Until it does, the objects created in the namespace skip the checks of a project: the availability of cluster-wide resources, the project template with its network and pod security policies, and the quota.

  The controller has no leader, fails to adopt the namespace, or has adopted it into a Project that does not reconcile. Check its pods and logs:

```
d8 k -n d8-multitenancy-manager get pods
d8 k -n d8-multitenancy-manager logs deploy/multitenancy-manager -c multitenancy-manager --
tail=200 | grep XXX
```

If the controller fails to adopt the namespace, it tries again with a delay of up to 30 seconds, so the namespace becomes a project and the alert resolves soon after the cause is gone, for example an admission policy or webhook that refuses the Project. Once the controller adopts the namespace, check the objects created in it in the meantime.

If a Project named like the namespace exists already, the controller takes the adoption as done and does not try again, and the logs of the namespace controller show nothing. The project may be in `Error`, for example with the `HelmOwnership` condition when the namespace belongs to another Helm release, and then it never labels the namespace: until the conflict is removed, this Project is not updated at all. Check the project:

```
d8 k get project XXX -o jsonpath='{.status.state}{"\n"}{range .status.conditions[*]}
{.type}={.status} {.reason}: {.message}{"\n"}{end}'
```

Remove the cause the condition names, for example the foreign release or its `meta.helm.sh/*` annotations on the namespace, and the project labels the namespace. This also happens to the namespaces that existed before the upgrade.

- D8ProjectQuotaExceeded CE S7
  ▼ **Project XXX has a quota set below its usage.**

  The usage of project `XXX`, summed over all of its namespaces, is above the limits of its quota: the limits were set below the usage, by a change of the quota or when it was created (the `HardLowered` reason of the `Exceeded` condition).

  Nothing running is evicted. Creating more of the resources whose limits are exceeded is denied until the usage is back within the limits.

  1. See which limits are exceeded and by how much:

     ```
     d8 k get projectquotastatus XXX -o jsonpath='{range .status.conditions[*]}{.type}=
     {.status} {.reason}: {.message}{"\n"}{end}'
     ```

  2. See which namespaces use the most (the usage of every namespace is in its `d8-project-quota` ResourceQuota):

     ```
     d8 k get projectquotastatus XXX -o jsonpath='{range .status.topNamespaces[*]}
     {.name}: {.used}{"\n"}{end}'
     d8 k get resourcequota -A -l projects.deckhouse.io/project=XXX
     ```

  3. Raise the limits in `spec.quota` of the Project, or delete what the project does not need.

- D8ProjectQuotaLeaderFlapping CE S5
  ▼ **The leader of the project quota ledger changes too often.**

  The lease of the ledger changed hands more than three times in ten minutes; every change refuses counted creates for a second or more. The `reason` label of `d8_multitenancy_quota_ledger_handover_total` says why: `expired` points at late renewals (the API server, the `leader-election` priority level), `stepdown` at the canary, `graceful` at restarts of the pods (rollouts, evictions).

- D8ProjectQuotaLedgerCanaryFailing CE S4
  ▼ **Most API servers do not reach the leader of the project quota ledger.**

  The canary writes of the ledger do not reach its webhook through most of the API servers. The leader hands the lease over when another replica is ready; this alert says it could not, or that the new leader is not reached either. Check the network from the master nodes to the pods of `d8-multitenancy-manager` and the CNI on the masters. The steps of `D8ProjectQuotaLedgerDown` apply.

- D8ProjectQuotaLedgerDown CE S4
  ▼ **No replica of the project quota ledger answers.**

  No replica of the `quota-ledger` container of the `multitenancy-manager` module holds its lease with synced informers. Creating the objects a project quota counts in the namespaces of projects with a quota fails with `project quota ledger unavailable`, or with `failed calling webhook`

`"quota-ledger.multitenancy-manager.deckhouse.io"`. Deletions, running objects and other namespaces are not affected.

1. Check the pods, the lease and the route:

   ```
   d8 k -n d8-multitenancy-manager get pods,lease,endpointslices
   d8 k -n d8-multitenancy-manager logs deploy/multitenancy-manager -c quota-ledger --tail=200
   ```

   The logs say whether the ledger is `fenced` (its lease renewals are late) or `syncing`.

2. If the cause cannot be removed quickly, delete the webhook as `system:sudouser`. While no replica holds the route, the API servers reach none of them, so suspending the ledger with the `quota-ledger-suspend` ConfigMap does not help here. The sum check stops at once; Deckhouse puts the webhook back within about 4 minutes, so this buys time rather than switching the check off. Disabling the `multitenancy-manager` module removes the check together with the rest of the module.

   ```
   d8 k --as=system:sudouser delete validatingwebhookconfiguration d8-multitenancy-manager-quota-ledger
   ```

- D8ProjectQuotaLedgerDrift CE S6
  ▼ **The project quota ledger differs from the API server.**

  The ledger holds the usage of some quota differently from a quorum read of the same version of it. The state of the ledger is inconsistent. Save the logs of the `quota-ledger` container, then restart the pod of the leader once so that another replica takes over. Do not restart it in a loop.

- D8ProjectQuotaLedgerSlow CE S5
  ▼ **The project quota ledger answers slowly.**

  The 99th percentile of the calls of the ledger webhook, as the API servers see them, is above 100 ms. The ledger answers within 25 ms of its own, so the delay comes from the network or from the CPU of the `quota-ledger` container. Check the CPU of the master nodes and of the container, the `d8_multitenancy_quota_ledger_inflight` and `d8_multitenancy_quota_ledger_requests_total{result="busy"}` series, and other webhooks on `resourcequotas/status`.

- D8ProjectQuotaLedgerUnreachableFromAPIServer CE S5
  ▼ **The API server XXX does not reach the project quota ledger.**

  The canary writes through the API server `XXX` fail on the webhook of the ledger, while the other API servers reach it. Counted creates that land on this API server in the namespaces of projects with a quota wait for the webhook timeout and fail. Check the network of that master node to the pods of `d8-multitenancy-manager`; the webhooks of other modules are likely affected the same way.

- D8ProjectQuotaNotEnforced CE S6
  ▼ **The quota of project XXX does not apply in every namespace of the project.**

  The `Enforced` condition of the ProjectQuotaStatus of project `XXX` has been `False` for 15 minutes for one of these reasons:

  - `KeyRollout`: the `d8-project-quota` ResourceQuota of some namespace of the project is missing or not calculated with every limit of the quota. The resource quota controller of kube-controller-manager calculates a new quota within seconds, so a quota that stays uncalculated points at kube-controller-manager or at the multitenancy-manager controller; the message of the condition names the namespaces and the error of the controller, if any. Until it is calculated, the objects of users are refused in a namespace labelled `projects.deckhouse.io/quota: pending`. In a namespace labelled `projects.deckhouse.io/quota: enforced`, the objects the quota counts are refused only while its `d8-project-quota` has no calculated limit at all or has scopes; a limit added to a calculated quota holds nothing back.
  - `KeyNotServed`: some keys of the quota count nothing, because a `count/` key names a resource of an API group that the API server does not serve, or because the module that serves the resources of a key, such as `virtualization`, is disabled. Enable that module, or remove the key.
  - `WebhookMissing`: the `d8-multitenancy-manager-quota-ledger` webhook is missing or its `caBundle` is not the CA of the `quota-ledger-certs` Secret, so the sum is not checked. Deckhouse puts it back on the next run of the module; see the `D8ProjectQuotaWebhookMisconfigured` alert.
  - `WebhookMisconfigured`: the `d8-multitenancy-manager-quota-ledger` webhook is changed (its rules, `namespaceSelector`, `objectSelector`, `matchConditions`, `failurePolicy` or service) so that writes of `d8-project-quota` do not reach the ledger.

The message of the condition names the field. Deckhouse puts the webhook back on the next run of the module; see the `D8ProjectQuotaWebhookMisconfigured` alert.
- `WebhookNotCalled`: the canary of the ledger found API servers that admit objects without calling the `d8-multitenancy-manager-quota-ledger` webhook, so the sum is not checked for what they admit. The message of the condition names them; check the rules, `namespaceSelector` and `matchConditions` of the webhook.

Check the condition and the quotas of the namespaces:

```
d8 k get projectquotastatus XXX -o jsonpath='{range .status.conditions[*]}{.type}=
{.status} {.reason}: {.message}{"\n"}{end}'
d8 k get resourcequota -A -l projects.deckhouse.io/project=XXX -o custom-
columns=NAMESPACE:.metadata.namespace,HARD:.spec.hard,CALCULATED:.status.hard
```

- D8ProjectQuotaNotSupported CE S8
  ▼ The sum of a project quota is not enforced, because Deckhouse Platform does not manage the control plane.

  The cluster has projects with a quota, but the `control-plane-manager` module is disabled: Deckhouse Platform does not manage the control plane of the cluster. The sum over the namespaces of a project is enforced only where it does. Every ProjectQuotaStatus reports `Enforced=False` with the `ControlPlaneNotManaged` reason; the usage is counted and shown, and every namespace is limited by its `d8-project-quota` ResourceQuota, so no namespace alone uses more than the quota of the whole project.

  This is expected on a cluster whose control plane is managed outside Deckhouse Platform, for example by a cloud provider. Silence the alert if that is the case.

- D8ProjectQuotaOvershoot CE S5
  ▼ Usage of project XXX has grown past its quota.

  The usage of project `XXX` grew past its quota. The ledger allows that only for a status write of a quota saved long after it was approved (a change of the ledger leader at that moment, a stalled etcd, another slow webhook) or when kube-controller-manager recounts a quota, and then by at most a tenth of a limit. The `Exceeded` condition of the ProjectQuotaStatus names the keys, the difference and the probable cause. Nothing running is evicted; creating more of these resources is denied until the usage is back within the quota.

- D8ProjectQuotaSuspended CE S6
  ▼ The project quota ledger is suspended.

  The `quota-ledger-suspend` ConfigMap in `d8-multitenancy-manager` suspends the ledger: every write passes and the sum of the project quotas is not checked. Find who created it in the audit log and delete it when the reason is gone:

```
d8 k -n d8-multitenancy-manager delete configmap quota-ledger-suspend
```

- D8ProjectQuotaWebhookErrors CE S5
  ▼ The API servers fail to call the project quota ledger.

  For 10 minutes the API servers have been failing to call the webhook of the ledger: connections refused, timeouts or TLS errors. A change of the leader causes such errors for a second or two only. The steps of `D8ProjectQuotaLedgerDown` apply.

- D8ProjectQuotaWebhookMisconfigured CE S4
  ▼ The webhook of the project quota ledger is missing or misconfigured.

  The `d8-multitenancy-manager-quota-ledger` ValidatingWebhookConfiguration is missing, does not carry the CA of the `quota-ledger-certs` Secret, is changed so that writes of `d8-project-quota` do not reach the ledger (its rules, `namespaceSelector`, `objectSelector`, `matchConditions`, `failurePolicy` or service), or the API servers let the canary writes through without calling it. The sum of the project quotas is not checked; the `Enforced` condition of every ProjectQuotaStatus names the reason (`WebhookMissing`, `WebhookMisconfigured` or `WebhookNotCalled`) and the field or the API servers. Deckhouse puts the webhook back within about 4 minutes; if it does not, contact Deckhouse technical support. Compare the CA:

```
d8 k get validatingwebhookconfiguration d8-multitenancy-manager-quota-ledger -o
jsonpath='{.webhooks[0].clientConfig.caBundle}' | base64 -d | openssl x509 -noout -
subject
d8 k -n d8-multitenancy-manager get secret quota-ledger-certs -o jsonpath='{.data.ca\.crt}'
| base64 -d | openssl x509 -noout -subject
```

- D8ResourceQuotaAdmissionDegraded CE S4
  ▼ **The quota admission of the API servers is slow.**

  The 99th percentile of the ResourceQuota admission plugin is above one second. The plugin has a few workers for all creates in the cluster, so this slows down creates everywhere. The cause may be a slow webhook on `resourcequotas/status` (the project quota ledger or another one) or a slow etcd. Find the slow webhook by `apiserver admission webhook admission_duration_seconds` and check `etcd_disk_wal_fsync_duration_seconds`.

- MultitenancyManagerControllerUnavailable CE S4
  ▼ **The multitenancy-manager controller has had no available pods for more than 10 minutes.**

  The `multitenancy-manager` Deployment in the `d8-multitenancy-manager` namespace has had no available pods for more than 10 minutes.

  While this alert is active, projects are not reconciled, and the admission webhooks of the module, which refuse a request when they cannot be reached, refuse to create or change Project, ProjectTemplate and the other objects they check.

  Steps to troubleshoot:

  1. Check the pods of the controller:

     ```
     d8 k -n d8-multitenancy-manager get pods -l app=multitenancy-manager
     d8 k -n d8-multitenancy-manager describe pods -l app=multitenancy-manager
     ```

  2. A pod that is running but not ready may wait for the conversion of the CRDs. The controller does not start until each of the `clusterresourcegrantpolicies.multitenancy.deckhouse.io`, `projects.deckhouse.io` and `projecttemplates.deckhouse.io` CRDs converts through the webhook: until then, the API server would show it objects of an older version with only `apiVersion` rewritten. Look for the wait in the log:

     ```
     d8 k -n d8-multitenancy-manager logs deploy/multitenancy-manager -c multitenancy-manager |
     grep 'conversion'
     ```

     - `hold the controller until the webhook-handler of the deckhouse module registers the conversion webhook of the CRDs` means that the controller waits; the line names the CRDs and their current conversion strategy.
     - `the CRDs convert through the webhook` or `the CRDs already convert through the webhook` means that the wait is over.

  3. If the controller waits, check the conversion strategy of the CRDs and the ConversionWebhook resources of the module. The `webhook-handler` of the `deckhouse` module sets the strategy to `Webhook` for every ConversionWebhook resource:

     ```
     d8 k get crd clusterresourcegrantpolicies.multitenancy.deckhouse.io projects.deckhouse.io
     projecttemplates.deckhouse.io -o custom-
     columns=NAME:.metadata.name,STRATEGY:.spec.conversion.strategy
     d8 k get conversionwebhooks.deckhouse.io
     clusterresourcegrantpolicies.multitenancy.deckhouse.io projects.deckhouse.io
     projecttemplates.deckhouse.io
     d8 k -n d8-system logs deploy/webhook-handler -c handler --tail=200
     ```

     Do not set the strategy by hand: the conversion has to be served by the `webhook-handler`, which registers it once it has loaded the ConversionWebhook resource.

- MultitenancyManagerHelmProjectTemplate CE S9
  ▼ **ProjectTemplate XXX still renders its projects from a Helm text in resourcesTemplate.**

  ProjectTemplate `XXX` describes the objects of its projects with a Helm text in `resourcesTemplate`, and its projects are rendered from that text. They keep working as before. This form of a template is deprecated, and `resourcesTemplate` goes away in a future release, so move the template to structured fields and `manifests` before then. Moving a template from a Helm text describes the move step by step.

  The built-in templates `default`, `secure` and `secure-with-dedicated-nodes` are structured and accept the same parameters as their Helm texts did, except `administrators` and `resourceQuota`, so they show how a text maps to the fields. The full mapping is in Moving a template from a Helm text. Objects of the text that have no structured field go to `manifests`,

which the controller applies with the `d8:project:admin` role of the project. An AuthorizationRule of the `Admin` access level goes to `.spec.administrators` of each Project instead, because `manifests` does not create one. Cluster-scoped objects have no place in a template.

Once the template has structured fields in place of `resourcesTemplate`, the AuthorizationRule and ResourceQuota objects that `.spec.administrators` and `.spec.quota` replace are deleted after these fields work, and an AuthorizationRule that names nobody from `.spec.administrators` any more is deleted at once. Every other object of the text that the structured fields do not render under the same kind and name is left in place, and the `MultitenancyManagerProjectKeepsHelmTemplateObjects` alert names the project until `manifests` takes the object over or it is deleted. The administrators then have the `d8:project:admin` role in place of the `Admin` access level, and the two roles do not grant the same permissions. See Switching a project from a Helm text.

Steps:

1. Read the template and compare it with the built-in template it was copied from, if any:

   ```
   d8 k get projecttemplate XXX -o yaml
   d8 k get projecttemplate default -o yaml
   ```

2. List the projects of the template. A template that no project uses can be deleted, and the alert goes with it:

   ```
   d8 k get projects -l projects.deckhouse.io/project-template=XXX
   ```

3. Find the projects of the template that still set `administrators` or `resourceQuota` in `.spec.parameters`:

   ```
   d8 k get projects -l projects.deckhouse.io/project-template=XXX -o json | jq -r '.items[]
   | select((.spec.parameters // {}) | has("administrators") or
   has("resourceQuota")) | .metadata.name'
   ```

   These values get no standard fields and are not handed over, so move them to `.spec.administrators` and `.spec.quota` first, and only as far as they mean the same there. `.spec.administrators` gives users and groups the `d8:project:admin` role, so an administrator with another access level or another kind of subject needs a ProjectRoleBinding of its own. `.spec.quota` enforces every limit it holds, `0` included, so leave out a limit that the text did not render, such as a `0` that it skipped.

4. If the structured fields and `manifests` cover what the projects need, which they do unless the projects need cluster-scoped objects of the text or objects that the `d8:project:admin` role does not allow, write the template as `deckhouse.io/v1alpha2` with these fields and `manifests` and without `resourcesTemplate`, in one change, where the template is applied from, for example in Git or in CI. A template that projects use cannot lose `resourcesTemplate` without structured fields or `manifests` in its place, and once it has fields that `deckhouse.io/v1alpha1` cannot describe, a write of it through `deckhouse.io/v1alpha1` is refused. If the template is an unchanged copy of a built-in template, you can instead move its projects to that template in `.spec.projectTemplateName` and then delete the copy.

5. Check each project after the switch. Its `HandoverPending` condition is removed once the replaced objects are deleted, its `ManifestsApplied` condition says whether the objects of `manifests` are applied, and `.status.keptObjects` lists the objects left in place:

   ```
   d8 k get project PROJECT_NAME -o jsonpath='{range .status.conditions[*]}{.type}=
   {.status}: {.message}{"\n"}{end}{range .status.keptObjects[*]}{.kind}
   {.namespace}/{.name}{"\n"}{end}'
   ```

- MultitenancyManagerPreviousRevisionStillRunning CE S6
  ▾ Pods of several revisions of the multitenancy-manager controller have run side by side for more than 15 minutes.

  Pods of VALUE revisions of the `multitenancy-manager` Deployment in the `d8-multitenancy-manager` namespace have been pending or running side by side for more than 15 minutes.

  The rollout of the controller is stuck: the new pod is pending or not ready, or an old pod is stuck terminating on a lost node. The new pod waits for the pods of older revisions for 10 minutes at most and then starts its controllers anyway. If an old pod of a revision that runs without leader

election is still running, both pods write the Helm releases of the projects, and objects in the project namespaces may be deleted and created again.

Steps to troubleshoot:

1. List the controller pods with their revisions and nodes:

   ```
   d8 k -n d8-multitenancy-manager get pods -L pod-template-hash -o wide
   ```

2. Find out whether the new pod has started its controllers:

   ```
   d8 k -n d8-multitenancy-manager logs NEW_POD_NAME -c multitenancy-manager | grep 'other revisions'
   ```

   - `hold the controllers until the pods of other revisions finish` means that the new pod holds the lease and waits.
   - `no pods of other revisions to wait for` means that it has started its controllers at once, because the old pods had finished or were deleted more than 10 minutes ago.
   - `the pods of other revisions finished` means that it has started its controllers after waiting, because the old pods finished or were deleted more than 10 minutes ago.
   - `the pods of other revisions did not finish in time, starting the controllers anyway` means that it has started its controllers after 10 minutes of waiting.

   Without any of these lines, the new pod waits for the lease that the old pod holds. When the wait ends after 10 minutes, the new pod also writes a Warning event with the reason `PreviousRevisionStillRunning`, and the message of the event names the old pods. An event is kept for an hour by default:

   ```
   d8 k -n d8-multitenancy-manager get events --field-selector reason=PreviousRevisionStillRunning
   ```

3. Check the node of the old pod, shown in the `NODE` column:

   ```
   d8 k get node NODE_NAME
   ```

4. Act on what you see:

   - The old pod is `Running`, not terminating, and the new pod is not ready. The Deployment removes the old pods only after the new ones are ready, and deleting an old pod does not help, since its ReplicaSet creates it again. Find out why the new pod is not ready:

     ```
     d8 k -n d8-multitenancy-manager describe pod NEW_POD_NAME
     ```

   - The old pod is `Terminating` on a node that is `NotReady`. Such a pod stays until its node comes back or the Node object is deleted. If the node is lost for good, delete the Node object, and its pods are deleted with it. If you know the machine of the node is powered off, you can force-delete the old pod instead:

     ```
     d8 k -n d8-multitenancy-manager delete pod OLD_POD_NAME --force --grace-period=0
     ```

     Do not force-delete a pod whose containers may still run. The pod disappears from the API, while its process keeps writing the Helm releases.

- MultitenancyManagerProjectHandoverStuck CE S6
  ▼ Project XXX still keeps the AuthorizationRule and ResourceQuota objects its standard fields replace.

  An upgrade of the release of project `XXX` dropped AuthorizationRule or ResourceQuota objects that the Helm text of its template had rendered for the administrators and the quota of the project. These are the AuthorizationRule objects with the `Admin` access level of the administrators and a quota such as `all-pods` whose every limit `.spec.quota` sets. That happens when a template switches from `resourcesTemplate` to structured fields, when a project moves to such a template, or when the text no longer renders these objects. The controller kept them through the upgrade, so that the administrators never lost access and the namespace never lost its quota, and deletes them once the standard fields of the project replace them. The handover began more than 30 minutes ago and has not finished.

Until it does, the kept AuthorizationRule objects keep granting the `Admin` access level, the `user-authz:admin` role, next to the `d8:project:admin` role of the `d8-administrators` ProjectRoleBinding. The kept quotas keep applying next to the `d8-project-quota` ResourceQuota, and the tighter of them wins.

The kept objects are deleted by a reconcile of the project that succeeds once all of the following hold, and not earlier than 2 minutes after `d8-administrators` became `Ready` and after the handover began:

- the `d8-administrators` ProjectRoleBinding names the administrators from `.spec.administrators` and is `Ready` for its current generation, when a kept AuthorizationRule names one of them;
- the `d8:project:admin` ClusterRole has its aggregated rules, when a kept AuthorizationRule names one of the administrators;
- the `d8-project-quota` ResourceQuota has the limits from `.spec.quota` and is calculated, that is, its `status.hard` matches its `spec.hard`, when a kept quota has limits.

A kept AuthorizationRule that names nobody from `.spec.administrators` any more is deleted at once, and a subject removed from `.spec.administrators` is removed at once from a kept AuthorizationRule that names other administrators too. A reconcile that cannot find the template, validate the project against it, upgrade the release or apply the standard fields stops before the deletion, and the kept objects stay. A template that grants a role forbidden in projects puts the project in the `Error` state too, but it does not stop the deletion.

The `HandoverPending` condition of the project says what the controller waits for.

Steps to troubleshoot:

1. Read what the controller waits for, and the state and the other conditions of the project:

   ```
   d8 k get project XXX -o jsonpath='{.status.state}{"\n"}{range
   .status.conditions[*]}{.type}={.status}: {.message}{"\n"}{end}'
   ```

2. Check the administrators binding. Its `status.observedGeneration` must match `metadata.generation`, and its `Ready` condition must be `True`:

   ```
   d8 k -n XXX get projectrolebinding d8-administrators -o yaml
   ```

   If the binding lags behind, the controller could not create its RoleBinding in some namespace of the project. The logs of the controller name the namespace and the error:

   ```
   d8 k -n d8-multitenancy-manager logs -l app=multitenancy-manager -c multitenancy-manager --
   tail=-1 --prefix | grep d8-administrators
   ```

3. Check that the `d8:project:admin` ClusterRole has rules. The aggregation controller of kube-controller-manager fills them:

   ```
   d8 k get clusterrole d8:project:admin -o jsonpath='{.rules}'
   ```

4. Check the project quota and the events in the namespace of the project:

   ```
   d8 k -n XXX get resourcequota d8-project-quota -o yaml
   d8 k -n XXX get events --sort-by=.lastTimestamp
   ```

   A quota whose `status.hard` stays empty is not processed by the resource quota controller of kube-controller-manager.

5. Fix what the checks show, for example a RoleBinding that an admission policy refuses in one of the namespaces of the project, a kube-controller-manager that does not process the quota, or the condition that stops the reconcile of the project. The controller checks again whenever `d8-administrators` or `d8-project-quota` changes, and at least every minute, and deletes the kept objects once the conditions hold.

- MultitenancyManagerProjectKeepsHelmTemplateObjects CE S7
  ▼ Project XXX has VALUE objects its release left in place.

  The release of project `XXX` no longer holds VALUE objects, and the controller left them in place instead of deleting them. That happens when the project switches off a Helm text in `resourcesTemplate` and the structured fields do not render the object. It also happens when

`.spec.quota` stops covering a quota kept for a handover. The release of the structured fields leaves an object in place too when `manifests` of the template render it, so that `manifests` take it over. Examples are AuthorizationRule or RoleBinding objects, quotas, network policies, workloads or their volumes. The objects left in place behave as follows:

- They keep working as before. The rules and the bindings keep granting access, the quotas keep applying, and the workloads keep running.
- The project no longer manages them. A change of the template or of the project does not change them. When the project is deleted, the ones in its namespaces go with the namespaces, and the controller deletes the cluster-scoped ones that still carry the label.
- They carry the `projects.deckhouse.io/kept-from-helm-template: "true"` label and the `helm.sh/resource-policy: keep` annotation, and they have lost the `heritage: multitenancy-manager` label. While they carry the label, only a requester who may make the same change to objects of their kind across the cluster may change or delete them, so the users of the project may not.

The project lists them in `.status.keptObjects` until each of them is deleted, loses the label, is rendered by the template again, or is taken over by the `manifests` of the template. Decide for each object:

- If it is still needed, describe it in the template or in the project, for example with a ProjectRoleBinding in place of an AuthorizationRule or a RoleBinding, or with a limit in `.spec.quota`, and then delete the object. Or remove the label to hand it over to the project, whose users may then change and delete it.
- If it is in a namespace of the project, `manifests` of the template can take it over. Once `manifests` renders an object of the same kind, namespace and name, the controller applies it as the `system:multitenancy-manager:project:XXX` user, removes the label and takes the object off the list. The object then has what `manifests` renders, and a field that the release set and `manifests` leaves out is removed.
- If it is not needed, delete it. An access it grants ends only when it is deleted.
- If the template renders an object of the same kind and name again, the project release takes it over. The controller then removes the label, puts the `heritage: multitenancy-manager` label back and removes the `helm.sh/resource-policy: keep` annotation, unless the template sets it itself.

Steps:

1. List the objects:

   ```
   d8 k get project XXX -o jsonpath='{range .status.keptObjects[*]}{.kind}
   {.namespace}/{.name}{"\n"}{end}'
   ```

2. Keep an object as your own:

   ```
   d8 k -n NAMESPACE label KIND NAME projects.deckhouse.io/kept-from-helm-template-
   ```

3. Delete an object:

   ```
   d8 k -n NAMESPACE delete KIND NAME
   ```

The controller looks at the list every 10 minutes, and at a reconcile of the project at most once a minute.

- MultitenancyManagerProjectNamedLikeAdditionalNamespace CE S8
  ▼ Project XXX is named like an additional namespace of project XXX.

  The name of project `XXX` is the name of project `XXX`, a dash and a suffix. Additional namespaces of a project are named this way (`project-spec.name` of a ProjectNamespace), but `XXX` is not one of them. It is a separate project with a namespace of its own. The administrators, quota, bindings and template of project `XXX` do not apply to it.

  Such a pair appears when both namespaces existed before they became projects, or when a project is created under such a name. Nothing is broken, but the names read as one project to anyone who looks at them.

  If the two projects are meant to be separate, nothing has to change in the cluster. The alert keeps firing for as long as both projects exist, so silence it for this pair in Alertmanager.

  If `XXX` is meant to be an additional namespace of project `XXX`, recreate it as one. A namespace cannot move between projects in place. Deleting the project deletes its namespace with everything in it.

1. Make sure that everything running in the `XXX` namespace can be deployed again, or move it elsewhere first.
2. Find the ClusterProjectRoleBinding objects that name the ServiceAccounts of the `XXX` namespace. While a cluster-wide binding names them, the ProjectNamespace in step 4 is refused, so remove these subjects from the bindings first and add them back once the namespace is there again:

   ```
   d8 k get clusterprojectrolebindings -o json | jq -r --arg ns XXX '.items[] |
   select(any(.spec.subjects[]?; (.kind == "ServiceAccount" and .namespace ==
   $ns) or (.kind == "User" and (.name | startswith("system:serviceaccount:" +
   $ns + ":"))) or (.kind == "Group" and .name == "system:serviceaccounts:" +
   $ns))) | .metadata.name'
   ```

3. Delete the project. The command returns once the namespace is gone:

   ```
   d8 k delete project XXX
   ```

4. Create a ProjectNamespace in the `XXX` namespace, with `spec.name` set to the part of the name after `XXX-`. The controller creates the `XXX` namespace again, as an additional namespace of project `XXX`.
5. Deploy the workloads into the namespace.

Module node-local-dns

- D8NodeLocalDNSCacheDenialEvictionsHigh BE S6
  ▼ **node-local-dns denial cache is being frequently evicted.**

  The `denial` (NXDOMAIN) cache in node-local-dns is evicting entries frequently.

  This might indicate that there are Services that are being recreated too often in cluster. So, denial cache size is not enough (`denial 65536` is currently configured).

  Affected node: `NODE_NAME`

- D8NodeLocalDNSCacheSuccessEvictionsHigh BE S6
  ▼ **node-local-dns success cache is being frequently evicted.**

  The `success` cache in node-local-dns is evicting entries frequently (>100 in 5 minutes).

  This could mean there are too many different DNS records application have to resolve (to many Services?). So, node-local-dns cache capacity is too small (`success 120000` is currently configured), or traffic patterns changed.

  Affected node: `NODE_NAME`

- D8NodeLocalDNSForwardMaxConcurrentRejects BE S5
  ▼ **The forward plugin is rejecting DNS queries due to max concurrency limit.**

  More than 20 queries were rejected within the last 5 minutes on node `NODE_NAME` because the max concurrent query limit was reached.

- D8NodeLocalDNSKubeforwardRequestLatencyP95High BE S4
  ▼ **High DNS request latency in kubeforward (p95 > 300ms under load).**

  The 95th percentile DNS request latency for A-records through kubeforward exceeded 300 milliseconds over the last 5 minutes while handling more than 0.1 QPS.

  This may indicate slow upstreams, network issues, or DNS overload on this node.

  Affected node: `NODE_NAME`

  For more detailed diagnostics, inspect `Top 5 upstreams by slow kubeforward requests` in Grafana.

  If the alert fires only on one node, run the checks below from node `NODE_NAME` (for example, from a debug pod on this node). If the alert fires on many nodes, treat it as a potential systemic issue first.

  Get kubeforward upstream IPs from a master host:

  ```
  d8 k -n kube-system get po -l k8s-app=kube-dns -o jsonpath='{.items[*].status.podIP}'
  ```

Then run latency checks on the affected node `NODE_NAME` (or from a debug pod on that node):

```
UPSTREAMS="paste kube-dns pod IPs here"
for ip in $UPSTREAMS; do
  echo "== upstream ${ip} =="
  for i in $(seq 1 20); do
    dig @"$ip" -p 5353 kubernetes.default.svc.cluster.local A +tries=1 +time=1 +stats | grep
"Query time"
  done
done
```

To identify slow requests, enable module logs (`enableLogs`) and inspect slow query messages:

```
pod=$(kubectl -n kube-system get po -l k8s-app=node-local-dns --field-selector
spec.nodeName=NODE_NAME -o jsonpath='{.items[0].metadata.name}')
d8 k -n kube-system logs "$pod" | grep '\[kubeforward\] slow query'
```

Example log line: `[kubeforward] slow query A kubernetes.default.svc.cluster.local. took 425ms (rcode=NOERROR, upstream=10.96.0.10:53)`

Interpretation:

- If most upstreams are slow and many nodes are affected, suspect systemic network/CoreDNS overload.
- If one upstream is slow or only one node is affected, suspect a localized issue.

- D8NodeLocalDNSUpstreamHealthcheckFailed BE S5
  ▼ **Too many upstream health check failures in forward plugin.**

  The health check system of the `forward` plugin failed more than 10 times within 5 minutes on node `NODE_NAME`. As a result, all upstreams were considered unhealthy.

Module node-manager

- CapsInstanceUnavailable CE S8
  ▼ **There are unavailable instances in the MACHINE_DEPLOYMENT_NAME MachineDeployment.**

  The MachineDeployment `MACHINE_DEPLOYMENT_NAME` has **VALUE** unavailable instances.

  Check the status of the instances in the cluster with the following command:

  ```
  d8 k get instance -l node.deckhouse.io/group=MACHINE_DEPLOYMENT_NAME
  ```

- ClusterHasOrphanedDisks CE S6
  ▼ **Cloud data discoverer found orphaned disks in the cloud.**

  The cloud data discoverer has found disks in the cloud that do not have a corresponding PersistentVolume in the cluster.

  You can safely delete these disks manually from your cloud provider:

  ID: ID, Name: NAME

- D8BashibleApiserverLocked CE S6
  ▼ **Bashible-apiserver has been locked for too long.**

  `Bashible-apiserver` has been locked for an extended period.

  To resolve the issue, check if the `bashible-apiserver` Pods are up-to-date and running:

  ```
  d8 k -n d8-cloud-instance-manager get pods -l app=bashible-apiserver
  ```

- D8CAPIControllerManagerNotAvailable CE S4
  ▼ **No capi-controller-manager replica is available.**

  No replica of `capi-controller-manager` has been available for more than 5 minutes.

  Its admission webhooks reject changes to Cluster API objects, so node groups served by Cluster API do not create or remove nodes.

To inspect the pods:

```
d8 k -n d8-cloud-instance-manager get pods -l app=capi-controller-manager -o wide
```

- D8CAPIControllerManagerReplicasUnavailable CE S7
  ▼ **Part of the capi-controller-manager replicas is unavailable.**

  Some replicas of `capi-controller-manager` have been unavailable for more than 30 minutes.

  The controller keeps working while at least one replica is available. Usually a master is down, cordoned, or its port is taken.

  To inspect the pods:

  ```
  d8 k -n d8-cloud-instance-manager get pods -l app=capi-controller-manager -o wide
  ```

- D8CloudDataDiscovererCloudRequestError CE S6
  ▼ **Cloud data discoverer cannot get data from the cloud.**

  Refer to the cloud data discoverer's logs for details:

  ```
  d8 k -n NAMESPACE logs deploy/cloud-data-discoverer
  ```

- D8CloudDataDiscovererSaveError CE S6
  ▼ **Cloud data discoverer cannot save data to a Kubernetes resource.**

  Refer to the cloud data discoverer's logs for details:

  ```
  d8 k -n NAMESPACE logs deploy/cloud-data-discoverer
  ```

- D8ClusterAutoscalerManagerPodIsNotReady CE S8
  ▼ **The POD_NAME Pod is NOT Ready.**

  To check the Pod's status, run the following command:

  ```
  d8 k -n NAMESPACE logs POD_NAME
  ```

- D8ClusterAutoscalerPodIsNotRunning CE S8
  ▼ **The cluster-autoscaler Pod is NOT Running.**

  The POD_NAME Pod is STATUS.

  To check the Pod's status, run the following command:

  ```
  d8 k -n NAMESPACE get pods POD_NAME -o json | jq .status
  ```

- D8ClusterAutoscalerPodIsRestartingTooOften CE S9
  ▼ **Too many cluster-autoscaler restarts detected.**

  The cluster-autoscaler has restarted VALUE times in the past hour.

  Frequent restarts may indicate a problem. The cluster-autoscaler is expected to run continuously without interruption.

  Check the logs for details:

  ```
  d8 k -n d8-cloud-instance-manager logs -f -l app=cluster-autoscaler -c cluster-autoscaler
  ```

- D8ClusterAutoscalerTargetAbsent CE S8
  ▼ **Cluster-autoscaler target is missing in Prometheus.**

  The cluster-autoscaler automatically scales nodes in the cluster. If it's unavailable, it will be impossible to add new nodes when there's not enough resources for scheduling Pods. It may also lead to unnecessary cloud costs due to unused but still provisioned cloud instances.

  To resolve the issue, follow these steps:

  1. Check availability and status of cluster-autoscaler Pods:

```
d8 k -n d8-cloud-instance-manager get pods -l 'app in (cluster-autoscaler,cluster-autoscaler-mcm)'
```

2. Verify that the cluster-autoscaler Deployment exists:

```
d8 k -n d8-cloud-instance-manager get deploy -l 'app in (cluster-autoscaler,cluster-autoscaler-mcm)'
```

3. Check the Deployment’s status:

```
d8 k -n d8-cloud-instance-manager describe deploy deployment-name
```

- D8ClusterAutoscalerTargetDown CE S8

  Prometheus is unable to scrape cluster-autoscaler’s metrics.

- D8ClusterAutoscalerTooManyErrors CE S8
  ▼ Cluster-autoscaler is issuing too many errors.

  The cluster-autoscaler encountered multiple errors from the cloud provider when attempting to scale the cluster.

  Check the logs for details:

  ```
  d8 k -n d8-cloud-instance-manager logs -f -l app=cluster-autoscaler -c cluster-autoscaler
  ```

- D8FencingAgentDown CE S6
  ▼ The fencing agent does not work on node NODE_NAME.

  The node `NODE_NAME` is Ready, but Prometheus does not get the metrics of its fencing agent for 5 minutes.

  Without the agent, the node does not detect a loss of the control plane, and its neighbors do not see it.

  To check the pod of the agent:

  ```
  d8 k -n d8-cloud-instance-manager get pods -l app=fencing-agent --field-selector spec.nodeName=NODE_NAME -o wide
  d8 k -n d8-cloud-instance-manager describe pods -l app=fencing-agent --field-selector spec.nodeName=NODE_NAME
  ```

- D8FencingAgentInvalidKey CE S6
  ▼ The fencing agent on node NODE_NAME cannot read the memberlist key.

  The fencing agent on the node `NODE_NAME` cannot read the memberlist key from the Secret `fencing-memberlist-key` in the namespace `d8-cloud-instance-manager`, because the key has a wrong format. The agent does not connect to the other agents and does not arm the watchdog, so the node is not protected.

  The `primary` key must have exactly 32 bytes. A frequent error is a key written as a base64 string into `stringData`. To check the length of the key:

  ```
  d8 k -n d8-cloud-instance-manager get secret fencing-memberlist-key -o jsonpath='{.data.primary}' | base64 -d | wc -c
  ```

  The command must show 32. To write the key correctly, refer to the module FAQ.

- D8FencingAgentRestarted CE S7
  ▼ The fencing agent restarted on node NODE_NAME.

  The container `fencing-agent` restarted on the node `NODE_NAME` in the last 15 minutes.

  After a crash of the agent, the watchdog stays armed. At the start, the new agent process disarms the watchdog if the control plane is available. If the control plane is not available, the watchdog timeout expires and the kernel panics. The node then stays stopped, because `kernel.panic` is `0`. Restart the node manually.

  If the agent crashes again and again, the watchdog of the node is not armed, and fencing does not

stop the node if the node fails.

To read the logs of the agent that crashed:

```
d8 k -n d8-cloud-instance-manager logs -l app=fencing-agent --field-selector
spec.nodeName=NODE_NAME -c fencing-agent --previous
```

- D8FencingEvictionNotProgressing CE S4
  ▼ **The evacuation of node NODE_NAME is not complete after 60 seconds.**

  The fencing controller put the taint `node.kubernetes.io/out-of-service` on the node `NODE_NAME`, but the evacuation is not complete after 60 seconds. The `FencingFailedNodeState` object stays in the phase `Evicting` and has the condition `Progressing` with the status `False` and the reason `XXX`. The controller examines the node again every 5 seconds. When the cause is gone, the evacuation completes, and the alert stops.

  The reasons:

  - `VolumesAttached`: the node still has `VolumeAttachment` objects. The volumes of its pods are not free for other nodes. Usually the CSI driver or the storage cannot detach the volumes.
  - `PodsRemaining`: the controller could not delete pods of the node, or another error of the API stops the evacuation. The message gives the pods and the errors.
  - `TooManyUnhealthyMachines`: the controller does not delete the node of a cloud machine, because the MachineHealthCheck does not replace it. More than 50 percent of the machines are unhealthy, or the cluster has no MachineHealthCheck that reports its machines. The message gives the numbers.

  To read the message of the condition:

  ```
  d8 k get fencingfailednodestate NODE_NAME -o yaml
  ```

  To find the `VolumeAttachment` objects of the node:

  ```
  d8 k get volumeattachments -o custom-
  columns=NAME:.metadata.name,NODE:.spec.nodeName,ATTACHER:.spec.attacher,PV:.spec.source.persistentVolu
  meName,ATTACHED:.status.attached | awk 'NR==1 || $2=="NODE_NAME"'
  ```

  To read the errors of the detach:

  ```
  d8 k get volumeattachments -o json | jq '.items[] | select(.spec.nodeName=="NODE_NAME")
  | {name: .metadata.name, detachError: .status.detachError}'
  ```

- D8FencingKernelPanicMismatch CE S6
  ▼ **The value of kernel.panic on node NODE_NAME is not the value that fencing needs.**

  The value of `kernel.panic` on the node `NODE_NAME` stays wrong for 30 minutes. The fencing agent does not arm the watchdog, so the node is not protected.

  Fencing needs `kernel.panic` set to `0`. After a fencing panic, the node must stay stopped and must not restart by itself.

  Bashible sets the value. Check that bashible works on the node and that no other tool changes `kernel.panic`:

  ```
  d8 k get node NODE_NAME -o jsonpath='{.status.conditions[?(@.type=="Fencing")]}' | jq
  sysctl kernel.panic
  ```

- D8FencingKeyRegenerated CE S9
  ▼ **The memberlist key of fencing was generated again.**

  Deckhouse generated a new memberlist key of fencing, because the Secret `fencing-memberlist-key` in the namespace `d8-cloud-instance-manager` was deleted. The agents use the new key. The old key is lost.

  Agents that did not get the new key cannot talk with the other agents. If you keep a copy of the key outside the cluster, replace it.

  The alert goes out 24 hours after the key was generated. It does not rise when Deckhouse creates the key for the first time or when you rotate the key yourself.

- D8FencingNodeAliveAfterAttestation CE S4

▼ Node NODE_NAME sends heartbeats after a witness confirmed its stop.

A witness node confirmed that the node `NODE_NAME` stopped. After that, the fencing controller saw a heartbeat of the node. Thus the node can still work.

The fencing controller does not put the taint `node.kubernetes.io/out-of-service` on the node while the node sends heartbeats. When the heartbeats stop, the node gets the taint after the silent delay: `controlPlaneLostAfter` + 0.2s + `watchdog.timeout` + `watchdog.margin` + 0.9s of the profile after the last sign of life of the node.

Examine the node. To read the state of the incident:

```
d8 k get fencingfailednodestate NODE_NAME -o yaml
```

- D8FencingNodeFailed CE S4
  ▼ Fencing found a failure of node NODE_NAME.

  The node `NODE_NAME` has a `FencingFailedNodeState` object. The fencing agents of other nodes found that this node failed. The watchdog of the node is armed.

  The fencing controller puts the taint `node.kubernetes.io/out-of-service` on the node when the node is stopped, for one of these reasons:

  - A witness node confirmed that the node stopped, and the watchdog timeout of the node passed after the confirmation.
  - The node is silent: it does not send its heartbeat through the API server. A node that loses the control plane stops itself. The controller waits for the time that the node needs to stop: the control plane loss threshold, the watchdog timeout and a margin after the last sign of life.

  After the taint, the pods of the node move to other nodes. The phase of the object shows the progress. For the cases when the controller does not put the taint, refer to the FAQ of the `node-manager` module.

  If the phase is `FallbackAlive`, the node works. Refer to the alert `D8FencingNodeIsolatedFromPeers`.

  To read the state of the incident:

  ```
  d8 k get fencingfailednodestate NODE_NAME
  d8 k describe fencingfailednodestate NODE_NAME
  ```

  The alert stops when the object is deleted.

- D8FencingNodeIPMismatch CE S6
  ▼ The fencing agent on node NODE_NAME cannot find the IP address of the node.

  The fencing agent on the node `NODE_NAME` cannot use the IP address of its Node object. The Node object has no IPv4 address, or the node network interface does not have this address. The agent waits for the address and does not arm the watchdog, so the node is not protected.

  To compare the addresses:

  ```
  d8 k get node NODE_NAME -o jsonpath='{.status.addresses}' | jq
  ```

- D8FencingNodeIsolatedFromPeers CE S5
  ▼ Node NODE_NAME works, but the fencing agents of other nodes cannot connect to it.

  The fencing agents of other nodes found that the node `NODE_NAME` failed. But the node connects to the control plane and sends its heartbeat. Thus the node works, and the network between this node and the other nodes is broken.

  Usually a firewall rule or an ACL stops the traffic of the fencing agents. The fencing controller does not put the taint `node.kubernetes.io/out-of-service` on a node that sends its heartbeat.

  To read the state of the incident:

  ```
  d8 k get fencingfailednodestate NODE_NAME -o yaml
  ```

  Make sure that the network lets the fencing agents connect to each other.

- D8FencingProfileIsUnavailable CE S5
  ▼ Fencing of node NODE_NAME is blocked, because the controller cannot use its SLA profile.

The node `NODE_NAME` has a fencing incident, but the fencing controller cannot use the SLA profileXXX `XXX` XXX of the incident. The controller does not put the taint `node.kubernetes.io/out-of-service` on the node, and the pods of the node do not move to other nodes.

The controller calculates the times of the incident from the profile:

- the time from the confirmation of a witness to the taint: `watchdog.timeout` + `watchdog.margin`;
- the time from the last sign of life of a silent node to the taint: `controlPlaneLostAfter`, `watchdog.timeout`, `watchdog.margin` and a fixed margin;
- the time after the last heartbeat of the node: `heartbeat.interval` and `heartbeat.apiTimeout`.

The message of the condition `ConfigurationError` of the incident gives the cause, for example the profile that is missing.

The profile of the incident is the profile of the node group of the node. Only an armed node needs a profile. For a node that is not armed, the controller uses a fixed time of 20 seconds after the last heartbeat and reads no profile.

The controller tries again with backoff. Thus the alert shows that the profile is not usable for some minutes.

The module installs the built-in profiles. If a profile is missing, a user usually deleted or changed it. XXX To read the profile:

```
d8 k get fencingslaprofile XXX -o yaml
```

XXX The controller did not find the name of the profile. The message of the condition `ConfigurationError` gives the cause. XXX

To read the cause and the events of the incident:

```
d8 k get fencingfailednodestate NODE_NAME -o jsonpath='{.status.conditions}' | jq
d8 k describe fencingfailednodestate NODE_NAME
```

To read the logs of the controller:

```
d8 k -n d8-cloud-instance-manager logs deploy/fencing-controller -c fencing-controller --all-pods=true
```

- D8FencingSystemNetworkNotFound CE S4
  ▼ **The SystemNetwork XXX of fencing does not exist.**

  The ModuleConfig `node-manager` names the SystemNetwork `XXX` in `settings.fencing.systemNetworkFallback.systemNetworkName`, but the cluster has no such SystemNetwork. The agents cannot use the second network.

  Deckhouse does not change the setting. Create the SystemNetwork, or set the name of another one, or delete the name to turn the second network off.

  To check the network:

  ```
  d8 k get systemnetwork XXX
  d8 k get moduleconfig node-manager -o jsonpath='{.spec.settings.fencing}'
  ```

  The alert goes out about 10 minutes after the network is back, because it looks at the last 10 minutes.

  While all node groups have the mode `Disabled`, the rules of fencing are not loaded, so the alert does not rise. The agents do not use the second network then. The alert rises when you turn fencing on.

- D8FencingWatchdogDeviceMissing CE S6
  ▼ **The fencing agent on node NODE_NAME has no watchdog device.**

  The fencing agent on the node `NODE_NAME` has no watchdog device for 30 minutes. The agent does not arm the watchdog, so the node is not protected.

  A new agent pod does not start without `/dev/watchdog`. Thus, usually this agent runs in a pod of the previous revision without the watchdog device, and the DaemonSet did not replace this pod

yet. On the node, `softdog` and `/dev/watchdog` can be present.

Do these checks:

1. Check the rollout of the DaemonSet of the node group. Find the agent pods of the group in the states `ContainerCreating` (with the `FailedMount` event) or `Terminating` on other nodes. Such a pod stops the rollout. A pod does not start if the NodeGroupConfiguration step failed on its node. A pod stays `Terminating` if its node is `NotReady`.

   ```
   d8 k -n d8-cloud-instance-manager rollout status ds/fencing-agent-group
   d8 k -n d8-cloud-instance-manager get pods -l app=fencing-agent,node-group-name=group -o wide
   d8 k -n d8-cloud-instance-manager get events --field-selector reason=FailedMount
   ```

2. On the node, check that bashible ran the NodeGroupConfiguration `enable-watchdog-for-nodegroup-*` without errors, that `softdog` is loaded and that `/dev/watchdog` is present:

   ```
   d8 k get node NODE_NAME -o jsonpath='{.status.conditions[?(@.type=="Fencing")]}' | jq
   journalctl -u bashible --since -1h
   lsmod | grep softdog
   ls -l /dev/watchdog
   ```

- D8FencingWatchdogTimeoutMismatch CE S6
  ▼ The watchdog timeout on node NODE_NAME differs from the timeout of the fencing profile.

  The watchdog of the node `NODE_NAME` reports a timeout that is not the timeout of the fencing profile of its node group. The fencing agent does not arm the watchdog, so the node is not protected.

  A watchdog driver can round the timeout or accept only some values. To read the reason:

  ```
  d8 k get node NODE_NAME -o jsonpath='{.status.conditions[?(@.type=="Fencing")]}' | jq
  ```

- D8KubeletCheckpointStateUnpinnedContainers CE S4
  ▼ Pod NAMESPACE/POD_NAME may run in a NUMA zone other than the one recorded by kubelet.

  Kubelet on Node `NODE NAME` reset the memory manager checkpoint and recorded new NUMA zones for Pod `NAMESPACE/POD_NAME`. Zones are applied only when a container is created, so the running containers stay in their previous zones, which may differ from the recorded ones.

  As a result, the zone the Pod really uses may also be assigned to another Guaranteed Pod, causing both Pods to share its memory resources. The Pod's CPUs and memory may also be assigned to different NUMA zones, which slows down its memory access.

  The Pod is not restarted automatically. The restart time depends on the workload. To restore resource isolation, do the following:

  - To recreate the Pod's containers in newly assigned NUMA zones, delete the Pod:

    ```
    d8 k -n NAMESPACE delete pod POD_NAME
    ```

  - For a virtual machine, perform a live migration to another node instead, without stopping it.
  - If the node runs many such Pods, you can drain it instead of deleting them one by one.

  The alert resolves within a few minutes after the Pod is recreated. No kubelet restart is needed.

- D8MachineControllerManagerPodIsNotReady CE S8

  The POD_NAME Pod is NOT Ready.

- D8MachineControllerManagerPodIsNotRunning CE S8
  ▼ The machine-controller-manager Pod is NOT Running.

  The POD_NAME Pod is STATUS.

  To check the Pod's status, run the following command:

  ```
  d8 k -n NAMESPACE get pods POD_NAME -o json | jq .status
  ```

- D8MachineControllerManagerPodIsRestartingTooOften CE S9
  ▼ **Too many machine-controller-manager restarts detected.**

  The `machine-controller-manager` has restarted VALUE times in the past hour.

  Frequent restarts may indicate a problem. The `machine-controller-manager` is expected to run continuously without interruption.

  Check the logs for details:

  ```
  d8 k -n d8-cloud-instance-manager logs -f -l app=machine-controller-manager -c controller
  ```

- D8MachineControllerManagerTargetAbsent CE S8
  ▼ **Machine-controller-manager target is missing in Prometheus.**

  `Machine-controller-manager` controls ephemeral nodes in the cluster. If it becomes unavailable, it will be impossible to create or delete nodes in the cluster.

  To resolve the issue, follow these steps:

  1. Check availability and status of `machine-controller-manager` Pods:

     ```
     d8 k -n d8-cloud-instance-manager get pods -l app=machine-controller-manager
     ```

  2. Verify availability of the `machine-controller-manager` Deployment:

     ```
     d8 k -n d8-cloud-instance-manager get deployment machine-controller-manager
     ```

  3. Check the Deployment’s status:

     ```
     d8 k -n d8-cloud-instance-manager describe deployment machine-controller-manager
     ```

- D8MachineControllerManagerTargetDown CE S8

  Prometheus is unable to scrape the machine-controller-manager’s metrics.

- D8NeedMigrateStateToOpenTofu CE S4
  ▼ **Terraform state must be migrated to OpenTofu.**

  This likely means the automatic migration to OpenTofu was canceled due to destructive changes detected in the cluster state.

  Verify the following:

  - Current Terraform version:

    ```
    d8 k -n d8-system exec -it deployments/terraform-state-exporter -c exporter -- terraform version
    ```

  - Version in the Terraform state:

    ```
    d8 k -n d8-system get secret d8-cluster-terraform-state -o json | jq -r '.data["cluster-tf-state.json"] | @base64d | fromjson | .terraform_version'
    ```

  - Check for destructive changes:

    ```
    d8 k exec -it deploy/terraform-state-exporter -n d8-system -- dhctl terraform check
    ```

  To resolve the issue and migrate to OpenTofu manually, follow these steps:

  1. Using the `install` container with the previous major Deckhouse release (for example, `1.69.X`, while the cluster is now on `1.70.X`), run:

     ```
     dhctl converge
     ```

     This should resolve all destructive changes in the cluster.

  2. After that, the `terraform-auto-converger` Pod should complete the migration

automatically.

If the automatic migration doesn't happen, use the `install` container with the current Deckhouse release and run the following command to enforce migration of the Terraform state to OpenTofu:

```
dhctl converge-migration
```

If this alert appears in a cluster created by Deckhouse Commander, it means the cluster has been updated to a new Deckhouse version without approving state changes (for example, destructive changes).

To resolve this, follow these steps:

1. In Deckhouse Commander, click **Delete manually** to temporarily remove the cluster from control.
2. In the cluster, remove the `commander-agent` module using the following command:

   ```
   d8 k delete mc commander-agent
   ```

3. Using the `install` container with the previous major Deckhouse release (for example, `1.69.X`, while the cluster is now on `1.70.X`), run the following command to resolve all destructive changes in the cluster:

   ```
   dhctl converge
   ```

4. In Deckhouse Commander, click **Attach** to reattach the cluster.

- D8NodeCgroupV2NotSupported CE S8
  ▼ **Node NODE_NAME is using deprecated cgroup v1 – migration to v2 required.**

  Node NODE_NAME in NodeGroup NODE_GROUP_NAME does not support cgroup v2. Starting from Kubernetes 1.35, cgroup v1 is deprecated. To migrate to cgroup v2, please upgrade the kernel to version 5.8 or newer. For more information, please refer to the documentation.

- D8NodeContainerdV2NotSupported CE S8
  ▼ **Node NODE_NAME is using deprecated containerd v1 – migration to v2 required.**

  Node NODE_NAME in NodeGroup NODE_GROUP_NAME does not support containerd v2. Starting from Kubernetes 1.38, containerd v1.y will no longer be supported. Please check the requirements for containerd v2 and schedule your migration plan.

  The exact reason is listed in the `node.deckhouse.io/containerd-v2-err` annotation on the node.

  If the reason is `erofs` and the node runs Ubuntu in AWS, the module is shipped in a separate `linux-modules-extra` package. DKP installs it automatically, but for some kernels, mostly outdated ones, the package is no longer published in the APT repository. In that case, the installation is skipped and a warning is written to the node logs. The problem has been confirmed for the `5.15.0-1028-aws`, `6.8.0-1024-aws`, and `6.8.0-1029-aws` kernels. Switch the node group to a newer AMI or kernel version that includes `erofs`.

- D8NodeControllerReconcileErrorsHigh CE S8
  ▼ **Node-controller reconcile errors are high for CONTROLLER_NAME.**

  Controller `CONTROLLER_NAME` has a reconcile error rate above 0.1 errors per second for more than 10 minutes.

  Check node-controller logs:

  ```
  kubectl -n d8-cloud-instance-manager logs deploy/node-controller --all-pods=true
  ```

- D8NodeControllerReconcileP99High CE S8
  ▼ **Node-controller reconcile p99 is high for CONTROLLER_NAME.**

  The p99 reconcile duration for controller `CONTROLLER_NAME` has been above 5 seconds for more than 10 minutes.

  This may indicate slow reconciliation, Kubernetes API latency, or degraded controller performance.

  To inspect node-controller logs:

```
kubectl -n d8-cloud-instance-manager logs deploy/node-controller --all-pods=true
```

- D8NodeControllerWorkqueueDepthHigh CE S8
  ▼ **Node-controller workqueue NAME has a high backlog.**

  The node-controller workqueue `NAME` has more than 50 queued objects for more than 15 minutes.

  This may indicate that the controller cannot process reconciliation events fast enough.

  To inspect node-controller logs:

  ```
  kubectl -n d8-cloud-instance-manager logs deploy/node-controller --all-pods=true
  ```

- D8NodeGroupFencingDeprecatedSettings CE S9
  ▼ **NodeGroup NAME uses a deprecated fencing setting.**

  NodeGroup `NAME` has a deprecated fencing setting in `spec.fencing`:

  - `mode: Watchdog` works as `mode: Slow`. To remove the alert, set `mode: Slow`, or choose another mode.
  - `watchdog.timeout` has no effect. The timeout comes from the fencing profile of the mode. To remove the alert, delete `watchdog.timeout`.

  To read the settings of the NodeGroup:

  ```
  d8 k get nodegroup NAME -o jsonpath='{.spec.fencing}'
  ```

- D8NodeGroupIsNotUpdating CE S8
  ▼ **NodeGroup NODE_GROUP_NAME is not handling the update correctly.**

  There is a new update available for Nodes in the `NODE_GROUP_NAME` NodeGroup. Although Nodes have detected the update, none of them have received approval to start the update process.

  Most likely, there is a problem with the `update_approval` hook of the `node-manager` module.

- D8NodeIsNotUpdating CE S7
  ▼ **Node NODE_NAME cannot complete the update.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` detected a new update, requested and received approval, started the update, and encountered a step that could cause downtime. The update manager (the `update_approval` hook of the `node-group` module) granted downtime approval, but no success message was received, which indicates that the update has not completed.

  To investigate the details, view Bashible logs on the Node:

  ```
  journalctl -fu bashible
  ```

- D8NodeIsNotUpdating CE S8
  ▼ **Node NODE_NAME cannot complete the update.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` has detected a new update, requested and received approval, but failed to complete the update.

  To investigate the details, view Bashible logs on the Node:

  ```
  journalctl -fu bashible
  ```

- D8NodeIsNotUpdating CE S9
  ▼ **Node NODE_NAME is not updating.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` has a pending update but it’s neither receiving it nor attempting to.

  Most likely, Bashible is not handling the update correctly. It should annotate the Node with `update.node.deckhouse.io/waiting-for-approval` before the update can proceed.

  Options to investigate the details:

  - Check the expected configuration checksum for the NodeGroup:

```
d8 k -n d8-cloud-instance-manager get secret configuration-checksums -o jsonpath=
{.data.NODE_GROUP_NAME} | base64 -d
```

- Check the current configuration checksum on the Node:

```
d8 k get node NODE_NAME -o
jsonpath='{.metadata.annotations.node\.deckhouse\.io/configuration-
checksum}'
```

- View Bashible logs on the Node:

```
journalctl -fu bashible
```

- D8NodeIsUnmanaged CE S9
  ▼ **The NODE_NAME Node is not managed by the node-manager module.**

  The NODE_NAME Node is not managed by the `node-manager` module.

  To resolve this issue, follow the instructions how to clean up the node and add it to the cluster.

- D8NodeOutOfServiceTainted CE S6
  ▼ **Node NODE_NAME has the taint node.kubernetes.io/out-of-service for 30 minutes.**

  The node `NODE_NAME` has the taint `node.kubernetes.io/out-of-service` for 30 minutes. Kubernetes does not run pods on the node.

  The fencing controller or a user puts the taint on a node that stopped. Start the node again or remove it from the cluster.

  To read the taints of the node:

  ```
  d8 k get node NODE_NAME -o jsonpath='{.spec.taints}' | jq
  ```

  If a user put the taint and the node works, remove the taint:

  ```
  d8 k taint node NODE_NAME node.kubernetes.io/out-of-service-
  ```

- D8NodeUpdateStuckWaitingForDisruptionApproval CE S8
  ▼ **Node NODE_NAME cannot obtain disruption approval.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` detected a new update, requested and received initial approval, and started the update. However, it reached a stage that could cause downtime and was unable to obtain disruption approval. A disruption approval is normally issued automatically by the `update_approval` hook of the `node-manager` module.

  To resolve this issue, investigate why the approval could not be granted to proceed with the update.

- D8ProblematicNodeGroupConfiguration CE S8
  ▼ **Node NODE_NAME cannot begin the update.**

  There is a new update available for Nodes in the `NODE_GROUP_NAME` NodeGroup. However, Node `NODE_NAME` cannot begin the update.

  The Node is missing the `node.deckhouse.io/configuration-checksum` annotation, which may indicate that its bootstrap process did not complete correctly.

  Troubleshooting options:

  - Check the `cloud-init` log (`/var/log/cloud-init-output.log`) on the node.
  - Check the NodeGroupConfiguration resource associated with the `NODE_GROUP_NAME` NodeGroup for potential issues.
- NodeGroupHasStaticInternalNetworkCIDRsField CE S9
  ▼ **NodeGroup NAME uses deprecated field spec.static.internalNetworkCIDRs.**

  The `spec.static.internalNetworkCIDRs` field is deprecated and has been moved to the static cluster configuration.

  To resolve this issue, delete the field from NodeGroup NAME. This is safe, as the setting has already been migrated automatically.

- NodeGroupMasterTaintIsAbsent CE S4
  ▼ **The master NodeGroup is missing the required control-plane taint.**

  The `master` NodeGroup doesn't have the `node-role.kubernetes.io/control-plane: NoSchedule` taint. This may indicate a misconfiguration where control-plane nodes can run non-control-plane Pods.

  To resolve the issue, add the following to the `master` NodeGroup spec:

  ```
  nodeTemplate:
    taints:
    - effect: NoSchedule
      key: node-role.kubernetes.io/control-plane
  ```

  Note that the taint `key: node-role.kubernetes.io/master` is deprecated and has no effect starting from Kubernetes 1.24.

- NodeGroupProviderTypeIsInvalid CE S4
  ▼ **The spec.providerType field is set incorrectly in NodeGroup NAME.**

  The `spec.providerType` field of NodeGroup `NAME` is set to `XXX`, which is not the cloud provider the nodes of the group run in.

  To resolve this issue, set the field to a correct value:

  - If the nodes of the group run in a cloud, set the field to the `type` of that cloud provider, as published in its registration secret:

    ```
    kubectl -n kube-system get secrets -l cloud-provider.deckhouse.io/registration -o json \
    | jq -r '.items[] | .data.type | @base64d'
    ```

  - If the cluster is static, or the NodeGroup has `nodeType: Static`, set the field to `None` or leave it empty:

    ```
    kubectl patch nodegroup NAME --type=merge -p '{"spec":{"providerType":"None"}}'
    ```

- NodeGroupReplicasUnavailable CE S7
  ▼ **NodeGroup NODE_GROUP_NAME has no available instances.**

  This probably means that `machine-controller-manager` is unable to create Machines using the cloud provider module.

  Possible causes:

  1. Cloud provider resource limits.
  2. No access to the cloud provider API.
  3. Misconfiguration of the cloud provider or instance class.
  4. Problems with bootstrapping the Machine.

  Recommended actions:

  1. Check the status of the NodeGroup:

     ```
     d8 k get ng NODE_GROUP_NAME -o yaml
     ```

     Look for errors in the `.status.lastMachineFailures` field.

  2. If no Instances stay in the Pending state for more than a couple of minutes, it likely means that Instances are being continuously created and deleted due to an error:

     ```
     d8 k get instances
     ```

  3. If logs don't show errors, and an Instance continues to be Pending, check its bootstrap status:

     ```
     d8 k get instances INSTANCE_NAME -o yaml | grep 'bootstrapStatus' -B0 -A2
     ```

  4. If the output looks like the example below, use the `logsEndpoint` (or the command in `description`) to examine bootstrap logs:

```
bootstrapStatus:
  description: Use 'curl -N http://192.168.199.158:8000' to get bootstrap logs.
  logsEndpoint: http://192.168.199.158:8000
```

5. If there's no bootstrap log endpoint, `cloudInit` may not be working correctly. This could indicate a misconfigured instance class in the cloud provider.

- NodeGroupReplicasUnavailable CE S8
  ▼ **Too many unavailable instances in the NODE_GROUP_NAME NodeGroup.**

  The number of simultaneously unavailable instances in the NODE_GROUP_NAME NodeGroup exceeds the allowed threshold. This may indicate that the autoscaler has provisioned too many nodes at once. Check the state of the Machine in the cluster. This probably means that `machine-controller-manager` is unable to create Machines using the cloud provider module.

  Possible causes:

  1. Cloud provider resource limits.
  2. No access to the cloud provider API.
  3. Misconfiguration of the cloud provider or instance class.
  4. Problems with bootstrapping the Machine.

  Recommended actions:

  1. Check the status of the NodeGroup:

     ```
     d8 k get ng NODE_GROUP_NAME -o yaml
     ```

     Look for errors in the `.status.lastMachineFailures` field.

  2. If no Instances stay in the Pending state for more than a couple of minutes, it likely means that Instances are being continuously created and deleted due to an error:

     ```
     d8 k get instances
     ```

  3. If logs don't show errors, and an Instance continues to be Pending, check its bootstrap status:

     ```
     d8 k get instances INSTANCE_NAME -o yaml | grep 'bootstrapStatus' -B0 -A2
     ```

  4. If the output looks like the example below, use the `logsEndpoint` (or the command in `description`) to examine bootstrap logs:

     ```
     bootstrapStatus:
       description: Use 'curl -N http://192.168.199.158:8000' to get bootstrap logs.
       logsEndpoint: http://192.168.199.158:8000
     ```

  5. If there's no bootstrap log endpoint, `cloudInit` may not be working correctly. This could indicate a misconfigured instance class in the cloud provider.

- NodeGroupReplicasUnavailable CE S8
  ▼ **NodeGroup NODE_GROUP_NAME has unavailable instances.**

  There are VALUE unavailable instances in the NodeGroup NODE_GROUP_NAME. This probably means that `machine-controller-manager` is unable to create Machines using the cloud provider module.

  Possible causes:

  1. Cloud provider resource limits.
  2. No access to the cloud provider API.
  3. Misconfiguration of the cloud provider or instance class.
  4. Problems with bootstrapping the Machine.

  Recommended actions:

  1. Check the status of the NodeGroup:

     ```
     d8 k get ng NODE_GROUP_NAME -o yaml
     ```

Look for errors in the `.status.lastMachineFailures` field.

2. If no Instances stay in the Pending state for more than a couple of minutes, it likely means that Instances are being continuously created and deleted due to an error:

```
d8 k get instances
```

3. If logs don't show errors, and an Instance continues to be Pending, check its bootstrap status:

```
d8 k get instances INSTANCE_NAME -o yaml | grep 'bootstrapStatus' -B0 -A2
```

4. If the output looks like the example below, use the `logsEndpoint` (or the command in `description`) to examine bootstrap logs:

```
bootstrapStatus:
  description: Use 'curl -N http://192.168.199.158:8000' to get bootstrap logs.
  logsEndpoint: http://192.168.199.158:8000
```

5. If there's no bootstrap log endpoint, `cloudInit` may not be working correctly. This could indicate a misconfigured instance class in the cloud provider.

- NodeGroupUsesDeprecatedInCoreGPU CE S9
  ▼ **NodeGroup NAME uses the deprecated built-in GPU support.**

  NodeGroup `NAME` has `spec.gpu` configured while the `gpu` module is disabled. As a result, GPU nodes in the NodeGroup use the built-in GPU support, which is deprecated and will be removed in a future DKP release.

  To use the supported GPU implementation, enable the `gpu` module.

- NodeRequiresDisruptionApprovalForUpdate CE S8
  ▼ **Node NODE_NAME requires disruption approval to proceed with the update.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` has detected a new update, received initial approval, and started the update. However, it encountered a stage that may cause downtime and requires manual disruption approval, because the NodeGroup is configured with `disruptions.approvalMode: Manual`.

  To resolve the issue, ensure the Node is ready for unsafe updates (drained) and grant disruption approval by annotating the Node with `update.node.deckhouse.io/disruption-approved=`.

  Caution:

  - Nodes in manual mode aren't drained automatically.
  - Do not drain master nodes.

  1. To drain the Node and grant the update approval, run the following command:

```
d8 k drain NODE_NAME --delete-emptydir-data --ignore-daemonsets --force=true &&
  d8 k annotate node NODE_NAME update.node.deckhouse.io/disruption-approved=
```

  2. Uncordon the Node once the update is complete and the annotation `update.node.deckhouse.io/approved` is removed:

```
while d8 k get node NODE_NAME -o json | jq -e '.metadata.annotations |
has("update.node.deckhouse.io/approved")' > /dev/null; do sleep 1; done
d8 k uncordon NODE_NAME
```

  If the NodeGroup has multiple Nodes, repeat this process for each one, since only one Node is updated at a time. Consider temporarily switching to automatic disruption approval (`disruptions.approvalMode: Automatic`).

- NodeStuckInDraining CE S6
  ▼ **Node NODE_NAME keeps failing to drain.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` is stuck in the draining process.

  The Node has the error from the last attempt in the `update.node.deckhouse.io/drain-failed` annotation, truncated to 1 KB. To read it, run:

```
d8 k get node NODE_NAME -o json | jq -r
'.metadata.annotations["update.node.deckhouse.io/drain-failed"]'
```

The full error text is in the `DrainFailed` events on the Node:

```
d8 k -n default get event --field-selector involvedObject.name=NODE_NAME,reason=DrainFailed --
sort-by='.metadata.creationTimestamp'
```

The drain is retried until it succeeds, so the alert clears on its own once the cause is gone. Until then the Node holds the update slot of its NodeGroup, and no other Node in that group is updated.

The usual causes are a PodDisruptionBudget that never allows an eviction and a pod that never terminates. Fix the cause named in the error above.

- NodeStuckInDrainingForDisruptionDuringUpdate CE S6
  ▼ **Node NODE_NAME is stuck in draining.**

  Node `NODE_NAME` in NodeGroup `NODE_GROUP_NAME` has detected a new update, requested and received approval, started the update, and reached a step that could cause downtime. It is currently stuck in the draining process while waiting for automatic disruption approval.

  To get more details, run the following:

  ```
  d8 k -n default get event --field-selector involvedObject.name=NODE_NAME,reason=ScaleDown --
  sort-by='.metadata.creationTimestamp'
  ```

- StandbyHolderDeploymentReplicasUnavailable CE S5
  ▼ **No available replicas in Deployment standby-holder-NODE_GROUP_NAME.**

  Deckhouse has detected that there are no available replicas in the `standby-holder-NODE_GROUP_NAME` Deployment in the `d8-cloud-instance-manager` namespace.

  Check the Deployment and associated Pods for issues.

- UnmetCloudConditions CE S6
  ▼ **Deckhouse update is unavailable due to unmet cloud provider conditions.**

  Deckhouse has detected that some cloud provider–specific conditions have not been met. Until these issues are resolved, updating to the new Deckhouse release is not possible.

  ```

Module registry

- D8RegistryAgentNotReady CE S4
  ▼ The registry agent on node NODE_NAME is not ready.

  The registry agent on node `NODE_NAME` is not answering, or is not running at all. Every pull on the node goes through it, and without it containerd pulls straight from the registry an image names. Images of the platform itself, and of registries that need the cluster's credentials or certificate authority, then fail on that node; other images still pull, bypassing the in-cluster cache and any `RegistryUpstream`.

  The kubelet restarts an agent that stops answering for a minute, so a state that lasts this long is one a restart does not fix: an agent that fails on start, or one that is not on the node at all.

  What the pod says:

  ```
  d8 k -n kube-system get pod registry-agent-NODE_NAME -o wide
  d8 k -n kube-system describe pod registry-agent-NODE_NAME
  d8 k -n kube-system logs registry-agent-NODE_NAME --previous --tail=50
  ```

  An agent that exits on start names in its log what it could not use, usually its certificate material under `/etc/kubernetes/registry-agent/pki` or containerd's drop-in directory.

  No such pod means either that the kubelet has no manifest for it — on a node bashible configures, that is `/etc/kubernetes/manifests/registry-agent.yaml` — or that the API server refused the mirror pod, in which case the agent may well be running. The kubelet's log on the node says which:

  ```
  journalctl -u kubelet --since "1 hour ago" | grep registry-agent
  ```

  A node of a NodeGroup with `systemType: DeckhouseEngine` has no SSH: start a debug pod on it with `d8 k debug node/NODE_NAME -it --image=ubuntu` and run `chroot /host` first.

  Fifteen minutes, so that a node taking over the agent after the module starts managing it, or an update that replaces the agent on every node, does not raise it.

- D8RegistryAgentRestartingTooOften CE S5
  ▼ The registry agent on node NODE_NAME keeps restarting.

  The registry agent on node `NODE_NAME` has restarted five times or more in the last hour. Each restart drops every pull in flight on the node, and until the agent is back containerd pulls without it, where images of the platform cannot be pulled.

  Either the agent exits on its own, or the kubelet kills it because it stopped answering its liveness probe for a minute. The last state of the container says which:

```
d8 k -n kube-system get pod registry-agent-NODE_NAME -o
jsonpath='{.status.containerStatuses[0].lastState}' | jq
d8 k -n kube-system logs registry-agent-NODE_NAME --previous --tail=100
d8 k -n kube-system get events --field-selector involvedObject.name=registry-agent-NODE_NAME
```

`Liveness probe failed` in the events is an agent that hung: the log before the restart shows what it was doing. An exit code with an error in the log is an agent that gave up: the log names what it could not use.

- D8RegistryAirGapTransitionHeld CE S5
  ▼ The registry upstream cannot be removed yet.

  The configuration has no upstream, so the cluster is meant to be air-gapped, and the module is still holding the previous upstream: either the cache is not complete enough to stand alone, or the cache leader's report was not written by the `syncer` running on its node now, or workloads in the platform namespaces (`kube-system` and `d8-*`) still reference the upstream and would have nowhere to pull from without it. Workloads in other namespaces are not counted and do not hold the transition.

  This is the safe outcome and the cluster is pulling images normally. It is also the one transition in this module that could cut every node off from images, which is why it waits rather than proceeds — and why a wait this long is worth looking at: nothing about it resolves on its own if the cache has stopped filling, or if a rollout onto the in-cluster address is stuck.

  Check the cache and the current count of references to the upstream (`upstreamReferences`):

  ```
  d8 k get registrystorage registry -o jsonpath='{.status}' | jq
  '{phase,fill,safeToDropUpstream,upstreamReferences,leader}'
  d8 k get registryconfig registry -o jsonpath='{.status.effectiveUpstream}' | jq
  ```

  The `registry-controller` log names up to five of the referencing objects each time the count changes. To see the last such line:

  ```
  d8 k -n d8-system logs -l app=registry-controller -c registry-controller --prefix --tail=-1 | grep
  'still names the upstream' | tail -1
  ```

  If the leader is full and `upstreamReferences` is `0`, the upstream is held on the leader's report: its `syncerStartedAt` is missing or earlier than the start of the `syncer` container in the leader's storage pod. The `syncer` stamps its report once it has read its store, normally within two minutes of starting. The hold does not end while the leader's storage pod is not Ready, or while that pod runs a `syncer` from before `syncerStartedAt` existed (during a module update), which stamps nothing. To see the leader's report and the controller's reason:

  ```
  d8 k get registrystorage registry -o json | jq '.status as $s | $s.replicas[] | select(.node ==
  $s.leader) | {node,full,error,syncerStartedAt}'
  d8 k -n d8-system logs -l app=registry-controller -c registry-controller --prefix --tail=-1 | grep
  'the upstream is held' | tail -1
  ```

  Deleting the leader's storage pod is safe while the upstream is held: the replacement `syncer` reads its store and stamps its report, normally within two minutes.

- D8RegistryConfigInvalid CE S4
  ▼ The registry configuration was rejected.

  The `registry` module cannot use its configuration, so the cluster keeps whatever arrangement it already had. Nothing has broken yet; nothing new will take effect either.

  What was wrong is in the resource:

  ```
  d8 k get registryconfig registry -o jsonpath='{.status.conditions}' | jq
  ```

- D8RegistryControllerDown CE S5
  ▼ The registry controller is down or cannot be scraped.

  No replica of `registry-controller` in `d8-system` is both ready and answering Prometheus. Either every replica is down or not ready, or they run and their metrics cannot be read — through `kube-rbac-proxy`, which needs a TokenReview to let Prometheus in.

  Pulls are not affected: every node keeps pulling the way its agent was last told. What stops is everything that changes that. A change to the `registry` ModuleConfig, a new RegistryUpstream, a leader moving to another master, an air-gap transition — none of it reaches the nodes until the controller is back.

Beyond the registry, no namespace in the cluster can finish deleting: the controller also serves the `registry.deckhouse.io` API (the `RegistryImage` listing), and while nobody answers for it, discovery of that group fails and namespaces stay `Terminating` with the condition `NamespaceDeletionDiscoveryFailure`. They are deleted once a replica answers again.

And while this is firing, most other `D8Registry*` alerts are blind: they read what the controller exports, so they stay silent whatever happens in the meantime. The exceptions are `D8RegistryStorageLeaderAbsent`, which reads the cache replicas themselves, and the migration and drain alerts, which Deckhouse feeds; those keep working.

```
d8 k -n d8-system get deploy registry-controller
d8 k -n d8-system get pods -l app=registry-controller -o wide
d8 k -n d8-system logs deploy/registry-controller -c registry-controller --all-pods=true --tail=100
d8 k -n d8-monitoring get podmonitor registry-controller
```

If the pods are ready, the problem is in the scrape: look at the `kube-rbac-proxy` container's log for authentication errors.

- D8RegistryDrainStuck CE S6
  ▼ **The registry module cannot finish leaving the pull path.**

  The `registry` ModuleConfig asks for `Unmanaged`, and the module is still running its components and still serving `registry.d8-system.svc:5001`. That is deliberate: workloads in the cluster still name that address, and taking it away before they move would leave them unable to pull. It has been waiting for half an hour, which is longer than it should take.

  Nothing is degraded while this alert is firing. The cluster pulls, the module serves, and the only thing not happening is the withdrawal.

  What to look at:

  1. What still names the address. The module logs the first few on every pass, and the count is a metric:

     ```
     d8 k -n d8-system logs deploy/deckhouse -c deckhouse | grep "still serving the in-cluster
     registry"
     ```

  2. Then the workloads themselves, which is where the answer usually is:

     ```
     d8 k get pods,deployments,daemonsets,statefulsets -A -o json \
       | jq -r '.items[] | select([.spec.template.spec.containers[]?.image,
     .spec.containers[]?.image] | any(startswith("registry.d8-system.svc:5001"))) | "\(.kind) \
     (.metadata.namespace)/\(.metadata.name)"'
     ```

  A third cause is a cluster with nowhere to go, and it is the one to check first on a cluster that was air-gapped or installed with no upstream. Leaving the pull path means pointing the cluster back at the registry the module was fetching from, and a module serving purely from its own store has no such registry to name. It says so in the log:

  ```
  d8 k -n d8-system logs deploy/deckhouse -c deckhouse | grep "no upstream to point the cluster back
  at"
  ```

  Give the cluster a registry to pull from, or ask for `Managed` again. Nothing is degraded while it waits, and the withdrawal will not complete until one of the two happens.

  Otherwise two causes account for it. Either a release is not being re-rendered — check that the operator queue is not stuck, since the references move only as each module's release is rendered again:

  ```
  d8 k -n d8-system exec deploy/deckhouse -c deckhouse -- deckhouse-controller queue main
  ```

  Or something outside the platform's own renders names the address: a workload of yours that hardcoded it, or a manually edited manifest. Those will never move on their own, and until they are changed to pull from the registry the cluster was installed with, the module will keep serving them — which is the intended behaviour, not a failure.

  One shape of this is worth naming, because it was hit the first time this ran on a live cluster: a rolling update stuck for reasons of its own. The new pod is already on the upstream registry and never becomes ready, so the superseded ReplicaSet keeps its old pod, and that pod names the in-cluster address. A pod that has already pulled is not waited on, so this alone does not hold the withdrawal — but a pod stuck BEFORE its containers start does, and rightly, since it is exactly what would fail. Fix the rollout, or delete the pod that cannot start:

```
d8 k get pods -A --field-selector status.phase=Pending
```

A drain can also be abandoned by asking for `Managed` again: the module then keeps the pull path it never finished giving up, and this alert goes away.

- D8RegistryMigrationPending CE S8
  ▼ The registry module is held on its v1 implementation.

  This cluster still pulls images the way the v1 implementation of the `registry` module arranged it, and the handover to the current implementation has not happened. This alert does not resolve on its own while the reason stays, and the following DP releases stay blocked by the `registryImplementation` requirement.

  Reason: `XXX`

  The handover waits because both implementations configure the same thing on every node: which registry the container runtime asks, and with which credentials. Running both would not merge those two answers, it would race them. So the current implementation takes over only from a state it can take over from.

  What to do depends on the reason:

  - The reason names the **`Direct`** mode. This release can take over on its own once it knows where images come from: set `mode: Managed` in the `registry` ModuleConfig together with `primary.upstream`. Take the values from the `registry.direct` section of the `deckhouse` ModuleConfig, as the module's FAQ shows for the `Direct` mode: `imagesRepo` splits into `host` and `path`, the credentials stay the same, plus `ca` if the registry requires one. The handover happens on the module's next reconciliation and this alert clears.
  - The reason names the **`Proxy`** or **`Local`** mode, says the v1 implementation is **transitioning**, has **not recorded a mode**, or that its state or node configuration **cannot be read**. This state is not supported. A cluster gets here only through an update that bypassed the `registryImplementation` release requirement: a forced release, an edited image, or a jump from a release older than DP 1.77.1. DP 1.78 has no code that can manage or migrate this state.

    DP 1.78 does not deploy the v1 implementation, and the update removed the components that managed its node services on the masters. Depending on the timing of the update, those services were stopped, or keep running with nothing to manage them or renew their certificates. The nodes keep the registry configuration the v1 implementation gave them. Images already on a node keep working; pulling any other image may fail.

    Do not change the `registry` or `deckhouse` ModuleConfigs and do not delete the `registry-*` secrets in `d8-system`: those secrets keep the handover closed, so that the current implementation is not deployed next to what the v1 implementation left. Contact Deckhouse Platform technical support.

  To see the mode the v1 implementation recorded:

  ```
  d8 k -n d8-system get secret registry-state -o jsonpath='{.data.state}' | base64 -d | head
  ```

  If that secret is gone, the node configuration the v1 implementation left still shows the mode. This prints the mode and the proxy endpoints only, without credentials:

  ```
  d8 k -n d8-system get secret registry-bashible-config -o jsonpath='{.data.config}' | base64 -d \
    | awk '/^(agent|mode):/ {print; next} /^proxyEndpoints:/ {p=1; print; next} p && /^ *- / {print;
  next} {p=0}'
  ```

- D8RegistryNodeForeignRegistryConfig CE S5
  ▼ Node NODE_NAME carries container runtime registry configuration the registry module did not write.

  Node `NODE NAME` has a file under `/etc/containerd/conf.d/` (containerd v1) or `/etc/containerd/conf2.d/` (containerd v2) that configures a registry, and the `registry` module manages this cluster's registry configuration. Two writers of that configuration is not a state the platform supports, so bashible refuses to merge such a file.

  One exception for now: on containerd v1 with the module in the `Unmanaged` mode, a `conf.d` file is still merged. The refusal described below starts there once the module is switched to `mode: Managed`, so fix the file before that switch.

  Right now nothing is broken, and that is the danger. The refusal happens inside the bashible step that builds the container runtime configuration, and that step only runs when

something makes it run. Until then the file has no effect at all: bashible compares the node's configuration checksum, finds it unchanged and reports "Configuration is in sync, nothing to do".

The step does run on its own, though: a node re-applies its whole configuration periodically (roughly every four hours), and also on any registry change, platform upgrade or reboot. At that point the step fails with

```
Failed to merge /etc/containerd/conf.d/file: it contains custom registry fields,
configure them in /etc/containerd/registry.d instead
```

and retries, so the node stops applying configuration entirely — hours after the change that caused it, and with nothing else to connect the two.

What to do, before that happens:

1. Find the file on the node:

   ```
   ls /etc/containerd/conf.d/ /etc/containerd/conf2.d/ 2>/dev/null
   grep -l registry /etc/containerd/conf.d/*.toml /etc/containerd/conf2.d/*.toml 2>/dev/null
   ```

2. Move the registry part of it to a host directory, which is where this platform configures registries and where the module's node agent leaves other people's entries alone:

   ```
   /etc/containerd/registry.d/registry host/hosts.toml
   ```

3. Remove the registry section from the `conf.d` file (anything non-registry in it can stay), and remove the `NodeGroupConfiguration` that writes it if that is where it comes from.

Doing it across a fleet with a `NodeGroupConfiguration` has one catch worth knowing in advance: give it a **weight below 32**. The step that refuses the file is `032_configure_containerd`, and a node stops at the step that fails — so a repair placed at a later weight never runs on the nodes that need it most. Measured: a cleanup configuration at weight 10 reached both nodes and cleared the label in 90 seconds.

A node already stuck in the retry loop recovers on its own once the file is gone: measured, the configuration checksum returned in 75 seconds.

- D8RegistryNodeNotConverged CE S5
  ▼ **Some nodes have not applied their registry configuration.**

  The agent on one or more nodes has not applied the layout it was given. Those nodes keep pulling images the way they were configured before, so this is not an outage — but a change made to the registry configuration has not reached them, and the next one will not either.

  Which nodes, and what their agents say:

  ```
  d8 k get registrynodes -o custom-columns=\
  NODE:.metadata.name,GEN:.metadata.generation,APPLIED:.status.observedGeneration,OK:.status.reconciled

  d8 k -n kube-system logs -l component=registry-agent --tail=50
  ```

  Twenty minutes, because the agent re-reads its layout on a timer and a node that is merely slow or briefly unreachable resolves this on its own.

- D8RegistryNodeRunningFromDisk CE S6
  ▼ **Some nodes are routing pulls from their on-disk copy of the configuration.**

  The agent on one or more nodes read its layout from the API server and could not use it, so it is routing pulls from the copy it keeps on disk. Most often the credentials the layout references cannot be read; a read that failed while the status write after it went through looks the same. That is the copy working as designed — those nodes pull images normally, which is exactly why this is worth saying out loud: from every other angle it looks like success, and their configuration can drift arbitrarily far behind the cluster's.

  An hour, because a node that falls back for a pass or two is not news; a node that has not come off the copy since is.

```
d8 k get registrynodes -o json | jq -r '
  .items[] | select(.status.conditions[]? | select(.type=="Reconciled" and
.reason=="AppliedFromCache"))
  | .metadata.name'
d8 k -n kube-system logs -l component=registry-agent --tail=200 | grep 'cannot resolve the
credentials'
```

What this alert cannot see is an agent that cannot write its status at all, since that write is how it reports the fallback. A node cut off from the API server is the main case: the agent reaches the API server the way the kubelet does, so the node shows as `NotReady` and is reported as such. An agent whose own access is refused is the other, and while its node stays `Ready` nothing reports it.

- D8RegistryStaleCacheData CE S8
  ▼ A node still holds registry cache data that nothing uses.

  Node `NODE_NAME` holds data of the in-cluster registry cache while no cache is configured. Nothing reads it, and nothing will unless the cache is turned back on.

  It is kept on purpose. Turning the cache back on refills from what is already there rather than from scratch, and over a slow link that difference is hours — so the module does not delete it, because that would make the decision irreversible in the one direction that hurts. What it will not do is keep it quietly, which is what this alert is.

  Nothing is wrong and nothing needs doing urgently. To reclaim the space, remove the contents of the directory the store kept its blobs in: `/var/lib/deckhouse/registry` on a node of a NodeGroup with `systemType: DeckhouseEngine`, `/opt/deckhouse/registry` on other nodes. Keep the directory itself: the agent has it mounted, and once it is removed the agent no longer sees the node's directory, so data a cache leaves there later goes unreported until the agent restarts. With the cache off there is no RegistryStorage left to ask, so the command below looks at both.

  Open a root shell on the node over SSH. A node of a NodeGroup with `systemType: DeckhouseEngine` has no SSH: start a debug pod on it and switch to the node's root filesystem:

  ```
  d8 k debug node/NODE_NAME -it --image=ubuntu
  chroot /host
  ```

  Then remove the data, keeping the directories themselves:

  ```
  for dir in /opt/deckhouse/registry /var/lib/deckhouse/registry; do
    [ -d "$dir" ] && du -sh "$dir" && find "$dir" -mindepth 1 -delete
  done
  ```

  Twenty-four hours, so that turning the cache off and on again in one working session never raises it.

- D8RegistryStorageIncomplete CE S6
  ▼ Some registry cache replicas do not hold the whole image set.

  One or more replicas of the in-cluster cache are still filling, or have stopped short. While an upstream is configured this costs nothing at pull time — a node falls back to it — but it does mean the cluster could not survive losing that upstream, and it is what holds an air-gap transition back.

  Two hours, because filling a cache over a slow link legitimately takes that long.

  A replica that reports an `error` counts as not holding the set, whatever it holds: the error says why — a store that is not on the disk meant for it, for one. A replica whose store the registry cannot write to is left out: it is neither filling nor going to, and `D8RegistryStoreWritesRefused` reports it with what to do.

  ```
  d8 k get registrystorage registry -o json | jq '.status.replicas[] | {node, full, error}'
  ```

- D8RegistryStorageLeaderAbsent CE S4
  ▼ The registry cache has no leader.

  No ready replica of the in-cluster registry cache (`registry-storage` in `d8-system`) reports holding the storage lease.

  The leader is where the nodes pull from, and the only replica that writes. Without it nothing fills the cache, the followers have nobody to replicate from, and `d8 mirror push` has nowhere to go. The agents still route pulls to the replica named as leader in their layout and wait for it before anything else: with an upstream configured a pull is slower and comes from the upstream; in an air-gapped cluster an image a node does not already hold cannot be pulled at all.

Which of three things it is decides what to do, so look first:

```
d8 k -n d8-system get pods -l app=registry-storage -o wide
d8 k -n d8-system get lease registry-storage -o jsonpath='{.spec.holderIdentity} {.spec.renewTime}
{"\n"}'
d8 k get registrystorage registry -o jsonpath='{.status.leader}{"\n"}'
d8 k get registrystorage registry -o json | jq '.status.replicas[] | {node, role, full, error}'
```

- The Lease is held and its `renewTime` keeps moving: the leader is alive, but its report is not counted. Look at the replica on the node named in `holderIdentity`:

  ```
  d8 k -n d8-system get pods -l app=registry-storage -o wide --field-selector
  spec.nodeName=holderIdentity
  d8 k -n d8-system describe pod the pod from the line above
  ```

  If it is not ready, Prometheus does not scrape it, since it scrapes only ready pods. `syncer` has no readiness probe; it is usually the `distribution` or `auth` container that is not ready, and a leader with either of them not ready serves pulls badly or not at all. Find out which one fails and why. If the pod is ready, its scrape fails while the others' do not: look at its `kube-rbac-proxy` container's log for errors.

- The Lease's `renewTime` has stopped while other replicas are ready: nobody leads. First rule out a master that has gone down: the Lease's `holderIdentity` above is the node the last leader ran on.

  ```
  d8 k get nodes -l node-role.kubernetes.io/control-plane
  ```

  If a master is down and is not coming back, delete its Node object: the replica that ran on it then no longer counts in the election. Otherwise, or if the alert keeps firing after that, look at the `error` each replica reports in the list above and at the `syncer` logs of the replicas that are up:

  ```
  d8 k -n d8-system logs registry-storage-0 -c syncer --tail=100
  ```

- No replica is ready, or none can be scraped. Then this is not about the election: the pods are down or not ready (where the `extended-monitoring` module is enabled, `KubernetesStatefulSetReplicasUnavailable` says so as well), or Prometheus cannot read them through `kube-rbac-proxy`, and the leader may well be alive. The Lease above tells it: a `renewTime` that keeps moving means somebody holds it.

- D8RegistryStorageNotReclaimed CE S6
  ▼ **The registry cache has not reclaimed its disk for a week.**

  No replica of the in-cluster cache has finished a garbage collection in the last week. Nothing is broken yet: the cache serves images normally, and it will keep doing so until the disk fills.

  It is worth attention because the collection is the only thing that ever removes anything. Every release adds a slice of the repository, so a store nobody reclaims grows in one direction — and a full store cannot be written to, which in an air-gapped cluster means it cannot be updated.

  Where to look:

  ```
  d8 k get registryoperation -o wide
  d8 k get registrystorage registry -o jsonpath='{.status.replicas}' | jq \
    'map({node, collectedAt, collectionError})'
  d8 k get registrystorage registry -o jsonpath='{.spec.garbageCollection}' | jq
  ```

  The likely reasons, in the order they are worth checking:

  - the collection is turned off in the `registry` ModuleConfig under `storage.garbageCollection.enabled`;
  - the schedule has not come round yet, or names an hour that never arrives — an unreadable expression is refused rather than guessed at — and the image set has not changed either;
  - the collections are created and fail: the `RegistryOperation` objects of type `GarbageCollection` say why in `status.replicas`, for a day after they finish;
  - no release is deployed, which is the one input that justifies deleting anything: every deletion is "older than what the cluster runs", and without that there is nothing to compare against;
  - `collectionError` on a replica, which says what its own last attempt hit.

  One reading tells the first two apart from the rest. The controller logs every collection it creates and every firing of the schedule it skips, so their absence means none was ever started — a

different problem from one that is started and failing:

```
d8 k -n d8-system logs -l app=registry-controller -c registry-controller --tail=-1 | grep -iE
"garbage collection|schedule fired"
```

Collecting is not an outage — the replica keeps serving every image it holds — but it pauses filling the replica's store and can fail a `d8 mirror push` started meanwhile, so the schedule belongs at a quiet hour, which is where it defaults to.

- D8RegistryStorageUpdateBlocked CE S6
  ▼ The in-cluster registry cache cannot be updated to its new revision.

  The `registry-storage` StatefulSet has a new revision, and the controller that replaces its replicas has refused to replace the next one for an hour. Existing replicas remain running, but the cache update cannot proceed. The `reason` label identifies what is blocking it.

  Reason: `XXX`

  - `HolderNotReady` — the cache has one replica and no upstream, so its new images must be on its master before it is replaced. The `registry-storage-image-holder` DaemonSet keeps them there and has not got all of them yet. If its pod on the master is in `ImagePullBackOff`, the cache does not hold an image: push the Deckhouse Platform release the cluster is updating to with `d8 mirror push`, and the holder pulls it on its next retry. If the pod is in `CrashLoopBackOff` or `CreateContainerError`, the holder has the image but cannot run it, and a push does not help: the cause is in the events of the pod. Otherwise it is still rolling or pulling, and there is nothing to do.
  - `SingleReplicaWithoutHolder` — the same, and the DaemonSet has no pod on that master at all. For a moment this is normal while the DaemonSet creates its pod there; lasting an hour, it means the DaemonSet does not schedule a pod there. Find out why with `d8 k -n d8-system describe daemonset registry-storage-image-holder`.
  - `LeaderWithoutFullFollower` — only the leader is left to replace, and no follower holds the whole image set to take over from it. If the leader holds the set, the followers are copying it and the update continues once one of them finishes. If the leader reports that it does not hold it, the followers cannot complete the set either, since they copy it from the leader: pull the Deckhouse Platform release and the modules the cluster uses with `d8 mirror pull`, as described in the air-gapped update guide, and push them into the cache with `d8 mirror push`, as in step 2 of Going air-gapped. If the leader has not reported yet, reports an error or cannot tell which set the cluster needs, pushing does not help: the cause is in the log of the `syncer` container of the leader's pod.
  - `LeaderNotServing` — the storage lease names a master where no serving replica runs. The replicas move the lease on their own once it expires.
  - `StorageUnknown` — the `RegistryStorage` resource does not exist. The controller creates it; check the log of `registry-controller`.

  The event on the StatefulSet says which replica and what it is waiting for:

  ```
  d8 k -n d8-system get events --field-selector involvedObject.name=registry-
  storage,reason=UpdateBlocked
  ```

  And the two things it is waiting on:

  ```
  d8 k -n d8-system get pods -l app=registry-storage-image-holder -o wide
  d8 k get registrystorage registry -o jsonpath='{.status.replicas}' | jq
  ```

- D8RegistryStoreCorrupted CE S5
  ▼ The registry cache holds broken blobs that were not repaired.

  A replica of the in-cluster cache holds blobs whose content does not match their digest, and they have not been repaired for two hours. Every pull of an image that uses such a blob from this replica fails; while an image of the cluster's set uses one, the replica is not full, and a leader hands the lease to a replica that holds the set whole.

  The module creates a `RegistryOperation` of type `Repair` for these blobs on its own, and repeats it four hours after one that did not fix them. Where to look:

  ```
  d8 k get registrystorage registry -o jsonpath='{.status.replicas}' | jq 'map({node, full,
  corruptedBlobs})'
  d8 k get registryoperation -o wide
  d8 k get registryimages -l registry.deckhouse.io/state=Corrupted
  ```

  `status.replicas[].repair.digests[].message` of the last `Repair` says why a blob could not be repaired. The usual reasons:

  - no whole copy anywhere: the cache has one replica and no upstream, or every replica holds the blob broken — as after a `d8 mirror push` of a broken bundle. Push the release again with `d8 mirror push`, then create a `Repair` for the digests by hand;
  - another operation held the queue, such as a long garbage collection: the repair runs once it finishes;
  - the other replicas could not be reached from this one.

  The disk under the store is worth checking too: blobs that go bad on their own are a sign of a failing disk.

- D8RegistryStoreNearlyFull CE S6
  ▼ The registry cache on node NODE_NAME holds over 85% of storage.size.

  The in-cluster registry cache on node `NODE_NAME` holds more than 85% of its budget, `storage.size` in the `registry` ModuleConfig. Nothing is refused yet. The next release may not fit: once the budget is reached, the cache stops accepting writes and `D8RegistryStoreWritesRefused` follows.

  ```
  d8 k get registrystorage registry -o json | jq '.status.replicas[] | {node, store}'
  ```

  Raise `storage.size` if the disk under the store has room — `filesystemFreeBytes` above `reserveBytes` is what is left — or check that the garbage collection runs: it is the only thing that reclaims space, and `D8RegistryStorageNotReclaimed` says when it has not.

- D8RegistryStoreUnbounded CE S7
  ▼ The registry cache has no storage.size, so only the node's disk limits it.

  The in-cluster registry cache is on, and `storage.size` is not set in the `registry` ModuleConfig. The node is still protected: the store never takes the space kept free for the kubelet. But that is the only limit, so the store may grow until it leaves the node exactly that and no more — and on a master that shares its disk with the store, everything else on it then works with the minimum.

  Set `storage.size` to what the store may take on each master: enough for three releases of the image set together with the modules and the module catalog, and no more than fits on the disk under the store above the reserve:

  ```
  d8 k get registrystorage registry -o json | jq '.status.replicas[] | {node, store}'
  ```

  An hour, so that turning the cache on and setting the size in two steps does not raise it.

- D8RegistryStoreWritesRefused CE S4
  ▼ The registry cache on node NODE_NAME does not accept writes (XXX).

  The in-cluster registry cache on node `NODE_NAME` has stopped accepting writes, because `XXX`. It keeps serving every image it holds. What stops is everything that ADDS to it: filling the next release, replicating from the leader, `d8 mirror push`. In an air-gapped cluster a release that is not in the cache cannot be installed.

  What the replica measured, and the error it reports:

  ```
  d8 k get registrystorage registry -o json | jq '.status.replicas[] | {node, store, error}'
  ```

  `BudgetExhausted` — the store holds as much as `storage.size` allows. The node is safe: this is the limit doing its job, and images the store cannot keep are streamed from the upstream while there is one. Either raise `storage.size` in the `registry` ModuleConfig, if the disk has room for it, or let the garbage collection reclaim what no deployed release needs any more: it runs on `storage.garbageCollection.schedule` and keeps the deployed release, the previous one and everything newer.

  `ReserveExhausted` — the filesystem under the store is down to the space kept free on it. The node is safe for the same reason, and images are streamed the same way. `storage.size` is not what stops it, the disk is. On a filesystem shared with the node (`dedicatedFilesystem` absent from the replica's `store`) that is the kubelet's eviction threshold plus a margin: free space on the node, or — which is what fixes it for good — give the store a disk of its own, sized for `storage.size`. On a disk of the store's own (`dedicatedFilesystem: true`) it is the margin alone, and the disk itself is full: grow it — the reserve follows without a restart — or let the garbage collection reclaim what no deployed release needs, as for `BudgetExhausted`.

  `NotWritable` — the registry cannot create files in its tree in the store, whatever room the store has: `docker/registry/v2` and the directories under it, or the store's directory while that tree does not exist yet. It runs as root without capabilities, so those directories have to belong to root and let their owner write. Other causes are the immutable attribute, a read-only mount, or a security module such as SELinux or AppArmor. No limit is involved: neither the garbage collection

nor a larger `storage.size` helps, and the collection does not start for it. Until it is fixed, a pull the cache would keep from the upstream fails with an error instead of being streamed. The replica's `error` names the directory on the node, its owner and mode, and the command that fixes it:

```
d8 k get registrystorage registry -o json | jq -r '.status.replicas[] | select(.store.reason ==
"NotWritable") | "\(.node): \(.error)"'
```

`NotWritable` takes precedence over a limit the store is also at. Once it is fixed, the replica says so within a minute, and the alert clears or names the limit.

- D8RegistryUpstreamProbeFailing CE S4
  ▾ **The configured registry upstream does not pass its preflight check.**

  A change to the primary upstream was refused, and the cluster is still using the last one that worked. Nothing is degraded — that is what holding the previous upstream is for — but the change has not taken effect and will not until the check passes.

  The `outcome` label says which of three things is wrong, and they are not the same problem:

  - `unreachable` — the registry did not answer at all: network, firewall, or the registry itself.
  - `auth` — it answered and rejected the credentials. Usually an expired or wrong license key.
  - `sentinel` — it answered and accepted the credentials, but does not hold the Deckhouse images. Usually the wrong repository path.

  Current outcome: `XXX`

  ```
  d8 k get registryconfig registry -o jsonpath='{.status.conditions}' | jq
  ```

- D8RegistryUpstreamRejected CE S6
  ▾ **An additional registry was refused.**

  A `RegistryUpstream` resource was not accepted, so pulls for the registry it names are not intercepted on any node. Whatever asked for it — a module, or an operator — is not getting it.

  Reason: `XXX`

  ```
  d8 k get registryupstreams -o custom-columns=\
  NAME:.metadata.name,MATCH:.spec.match,ACCEPTED:.status.conditions[0].status,REASON:.status.conditions[
  0].reason
  ```

Module secret-copier

- D8SecretCopierDeprecatedLabels CE S9
  ▾ **Obsolete antiopa_secret_copier=yes label detected.**

  The `secret-copier` module has changed its labeling approach for original secrets in the `default` namespace.

  The label `antiopa-secret-copier: "yes"` is deprecated and will be removed soon.

  To resolve this issue, replace the label `antiopa-secret-copier: "yes"` with `secret-copier.deckhouse.io/enabled: ""` for all secrets used by the `secret-copier` module in the `default` namespace.

Module terraform-manager

- D8TerraformStateExporterClusterStateChanged CE S8
  ▾ **Terraform-state-exporter cluster state change detected.**

  The current Kubernetes cluster state is `STATUS_REFERENCE` compared to the Terraform state.

  It is important to reconcile the states.

  Troubleshooting steps:

  1. View the differences:

     ```
     dhctl terraform check
     ```

  2. Apply the necessary changes to bring the cluster in sync:

     ```
     dhctl converge
     ```

- D8TerraformStateExporterClusterStateError CE S8
  ▼ **Terraform-state-exporter cluster state error.**

  The `terraform-state-exporter` can’t check difference between the Kubernetes cluster state and the Terraform state.

  That was likely caused by `terraform-state-exporter` failing to run Terraform with the current state and configuration.

  Troubleshooting steps:

  1. View the differences:

     ```
     dhctl terraform check
     ```

  2. Apply the necessary changes to bring the cluster in sync:

     ```
     dhctl converge
     ```

- D8TerraformStateExporterHasErrors CE S8
  ▼ **Terraform-state-exporter has encountered errors.**

  Errors occurred during the operation of the `terraform-state-exporter`.

  To get more details, check the Pod logs:

  ```
  d8 k -n d8-system logs -l app=terraform-state-exporter -c exporter
  ```

- D8TerraformStateExporterNodeStateChanged CE S8
  ▼ **Terraform-state-exporter node state change detected.**

  The current state of node `NODE_GROUP_NAME/NAME` is `STATUS_REFERENCE` compared to the Terraform state.

  It is important to reconcile the states.

  Troubleshooting steps:

  1. View the differences:

     ```
     dhctl terraform check
     ```

  2. Apply the necessary changes to bring the cluster in sync:

     ```
     dhctl converge
     ```

- D8TerraformStateExporterNodeStateError CE S8
  ▼ **Terraform-state-exporter node state error.**

  The `terraform-state-exporter` can’t check the difference between the node `NODE_GROUP_NAME/NAME` state and the Terraform state.

  Probably, it occurred because `terraform-manager` had failed to run Terraform with the current state and configuration.

  Troubleshooting steps:

  1. View the differences:

     ```
     dhctl terraform check
     ```

  2. Apply the necessary changes to bring the cluster in sync:

     ```
     dhctl converge
     ```

- D8TerraformStateExporterNodeTemplateChanged CE S8
  ▼ **Terraform-state-exporter node template change detected.**

  The `terraform-state-exporter` has detected a mismatch between the node template in the cluster provider configuration and the one specified in the NodeGroup NAME`.

  Node template is `STATUS_REFERENCE`.

Troubleshooting steps:

1. View the differences:

   ```
   dhctl terraform check
   ```

2. Adjust NodeGroup settings to fix the issue or bring the cluster in sync via the following command:

   ```
   dhctl converge
   ```

- D8TerraformStateExporterPodIsNotReady CE S8
  ▼ **Terraform-state-exporter Pod is not Ready.**

  The `terraform-state-exporter` cannot check the difference between the actual Kubernetes cluster state and the Terraform state.

  To resolve the issue, check the following:

  1. Deployment description:

     ```
     d8 k -n d8-system describe deployment terraform-state-exporter
     ```

  2. Pod status:

     ```
     d8 k -n d8-system describe pod -l app=terraform-state-exporter
     ```

- D8TerraformStateExporterPodIsNotRunning CE S8
  ▼ **Terraform-state-exporter Pod is not Running.**

  The `terraform-state-exporter` cannot check the difference between the actual Kubernetes cluster state and the Terraform state.

  To resolve the issue, check the following:

  1. Deployment description:

     ```
     d8 k -n d8-system describe deployment terraform-state-exporter
     ```

  2. Pod status:

     ```
     d8 k -n d8-system describe pod -l app=terraform-state-exporter
     ```

- D8TerraformStateExporterTargetAbsent CE S8
  ▼ **Terraform-state-exporter target is missing in Prometheus.**

  Prometheus cannot find the `terraform-state-exporter` target.

  To investigate the details:

  - Check the Pod status:

    ```
    d8 k -n d8-system get pod -l app=terraform-state-exporter
    ```

  - Check the container logs:

    ```
    d8 k -n d8-system logs -l app=terraform-state-exporter -c exporter
    ```

- D8TerraformStateExporterTargetDown CE S8
  ▼ **Prometheus can't scrape terraform-state-exporter.**

  Prometheus is unable to scrape metrics from the `terraform-state-exporter`.

  To investigate the details:

  - Check the Pod status:

    ```
    d8 k -n d8-system get pod -l app=terraform-state-exporter
    ```

- Check the container logs:

```
d8 k -n d8-system logs -l app=terraform-state-exporter -c exporter
```

Module user-authn

- D8DexAllTargetsDown CE S6
  ▼ **Prometheus is unable to scrape Dex metrics.**

  Prometheus cannot scrape any Dex pod in the `d8-user-authn` namespace. Users may be unable to sign in.

  Check the Dex pods and their logs:

```
d8 k -n d8-user-authn get pods -l app=dex
d8 k -n d8-user-authn logs deploy/dex
```

- D8DexAuthenticatorNamespaceUnusable CE S7
  ▼ **DexAuthenticator NAMESPACE/NAME is left out of the release because its namespace accepts no objects.**

  The `NAMESPACE` namespace is terminating, so the API server refuses every create in it. The `user-authn` module leaves the DexAuthenticator `NAME` out of its release: with it, the release would fail on the objects it cannot create and the Deckhouse main queue would stop behind the retrying module.

  A namespace does not finish terminating while something in it holds a finalizer, and the authenticator is usually that something. Check what keeps the namespace:

```
d8 k get namespace NAMESPACE -o jsonpath='{.status.conditions}'
d8 k -n NAMESPACE get dexauthenticator NAME -o jsonpath='{.metadata.finalizers}'
```

  Let the deletion finish: remove the finalizer that holds the authenticator, or delete the object that owns it. The authenticator is deleted with its namespace; to keep it, recreate it in a live namespace. The alert resolves once the authenticator is gone.

- D8DexAuthRequestsQuotaExhausted CE S3
  ▼ **Dex AuthRequest objects ResourceQuota is exhausted in namespace "d8-user-authn".**

  The ResourceQuota for `authrequests.dex.coreos.com` objects in namespace `d8-user-authn` has been fully exhausted.

  Dex is currently unable to create new AuthRequest custom resources, which will cause:

  - Dex health checks to fail immediately.
  - Authentication through external identity providers to stop working.
  - Users unable to log in via OAuth/OIDC flows.

  Immediate actions required:

  1. Check current AuthRequest objects and clean up stale ones:

```
d8 k get authrequests.dex.coreos.com -n d8-user-authn --no-headers | wc -l
d8 k delete authrequests.dex.coreos.com --all -n d8-user-authn
```

     Deleting AuthRequest objects interrupts sign-ins that are in progress.

  2. Temporarily increase the ResourceQuota limit:

```
d8 k patch resourcequota authrequest-quota -n d8-user-authn --type='json' -p='[{"op":
"replace", "path": "/spec/hard/count\/authrequests.dex.coreos.com",
"value": "20000"}]'
```

     The module restores the quota on its next run.

  3. Investigate why Dex is not cleaning up AuthRequest objects automatically.

  4. AuthRequest objects expire after 10 minutes. A growing count usually means that a client or a bot repeatedly starts sign-ins. Find the source in the Dex logs.

- D8DexAuthRequestsQuotaHigh CE S4

▾ Dex AuthRequest objects quota usage is higher than 80% in namespace "d8-user-authn".

The ResourceQuota for `authrequests.dex.coreos.com` objects in namespace `d8-user-authn` is approaching its limit.

Current usage: XXX%

When the quota is exhausted, Dex will be unable to create new AuthRequest custom resources, which may cause:

- Dex health checks to fail.
- Authentication through external identity providers (GitLab, GitHub, etc.) to stop working.

Investigation steps:

1. Check for stale AuthRequest objects that Dex should have cleaned up:

   ```
   d8 k get authrequests.dex.coreos.com -n d8-user-authn
   ```

2. AuthRequest objects expire after 10 minutes. A growing count usually means that a client or a bot repeatedly starts sign-ins. Find the source in the Dex logs.

3. Consider temporarily increasing the ResourceQuota limit if needed. The module restores the quota on its next run.

- D8DexProviderLDAPTLSConflict CE S8
  ▾ DexProvider NAME has a conflicting LDAP TLS configuration.

  DexProvider `NAME` combines mutually exclusive LDAP TLS settings: `XXX`. Dex silently ignores the redundant flag, which masks misconfiguration:

  - `insecureNoSSL + startTLS`: TLS is disabled (ldap://, port 389), so `startTLS` is ignored.
  - `insecureNoSSL + insecureSkipVerify`: TLS is disabled, there is no certificate to verify.
  - `insecureNoSSL + rootCAData`: TLS is disabled, the CA chain is ignored.

  The CRD schema rejects this combination on create/update; this DexProvider was created before the validation was added and remains active.

  Update the DexProvider to remove the conflict:

  - Plaintext LDAP (port 389): keep `spec.ldap.insecureNoSSL: true`, remove `startTLS`, `insecureSkipVerify`, and `rootCAData`.
  - STARTTLS on port 389: set `spec.ldap.insecureNoSSL: false`, `spec.ldap.startTLS: true`. Use `insecureSkipVerify` or `rootCAData` as needed.
  - `ldaps://` on port 636: leave `insecureNoSSL` and `startTLS` at `false`. Use `insecureSkipVerify` or `rootCAData` as appropriate.

  Audit all LDAP DexProvider objects:

  ```
  d8 k get dexproviders.deckhouse.io -o yaml | yq '.items[] | select(.spec.type=="LDAP") |
  {name: .metadata.name, ldap: .spec.ldap |
  pick(["insecureNoSSL","startTLS","insecureSkipVerify","rootCAData"])}'
  ```

- D8UserAuthnControllerReconcileErrorsHigh CE S8
  ▾ JOB_NAME reconcile errors are high for CONTROLLER_NAME.

  Controller `CONTROLLER_NAME` of `JOB_NAME` has a reconcile error rate above 0.1 errors per second for more than 10 minutes.

  Check logs:

  ```
  d8 k -n d8-user-authn logs deploy/JOB_NAME --all-pods=true
  ```

- D8UserAuthnControllerTargetDown CE S6
  ▾ Prometheus is unable to scrape user-authn-controller.

  Prometheus cannot scrape metrics from `user-authn-controller` in namespace `d8-user-authn`.

  The controller is down, not Ready (informer cache has not synced), or the PodMonitor is missing. Static user login, UserAccount, expire, and provider checks will not run.

  Check:

```
d8 k -n d8-user-authn get pods -l app=user-authn-controller
d8 k -n d8-user-authn describe pods -l app=user-authn-controller
```

- D8UserAuthnControllerUnavailable CE S6
  ▼ **user-authn-controller has unavailable replicas.**

  Deckhouse has detected unavailable replicas in the `user-authn-controller` deployment in the `d8-user-authn` namespace.

  While this alert is active, static Users may not get Dex Password objects, UserAccount projections stall, expired Users are not deleted, and DexProviderCheck / UserOperation stay pending.

  Check deployment and pod states:

  ```
  d8 k -n d8-user-authn get deploy user-authn-controller
  d8 k -n d8-user-authn get pods -l app=user-authn-controller
  d8 k -n d8-user-authn logs deploy/user-authn-controller --all-pods=true
  ```

- D8UserAuthnDexClientControllerTargetDown CE S6
  ▼ **Prometheus is unable to scrape dexclient-controller.**

  Prometheus cannot scrape metrics from `dexclient-controller` in namespace `d8-user-authn`.

  The controller is down, not Ready (informer cache has not synced), or the PodMonitor is missing. The credentials of DexClients are not kept up to date.

  Check:

  ```
  d8 k -n d8-user-authn get pods -l app=dexclient-controller
  d8 k -n d8-user-authn describe pods -l app=dexclient-controller
  ```

- D8UserAuthnDexClientControllerUnavailable CE S6
  ▼ **dexclient-controller has unavailable replicas.**

  Deckhouse has detected unavailable replicas in the `dexclient-controller` deployment in the `d8-user-authn` namespace.

  While this alert is active, a new DexClient gets no credentials Secret and no Dex client, and changes of DexClients are not applied.

  Check deployment and pod states:

  ```
  d8 k -n d8-user-authn get deploy dexclient-controller
  d8 k -n d8-user-authn get pods -l app=dexclient-controller
  d8 k -n d8-user-authn logs deploy/dexclient-controller --all-pods=true
  ```

- D8UserAuthnDexProviderTokenExchangeDeprecated CE S8
  ▼ **Tokens are exchanged through DexProvider XXX, which is deprecated.**

  In the last 24 hours, Dex exchanged tokens (RFC 8693 token exchange) through the DexProvider `XXX`. Token exchange through a DexProvider is deprecated. A DexProvider is meant for sign-in, and its connector does not check the audience of the token it exchanges.

  Move the exchange to a TokenExchangeProvider:

  1. Create a TokenExchangeProvider with the `issuer` of the DexProvider, the audience the exchanged tokens carry, and the DexClient that exchanges them in `spec.clients`.
  2. Set `spec.identity.username` to the claim the DexProvider took the user name from, for example `claim: email`, with a prefix such as `ci:`; the prefix is required.
  3. Before the switch, add the prefixed subjects to the ClusterAuthorizationRule, AuthorizationRule and RoleBinding objects that grant rights to the old names.
  4. In the exchange requests, replace `connector_id` with `status.connectorID` of the new object.
  5. After the switch, remove the old subjects from these objects.
  6. Turn off token exchange through the DexProvider by setting `spec.tokenExchange.enabled: false`. It cannot be turned on again, and token exchange through a DexProvider will be removed after the next LTS release.

  Find the clients that exchange tokens in the Dex log:

```
d8 k -n d8-user-authn logs deploy/dex -c dex --all-pods=true --since=24h | grep 'token
exchange successful' | grep '"connector_id":"XXX"'
```

The alert stops 24 hours after the last exchange through the DexProvider.

- D8UserAuthnIdentityMigrationIncomplete CE S6
  ▼ Dex user data is not fully copied into UserIdentity objects.

  For more than 30 minutes, `user-authn-controller` has not finished copying the 2FA (TOTP) secret and the lock of Dex users from OfflineSessions and Password objects into UserIdentity objects.

  Until the copy of a provider and user pair completes, its 2FA secret and lock are stored only in the OfflineSessions and Password objects.

  The controller retries failed pairs by itself. Find the reason in its logs:

  ```
  d8 k -n d8-user-authn logs deploy/user-authn-controller --all-pods=true | grep -E
  'identitymigration|UserIdentity'
  ```

  Typical reasons are API server errors and missing rights on `useridentities.dex.coreos.com`. Pairs that cannot be copied at all, for example an OfflineSessions object that cannot be decoded, are logged as `Not copying the pair into UserIdentity` and do not raise this alert.

- D8UserAuthnIDTokenTTLTooLong CE S6
  ▼ user-authn idTokenTTL is XXX, which is too long.

  The ModuleConfig `user-authn` sets `idTokenTTL: XXX`.

  Dex rotates the key that signs ID tokens every 6 hours (`signer.config.keysRotationPeriod: 6h`) and keeps a previous key only while tokens signed with it can still be valid.

  `idTokenTTL` maps to Dex `expiry.idTokens`. If that lifetime is greater than or equal to the signing-key rotation period (`6h`), every rotation must retain an extra previous key until all tokens from that key expire. Over time the set of retained signing keys grows without bound and Dex persists that growing key material.

  That is why `idTokenTTL` must be strictly less than `6h`. Lower it, for example:

  ```
  apiVersion: deckhouse.io/v1alpha1
  kind: ModuleConfig
  metadata:
    name: user-authn
  spec:
    version: 3
    settings:
      idTokenTTL: 1h
  ```

  Settings version 3 rejects `idTokenTTL >= 6h`. A ModuleConfig of an earlier settings version with such a value is still accepted and its value is converted to `5h59m`, so Dex already runs with `5h59m`; this alert keeps firing until the ModuleConfig itself is updated.

- D8UserAuthnRevocationFeedLagging CE S6
  ▼ The revocation feed of user-authn-controller is not delivering to dex-authenticator.

  For more than 5 minutes, a stream of the revocation feed of `user-authn-controller` has not written to its dex-authenticator for over 30 seconds. A stream writes at least a heartbeat every 10 seconds, so the stream is stuck.

  While the stream is stuck, a session that is revoked (user lock, password reset, logout) keeps working in that dex-authenticator until its next refresh in Dex: up to 30 seconds while Dex is reachable, and no longer than `idTokenTTL` otherwise.

  Check the logs of the controller and of the dex-authenticator pods:

  ```
  d8 k -n d8-user-authn logs deploy/user-authn-controller --all-pods=true | grep revocation-feed
  ```

  The controller closes a stream that falls behind, and the dex-authenticator reconnects by itself. A lag that does not go away usually means a network problem between the dex-authenticator pods and the controller pods.

- D8UserAuthnRevocationFeedNotConsumed CE S6
  ▼ **The dex-authenticator of the Dex client XXX does not receive the revocation feed.**

  For more than 15 minutes, no replica of `user-authn-controller` has had a stream of the revocation feed open for the Dex client `XXX`. The client belongs to a DexAuthenticator (the client ID is `dex-authenticator-name@namespace`).

  The dex-authenticator of this client works without the feed: a session revoked by a user lock, a password reset, or a logout stops working there only at its next refresh in Dex, within 30 seconds while Dex is reachable, and no later than `idTokenTTL`.

  What to check:

  - the logs of the dex-authenticator pods: errors connecting to `https://revocation-feed.d8-user-authn/revocations` and answers 401 or 429;
  - that the Secret of the DexAuthenticator holds the CA of the feed in the `revocation-feed-ca.crt` key;
  - network policies in the namespace of the DexAuthenticator: they must allow connections to the `user-authn-controller` pods in `d8-user-authn` on port 8443.

```
d8 k -n d8-user-authn get endpoints revocation-feed
d8 k -n d8-user-authn logs deploy/user-authn-controller --all-pods=true | grep revocation-feed
```

Module user-authz

- D8UserAuthzAuthorizationRuleInvalid CE S7
  ▼ **The bindings of XXX XXXXXX/XXXNAME cannot be applied (XXX).**

  `user-authz-controller` cannot apply the bindings of XXX `XXXXXX/XXXNAME`; the `Ready` condition of the object is `False` with the reason `XXX`.

  - `InvalidSpec`: the rule cannot be rendered into bindings (unsupported `accessLevel`, an `accessLevel` not allowed for a namespaced rule, an `additionalRoles` entry that is not a ClusterRole or has an invalid name). Fix the object.
  - `ApplyError`: the API server rejected a write. The message of the condition names the binding and the error; a binding whose `roleRef` was changed by hand has to be deleted so that the controller recreates it.

```
d8 k XXX-n XXX XXXget XXX NAME -o jsonpath='{.status.conditions}'
```

- D8UserAuthzAuthorizationRulesInvalid CE S7
  ▼ **VALUE XXX objects cannot be applied (XXX).**

  `user-authz-controller` reports VALUE XXX objects whose bindings cannot be applied, reason `XXX`. Up to 50 of them are named by the `D8UserAuthzAuthorizationRuleInvalid` alerts; a large number with the reason `ApplyError` points at a cluster-wide cause (an admission webhook, API server errors) rather than at the objects.

```
d8 k get XXX -A -o custom-
columns=NAMESPACE:.metadata.namespace,NAME:.metadata.name,READY:'.status.conditions[?
(@.type=="Ready")].status',REASON:'.status.conditions[?(@.type=="Ready")].reason'
| grep -v True
d8 k -n d8-user-authz logs deploy/user-authz-controller --all-pods=true
```

- D8UserAuthzBindingsDrift CE S7
  ▼ **user-authz-controller cannot converge the bindings of XXX.**

  For more than 15 minutes some bindings of `XXX` objects differ from the state `user-authz-controller` wants (missing, superfluous, or with different subjects, roleRef, labels or owner). The controller reports drift only while its writes fail, so users may be missing access or keep access they should have lost.

  Find the objects and the reason:

```
d8 k get clusterauthorizationrules -o custom-
columns=NAME:.metadata.name,READY:'.status.conditions[?
(@.type=="Ready")].status',REASON:'.status.conditions[?
(@.type=="Ready")].reason',MESSAGE:'.status.conditions[?
(@.type=="Ready")].message'
d8 k get authorizationrules -A -o custom-
columns=NAMESPACE:.metadata.namespace,NAME:.metadata.name,READY:'.status.conditions[?
(@.type=="Ready")].status',MESSAGE:'.status.conditions[?
(@.type=="Ready")].message'
d8 k -n d8-user-authz logs deploy/user-authz-controller --all-pods=true
```

- D8UserAuthzControllerReconcileErrorsHigh CE S8
  ▼ user-authz-controller reconcile errors are high for CONTROLLER_NAME.

  Controller `CONTROLLER_NAME` of `user-authz-controller` has a reconcile error rate above 0.1 errors per second for more than 10 minutes.

  Check logs:

  ```
  d8 k -n d8-user-authz logs deploy/user-authz-controller --all-pods=true
  ```

- D8UserAuthzControllerTargetDown CE S6
  ▼ Prometheus is unable to scrape user-authz-controller.

  Prometheus cannot scrape metrics from `user-authz-controller` in the `d8-user-authz` namespace.

  The controller is down, not Ready (its informer cache has not synced), or the PodMonitor is missing. Access rules are not reconciled while it is down.

  Check:

  ```
  d8 k -n d8-user-authz get pods -l app=user-authz-controller
  d8 k -n d8-user-authz describe pods -l app=user-authz-controller
  d8 k -n d8-monitoring get podmonitor user-authz-controller
  ```

- D8UserAuthzControllerUnavailable CE S6
  ▼ user-authz-controller has unavailable replicas.

  Deckhouse has detected unavailable replicas in the `user-authz-controller` deployment in the `d8-user-authz` namespace.

  While this alert is active, changes to ClusterAuthorizationRule and AuthorizationRule objects are not applied to their ClusterRoleBindings and RoleBindings, and the `d8:dict` bindings and the RoleBindings of system and subsystem roles in module namespaces are not updated. Existing bindings keep working.

  Check deployment and pod states:

  ```
  d8 k -n d8-user-authz get deploy user-authz-controller
  d8 k -n d8-user-authz get pods -l app=user-authz-controller
  d8 k -n d8-user-authz logs deploy/user-authz-controller --all-pods=true
  ```

- D8UserAuthzCustomRolesNotAggregated CE S6
  ▼ The aggregated ClusterRole of the XXX access level has no rules although custom roles for it exist.

  Custom ClusterRoles annotated with `user-authz.deckhouse.io/access-level` are granted to users through the aggregated ClusterRole `user-authz:level:custom`, which `kube-controller-manager` fills from the roles labelled with the level. For more than 10 minutes the aggregated role of the `XXX` level has no rules while custom roles it must aggregate exist, so users of that level (and every level above it) have none of the custom permissions.

  Check that the aggregated role exists and that the `clusterrole-aggregation` controller of `kube-controller-manager` is running:

```
d8 k get clusterrole -l user-authz.deckhouse.io/access-level
d8 k get clusterrole -o name | grep 'user-authz:.*:custom' | xargs -n1 d8 k get -o yaml
d8 k -n kube-system logs -l component=kube-controller-manager --tail=200 | grep -i aggregat
```

- D8UserAuthzDeprecatedRBACv2CapabilityInUse CE S5
  ▾ A binding references a deprecated RBACv2 capability that no longer grants access.

  The `XXX` `XXX` XXX in namespace `NAMESPACE` XXX binds the deprecated RBACv2 capability `XXX` directly.

  Capabilities (`d8:manage:permission:*`, `d8:use:capability:*`) are aggregation building blocks — they are meant to be composed into the `d8:{system,subsystem,namespace,project}:*` roles, not bound directly. They were renamed and have NO compatibility alias, so this binding **already grants nothing** after the upgrade.

  No ClusterRole named `XXX` exists in the cluster. The alert also names a binding to an old role name that a module no longer ships, for example after the module moved to the new role names.

  Recreate the binding against the appropriate new role (or a custom role aggregating the new capability). Because `roleRef` is immutable, delete and recreate the binding:

  ```
  d8 k get XXX XXXXXX -n NAMESPACEXXX -o yaml
  ```

- D8UserAuthzDeprecatedRBACv2ModuleRoleInUse CE S7
  ▾ A binding references the old name of a role a module renamed.

  The `XXX` `XXX` XXX in namespace `NAMESPACE` XXX references `XXX`, the old name of a role that a module renamed to `XXX`.

  The module keeps the old name as a compatibility alias, so the binding keeps working. The alias may grant less than `XXX`, for example when the module moved into a wider subsystem and the alias kept the rights of the old role, so check what the subjects of the binding need before recreating it. The module removes the alias in one of its own releases; the Deckhouse release is not held back by this binding. See the documentation of the module for when.

  Recreate the binding on the new name. Because `roleRef` is immutable, delete and recreate the binding pointing at `XXX`:

  ```
  d8 k get XXX XXXXXX -n NAMESPACEXXX -o yaml
  ```

- D8UserAuthzDeprecatedRBACv2RoleInUse CE S7
  ▾ A binding still references a deprecated RBACv2 role.

  The `XXX` `XXX` XXX in namespace `NAMESPACE` XXX references the deprecated RBACv2 ClusterRole `XXX`.

  The RBACv2 role model was renamed: `d8:manage:subsystem|all:level` became `d8:system:*` / `d8:subsystem:*:*`, and `d8:use:role:level` became `d8:namespace:level`. This name still works via a compatibility alias kept for one release and will be removed in the next one — after that this binding will grant nothing. The release that removes the aliases is held back by the `deprecatedRBACv2BindingsCount` release requirement until this binding is recreated on the new name.

  Migrate the binding to the new role name. Because `roleRef` is immutable, delete and recreate the binding pointing at the new role:

  ```
  d8 k get XXX XXXXXX -n NAMESPACEXXX -o yaml
  # Recreate it with roleRef.name set to the new role (d8:system:*,
  d8:subsystem:*, or d8:namespace:*).
  ```

  XXX `user-authz-controller` renders this binding from `spec.additionalRoles` of the ClusterAuthorizationRule `XXX` and creates it again when it is deleted. Replace `XXX` with the new role name in `spec.additionalRoles` of that ClusterAuthorizationRule instead.XXXIf a project template renders this binding, replace the role name in the ProjectTemplate instead, because `multitenancy-manager` renders the binding again from it.XXXXXXXXX

  In the new model the rights for `user-authn` and `user-authz` XXX and the right to assign rolesXXX come with `d8:subsystem:iam:XXX`, not with `d8:subsystem:security:XXX`. To keep them, replace this binding with two bindings with the same subjects, one to `d8:subsystem:iam:XXX` and one to `d8:subsystem:security:XXX`. `d8:subsystem:iam:XXX` also grants the rights for `multitenancy-manager`.XXX

The list of subsystems changed as well. `deckhouse`, `infrastructure` and `kubernetes` were merged into `cluster`, `networking` became `network`, the `user-authz` and `user-authn` modules moved from `security` to `iam`, and `multitenancy-manager` moved from `deckhouse` to `iam`. The aliases of the old subsystem roles select the capabilities of the modules these roles covered, and the old subsystem labels that modules released on their own may still carry. The capabilities themselves changed in this release, so the rights of the binding are close to the ones it had before the upgrade, not the same. The replacement `d8:subsystem:cluster:level` covers the whole `cluster` subsystem and grants more, and so do the roles of the other subsystems that the description of the alias names, so check which roles the subjects of the binding need. The user-authz documentation lists the remaining differences.

A ClusterRoleBinding to a deprecated `d8:manage:*` name also keeps the RoleBindings `d8:use:use role:binding:name` that the previous release created for it in the namespaces of the modules of its old subsystem (`d8-cloud-provider-*`, `d8-monitoring` and the rest). The use role is `viewer` for a `viewer` alias and `user` for a `manager` alias. When the binding is recreated on the new role name, they are replaced by RoleBindings to the namespace role of the new role in the namespaces of the modules of the new subsystem.

Note: the new `d8:namespace:admin` no longer grants `serviceaccounts/token` creation or impersonation — these disaster-grade actions now require a `superadmin` role by design.

- D8UserAuthzForeignAggregationLabel CE S6
  ▾ ClusterRole NAME carries the XXX aggregation label without being a custom capability.

  The ClusterRole `NAME` carries the `rbac.deckhouse.io/aggregate-to-XXX-as` label but is not labelled `rbac.deckhouse.io/kind: custom-capability`XXX (its kind label is `XXX`)XXX. The aggregation controller reads nothing but that label, so it merges the rules of this role into XXXthe platform `d8:XXX:*` rolesXXXthe deprecated `d8:manage:all:*` and `d8:use:role:*` roles and every custom role that selects the labelXXXthe `d8:subsystem:XXX:*` roles, if a subsystem has this name, and into every custom role that selects the labelXXX. Every holder of these roles in the cluster gets the rules, outside the role model’s contract.

  For the aggregation label of the system scope, of the namespace or project scope, or of a built-in subsystem, the `rbacv2-cluster-roles.deckhouse.io` webhook refuses such an object, and every `UPDATE` of this role, including a GitOps re-apply, is denied until it is fixed. Choose one:

  - If the role is meant to extend the platform roles, replace it with a custom capability. The name of an object cannot be changed, so create `d8:custom:scope-capability:name` with the same rules and aggregation label, the `rbac.deckhouse.io/kind: custom-capability` and `rbac.deckhouse.io/scope: scope` labels, and no `aggregationRule`, and then delete this role. Deckhouse reads `rbac.deckhouse.io/namespace` only on the ClusterRoles it ships: if this role has that label, neither it nor its replacement gives RoleBinding objects in that namespace, so bind the subjects to a namespace role there with a RoleBinding. A capability of the old scheme with the `rbac.deckhouse.io/kind: use` label and `rbac.deckhouse.io/aggregate-to-kubernetes-as: LEVEL` or `rbac.deckhouse.io/aggregate-to-all-as: LEVEL` extended the namespace roles, so its replacement is `d8:custom:namespace-capability:name` with `rbac.deckhouse.io/scope: namespace` and `rbac.deckhouse.io/aggregate-to-namespace-as: LEVEL` instead. For the commands, refer to the corresponding section in the `user-authz` module FAQ.
  - Otherwise remove the `rbac.deckhouse.io/aggregate-to-*-as` labels from it.

  List every such role:

  ```
  d8 k get clusterroles -o json | jq -r '.items[] | select((.metadata.labels // {}) |
  to_entries | any(.key | startswith("rbac.deckhouse.io/aggregate-to-"))) |
  select((.metadata.labels.heritage // "") != "deckhouse") |
  select((.metadata.labels["rbac.deckhouse.io/kind"] // "") != "custom-
  capability") | .metadata.name'
  ```

- D8UserAuthzLegacyRBACv2CustomRoleFound CE S7
  ▾ The custom role NAME has lost access it gave through the labels of an earlier role model.

  The ClusterRole `NAME` has no `heritage: deckhouse` label and has an `aggregationRule` field, and one of the following holds:

  - A selector of its `aggregationRule` field requires the `rbac.deckhouse.io/kind: manage` or `use` label of the experimental role model. The built-in capabilities no longer carry these labels, so such a selector matches none of them. The Kubernetes aggregation controller keeps from it only the rules of the custom capabilities that still carry the old labels, and the subjects of the role have lost the other permissions it gave. Custom roles get no compatibility aliases.

- The role has the `rbac.deckhouse.io/use-role` label without `rbac.deckhouse.io/scope: system` or `subsystem`. Deckhouse creates the RoleBinding objects for the subjects of a role in the namespaces of the modules only for roles with that scope, so it has deleted the ones it had created for this role, even if its selectors are already rewritten.
- A selector of its `aggregationRule` field requires the aggregation label of a lineage that no built-in role collects, such as `rbac.deckhouse.io/aggregate-to-all-as` of the old scheme, the label of a subsystem the role model no longer has, or the label of a subsystem a module has left. The modules label their capabilities only with the lineages that the built-in roles collect, so such a selector matches none of the built-in capabilities either. A selector by a lineage that a custom capability carries is not counted, because it still gets the rules of that capability. A custom capability here is a ClusterRole without the `heritage: deckhouse` label and without an `aggregationRule` field. Neither is a selector by the lineage of the subsystem in the `rbac.deckhouse.io/subsystem` label of the role, because the custom capabilities of that subsystem carry it. Neither exception applies to the `all`, `deckhouse`, `infrastructure`, `kubernetes` and `networking` lineages, which do not count as custom ones. A compatibility alias of an old role, a ClusterRole with the `rbac.deckhouse.io/deprecated: "true"` label, does not count as a built-in role that collects a lineage, because it collects the lineage of an old subsystem only for the bindings to the old name.

Repair the access in this order:

1. Create a role of the new scheme next to this one. Give it the `d8:custom:` name prefix and the `rbac.deckhouse.io/kind: custom-role` label, and select the capabilities by the labels of the new scheme, without `rbac.deckhouse.io/kind`. Select the capabilities that a selector by a lineage no built-in role collects was meant for by their `rbac.deckhouse.io/capability` labels, or by `rbac.deckhouse.io/scope: system` and the `module` label of their module. If this role has the `rbac.deckhouse.io/use-role` label, keep the label on the new role and add `rbac.deckhouse.io/scope: subsystem` with `rbac.deckhouse.io/subsystem: SUBSYSTEM`, or `rbac.deckhouse.io/scope: system`, so that Deckhouse creates the RoleBinding objects in the namespaces of the modules again.
2. Create capabilities of the new scheme in place of the custom capabilities of the old scheme that this role aggregates. The `D8UserAuthzForeignAggregationLabel` alert names them.
3. For every RoleBinding and ClusterRoleBinding object to this role, create one with the same subjects to the new role. If this role has the `rbac.deckhouse.io/aggregate-to-all-as: LEVEL` label, what it extended depends on its kind label. With `rbac.deckhouse.io/kind: manage`, its permissions also reached the subjects of `d8:manage:all:LEVEL`. A custom role cannot be aggregated into `d8:system:LEVEL`, so bind the new role to those subjects with a ClusterRoleBinding. With `rbac.deckhouse.io/kind: use`, they reached the subjects of `d8:use:role:LEVEL` in every namespace, so move the permissions into a namespace capability with `rbac.deckhouse.io/aggregate-to-namespace-as: LEVEL`, which extends `d8:namespace:LEVEL`.
4. Check the permissions of the subjects with `d8 k auth can-i VERB RESOURCE --as=USER_NAME`.
5. Delete the old bindings, this role and the old capabilities.

For the commands, refer to the corresponding section in the `user-authz` module FAQ.

List all such roles:

```
d8 k get clusterroles -o json | jq -r '
  def lineages: [((.matchLabels // {}) | keys[]), (.matchExpressions[]? |
select(.operator == "In" or .operator == "Exists") | .key)]
    | map(capture("^rbac\\.deckhouse\\.io/aggregate-to-(?lineage.+)-
as$").lineage);
  ([.items[] | select(.metadata.labels.heritage == "deckhouse" and
.metadata.labels["rbac.deckhouse.io/deprecated"] != "true")
        | .aggregationRule.clusterRoleSelectors[]? | lineages[]] + ["system",
"namespace", "project"]) as $collected
  | ([.items[] | select(.metadata.labels.heritage != "deckhouse" and
.aggregationRule == null) | (.metadata.labels // {}) | keys[]
        | capture("^rbac\\.deckhouse\\.io/aggregate-to-(?lineage.+)-
as$").lineage]) as $carried
  | .items[]
  | select(.metadata.labels.heritage != "deckhouse" and .aggregationRule !=
null)
  | (.metadata.labels["rbac.deckhouse.io/subsystem"] // "") as $own
  | select(
      (
        ((.metadata.labels["rbac.deckhouse.io/use-role"] // "") != "")
        and (((.metadata.labels["rbac.deckhouse.io/scope"] // "") |
IN("system", "subsystem")) | not)
      )
      or (
        [
          .aggregationRule.clusterRoleSelectors[]?
          | (.matchLabels["rbac.deckhouse.io/kind"] // empty),
            (.matchExpressions[]? | select(.key == "rbac.deckhouse.io/kind" and
.operator == "In") | .values[])
        ]
        | any(IN("manage", "use"))
      )
      or (
        [
          .aggregationRule.clusterRoleSelectors[]? | lineages[]
          | select((IN($collected[]) | not)
              and (IN("all", "deckhouse", "infrastructure", "kubernetes",
"networking") or (. != $own and (IN($carried[]) | not))))
        ]
        | length > 0
      )
    )
  | .metadata.name'
```

- D8UserAuthzLegacyUseCapability CE S7
  ▼ ClusterRole NAME carries the use labels of the previous scheme, which the namespace and project roles do not collect.

  The ClusterRole `NAME`XXX of the `MODULE NAME` moduleXXX carries the `rbac.deckhouse.io/kind: use` and `rbac.deckhouse.io/aggregate-to-XXX-as: XXX` labelsXXX of the use roles that a module with a subsystem of its own shipped in the previous schemeXXX of a use capability of the previous schemeXXX. `rbac.deckhouse.io/kind: use` is the label of a use capability of the previous schemeXXX. XXXThe moduleXXXThe capabilityXXX is still on that scheme.

  XXXThe `d8:namespace:*` and `d8:project:*` roles do not collect this label. Only the deprecated `d8:use:role:*` aliases still collect it, and they will be removed in the next release. A RoleBinding moved from `d8:use:role:XXX` to `d8:namespace:XXX` and a project role therefore do not get the rules of this ClusterRole.XXXNo role collects a ClusterRole with `rbac.deckhouse.io/kind: use` and this label. The `d8:system:*` and `d8:subsystem:*` roles and the deprecated `d8:manage:*` aliases leave out `rbac.deckhouse.io/kind: use`, and the `d8:namespace:*`, `d8:project:*` and `d8:use:role:*` roles do not select this label. Only a binding to this ClusterRole itself gives its rules.XXX

  Choose one:

  - If the ClusterRole belongs to a module, update the module to a release that labels its namespace capabilities with `rbac.deckhouse.io/kind: capability` and `rbac.deckhouse.io/aggregate-to-namespace-as`. Until then, give the subjects that need these rules a RoleBinding to `NAME` in their namespace, next to their RoleBinding to the `d8:namespace:*` role of their level. Neither role is a deprecated alias, so these RoleBinding objects do not hold the next release. In a project namespace, the `cluster-objects-grants-validator.multitenancy.deckhouse.io` webhook admits a RoleBinding to `NAME` only if the ClusterRole has the `rbac.deckhouse.io/delegatable: "true"` labelXXX, which the use capabilities of the previous scheme do not haveXXX.XXX Where the webhook refuses it, keep the RoleBinding to the `d8:use:role:*` alias: it keeps these rules, but the `D8UserAuthzDeprecatedRBACv2RoleInUse` alert reports it, and the next release, which removes the aliases, stays pending until the module is updated and the RoleBinding is moved to the `d8:namespace:*` role.XXX Where the webhook refuses it, the subjects get these rules only once the module is updated.XXX
  - If it is a custom capability, replace it with `d8:custom:namespace-capability:NAME` with the same rules and the `rbac.deckhouse.io/kind: custom-capability`, `rbac.deckhouse.io/scope: namespace` and `rbac.deckhouse.io/aggregate-to-namespace-as: XXX` labels. For the commands, refer to the corresponding section in the `user-authz` module FAQ.

  List every such ClusterRole:

  ```
  d8 k get clusterroles -l rbac.deckhouse.io/kind=use -o json | jq -r '.items[] |
  select(.metadata.labels | keys | map(capture("^rbac\\.deckhouse\\.io/aggregate-
  to-(?lineage.+)-as$").lineage) | any(IN("kubernetes", "all", "system", "iam",
  "security", "cluster", "delivery", "network", "storage", "observability",
  "managed-services", "deckhouse", "infrastructure", "networking"))) |
  .metadata.name'
  ```

- D8UserAuthzPermissionBrowserUnavailable CE S6
  ▾ Permission Browser API server has unavailable replicas.

  Deckhouse has detected unavailable replicas in the `permission-browser-apiserver` deployment in the `d8-user-authz` namespace. Permission Browser requests can fail while this alert is active.

  Check deployment and pod states:

  ```
  d8 k -n d8-user-authz get deploy permission-browser-apiserver
  d8 k -n d8-user-authz get pods -l app=permission-browser-apiserver
  ```

- D8UserAuthzReleaseSlow CE S6
  ▾ The user-authz module release repeatedly takes more than 5 minutes.

  Applying the `user-authz` Helm release took more than 5 minutes on average over the last hour, and it was applied at least twice in that hour, so this is not the single slow pass of a cluster bootstrap or of the one-time migration to `user-authz-controller`. A release that does not finish within the module release timeout (20 minutes) fails, changes to ClusterAuthorizationRule and AuthorizationRule objects stop being applied and platform updates stall (the `D8DeckhouseCouldNotRunModule` alert fires in that case).

  The release itself no longer grows with the number of rules: bindings are managed by `user-authz-controller`, and custom ClusterRoles are aggregated. A slow release therefore points outside the module: an API server that answers slowly, an object stuck with a finalizer, a Deckhouse Pod short of CPU, or the release engine itself. Check what the release is waiting on:

  ```
  d8 s queue list
  d8 k -n d8-system logs deploy/deckhouse | grep '"module":"user-authz"'
  ```

  If the cluster has just been updated to the release that moved the bindings to the controller, one slow pass is expected and does not raise this alert by itself; if it fires anyway, the pass is being retried. It is proportional to the number of bindings and can exceed the timeout on clusters with more than 5000 of them; the module FAQ describes what to do in that case.

- D8UserAuthzRenderSlow CE S7
  ▾ Rendering the user-authz module templates repeatedly takes more than 30 seconds.

  Rendering the templates of the `user-authz` module took more than 30 seconds on average over the last 30 minutes, across at least three renders; normally one render takes about a second. Rendering is CPU work inside the Deckhouse Pod and does not depend on the number of ClusterAuthorizationRule or AuthorizationRule objects, so the cause is the node, not the module: most often the Deckhouse Pod is short of CPU (CPU steal on a virtual machine, a node running at

its limits, a bootstrap that starts every module at once).

A single slow render during a cluster bootstrap does not raise this alert by itself. If it fires, compare the module with the others and look at the node:

```
topk(10, increase(deckhouse_helm_operation_seconds_sum{operation="template"}[30m]) /
increase(deckhouse_helm_operation_seconds_count{operation="template"}[30m]))
rate(node_cpu_seconds_total{mode="steal"}[5m])
```

```
d8 k -n d8-system logs deploy/deckhouse | grep '"module":"user-authz"'
```

- D8UserAuthzRetiredAggregationLabel CE S7
  ▾ ClusterRole NAME aggregates by the label of the retired XXX subsystem.

  The ClusterRole `NAME`XXX of the `MODULE_NAME` moduleXXX carries the `rbac.deckhouse.io/aggregate-to-XXX-as` label.

  The role model has no `XXX` subsystem any more. `deckhouse`, `infrastructure` and `kubernetes` were merged into `cluster`, and `networking` was renamed to `network`. No `d8:system:*` or `d8:subsystem:*` role collects this label, so the holders of these roles do not get the rules of this ClusterRole. Only the deprecated `d8:manage:*` aliases still collect it, and they will be removed in the next release.

  Choose one:

  - If the ClusterRole belongs to a module, update the module to a release that labels its capabilities with the lineage of its new subsystem. For most modules of the old subsystem that is `rbac.deckhouse.io/aggregate-to-XXX-as`. The subsystem of each module is listed in the user-authz documentation.
  - If it is a custom capability, replace the label with `rbac.deckhouse.io/aggregate-to-XXX-as` or with the label of the subsystem the capability belongs to now.

  Until then, a subject bound to a new role gets the rules of such a capability of a module only through a custom role. Create a `d8:custom:system:NAME` ClusterRole with the `rbac.deckhouse.io/kind: custom-role` and `rbac.deckhouse.io/scope: system` labels and bind it to the subjects with a ClusterRoleBinding. A capability of the previous scheme has no `rbac.deckhouse.io/capability` label, so the role selects the capabilities of the module by the `module: XXXMODULE_NAMEXXXMODULEXXX` and `rbac.deckhouse.io/kind: manage` labels. Such a selector takes the capabilities of every level, so add `rbac.deckhouse.io/aggregate-to-XXX-as: viewer` to it for a role that only views. The `D8UserAuthzLegacyRBACv2CustomRoleFound` alert names this role, because it selects by a label of the previous scheme. Once the module carries the new labels, select its capabilities by their `rbac.deckhouse.io/capability` label instead. A capability that already carries `rbac.deckhouse.io/kind: capability` is selected by its `rbac.deckhouse.io/capability` label right away.

  List every such ClusterRole:

  ```
  d8 k get clusterroles -o json | jq -r '.items[] |
  select((.metadata.labels["rbac.deckhouse.io/kind"] // "") != "use") |
  select((.metadata.labels // {}) | keys | any(IN("rbac.deckhouse.io/aggregate-
  to-deckhouse-as", "rbac.deckhouse.io/aggregate-to-infrastructure-as",
  "rbac.deckhouse.io/aggregate-to-kubernetes-as", "rbac.deckhouse.io/aggregate-
  to-networking-as"))) | .metadata.name'
  ```

- D8UserAuthzRevocationCheckNotSynced CE S6
  ▾ The revocation check of the user-authz webhook has not loaded the revocations.

  For more than 10 minutes the `user-authz-webhook` instance `POD NAME` has not loaded the `Revocation` objects of the `user-authn` module (the objects in `d8-user-authn` that record revoked user credentials): it cannot list them, or cannot find out whether the API server serves them.

  Until it loads them, the instance has no opinion about revoked credentials: on the master node of this instance, `kubectl` with the token of a locked or logged-out user keeps working until the token expires. Other authorization decisions are not affected.

  Check the webhook’s access to the API and its logs:

  ```
  d8 k -n d8-user-authz logs POD_NAME -c webhook --tail=100 | grep -i revocation
  d8 k auth can-i list revocations.dex.coreos.com -n d8-user-authn --as=system:serviceaccount:d8-
  user-authz:webhook
  ```

- D8UserAuthzRevocationCheckStale CE S6
  ▾ **The revocation check of the user-authz webhook no longer sees new revocations.**

  For more than 15 minutes the `user-authz-webhook` instance `POD_NAME` has been unable to watch the `Revocation` objects of the `user-authn` module (the objects in `d8-user-authn` that record revoked user credentials).

  The instance keeps refusing the Dex tokens it already knows to be revoked, but a revocation made since its watch broke does not reach it: on the master node of this instance, `kubectl` with the token of a locked or logged-out user keeps working until the token expires.

  Check the webhook's access to the API and its logs:

  ```
  d8 k -n d8-user-authz logs POD_NAME -c webhook --tail=100 | grep -i revocation
  d8 k auth can-i watch revocations.dex.coreos.com -n d8-user-authn --as=system:serviceaccount:d8-user-authz:webhook
  ```

- D8UserAuthzRuleNeedsMultiTenancy CE S6
  ▾ **A ClusterAuthorizationRule asks for namespace limits that nothing enforces.**

  The `ClusterAuthorizationRule` `NAME` sets `XXX`, but the `enableMultiTenancy` setting of the `user-authz` module is off, so the authorization webhook that enforces those options is not deployed.

  The rule is not partially applied. It is applied without its limits: the subjects named in it hold its access level in **every** namespace of the cluster, the system ones included.

  Either enable multi-tenancy, or remove the options from the rule:

  ```
  d8 k get clusterauthorizationrule NAME -o yaml
  d8 k get moduleconfig user-authz -o jsonpath='{.spec.settings.enableMultiTenancy}'
  ```

- D8UserAuthzRulePropagationLag CE S6
  ▾ **One user-authz webhook instance stopped picking up rule changes.**

  One instance of `user-authz-webhook` has not updated its rules for more than an hour while another instance has. The rules are changing in the cluster and this instance does not see the changes.

  Find the instance and check its log:

  ```
  d8 k -n d8-user-authz get pods -l app=user-authz-webhook -o wide
  d8 k -n d8-user-authz logs -l app=user-authz-webhook -c webhook --tail=100
  ```

  An instance whose watch keeps failing becomes not ready, so check the readiness of the Pod as well.

- D8UserAuthzRulesNeedMultiTenancy CE S6
  ▾ **More ClusterAuthorizationRules ask for namespace limits than the per-rule alert names.**

  `VALUE` ClusterAuthorizationRules set `limitNamespaces`, `namespaceSelector` or `allowAccessToSystemNamespaces` while the `enableMultiTenancy` setting of the `user-authz` module is off. `D8UserAuthzRuleNeedsMultiTenancy` names the first 50 of them; this alert accounts for the rest.

  None of those rules is partially applied: the subjects named in each of them hold its access level in **every** namespace of the cluster, the system ones included.

  Check whether multi-tenancy was meant to be enabled, and list the affected rules:

  ```
  d8 k get moduleconfig user-authz -o jsonpath='{.spec.settings.enableMultiTenancy}'
  d8 k get clusterauthorizationrule -o json | jq -r '.items[] |
  select((.spec.limitNamespaces // [] | length > 0) or (.spec.namespaceSelector
  != null) or (.spec.allowAccessToSystemNamespaces == true)) | .metadata.name'
  ```

- D8UserAuthzWebhookDirectoryDiverged CE S6
  ▾ **The masters disagree about the multi-tenancy rules.**

  Instances of `user-authz-webhook` have been using different sets of `ClusterAuthorizationRules` for 10 minutes.

Each master node authorizes the requests that reach it, so the same request is answered differently depending on the node: a user can be inside their namespace limits on one node and outside them on another.

Find the instance that is behind and look at why:

```
d8 k -n d8-user-authz get pods -l app=user-authz-webhook -o wide
d8 k -n d8-user-authz logs -l app=user-authz-webhook -c webhook --tail=100 | grep -i
'list/watch'
```

A growing `user authz webhook rules watch errors total` on one instance points at its watch; a `user_authz_webhook_rules_directory_updated_timestamp_seconds` that has stopped moving points at rules that are no longer updated. Deleting the lagging Pod is the last resort: the DaemonSet recreates it, and on a cluster with a single master node every request that the authorization webhook has to answer is denied while the Pod restarts. Control plane components, kubelets, and the ServiceAccounts of the `kube-system` and `d8-*` namespaces keep working, because the webhook does not check them.

- D8UserAuthzWebhookRulesQuarantined CE S7
  ▾ **A ClusterAuthorizationRule cannot be compiled by the webhook.**

  For more than 10 minutes the `user-authz-webhook` has quarantined at least one `ClusterAuthorizationRule`: its `limitNamespaces` pattern or `namespaceSelector` does not compile, or the rule cannot be read at all.

  A rule with a broken filter is applied without that filter, so its subjects get a narrower scope than written and are denied where the filter was meant to allow. A rule that cannot be read is not applied at all, and its subjects are denied every namespace.

  Find the rule:

  ```
  d8 k get clusterauthorizationrules -o custom-
  columns=NAME:.metadata.name,LIMIT:.spec.limitNamespaces,SELECTOR:.spec.namespaceSelector
  d8 k -n d8-user-authz logs -l app=user-authz-webhook -c webhook --tail=100 | grep -i quarantin
  ```

- D8UserAuthzWebhookRulesWatchErrors CE S7
  ▾ **The user-authz webhook cannot watch the ClusterAuthorizationRules.**

  For more than 10 minutes the `user-authz-webhook` rules informer has been failing to watch the `ClusterAuthorizationRules` (a non-zero rate of watch errors). New or changed rules may not be reaching the webhook, so multi-tenancy decisions can lag behind what users configure.

  Check the webhook’s access to the API and its logs:

  ```
  d8 k -n d8-user-authz logs -l app=user-authz-webhook -c webhook --tail=100
  d8 k auth can-i watch clusterauthorizationrules.deckhouse.io --as=system:serviceaccount:d8-user-
  authz:webhook
  ```

- D8UserAuthzWebhookTargetDown CE S6
  ▾ **Prometheus is unable to scrape the user-authz webhook.**

  Prometheus cannot collect metrics from at least one instance of `user-authz-webhook` in the `d8-user-authz` namespace. One instance without metrics is enough for the alert to fire.

  If the instance is running and only its metrics are unreachable, it keeps answering authorization requests, but the other alerts of the module cannot see its state. If it is not running or has not read the rules yet, it answers `503` to every authorization request, and the API server denies the request, because the webhook is configured with `failurePolicy: Deny`.

  Check the DaemonSet, its metrics sidecar and the scrape target:

  ```
  d8 k -n d8-user-authz get pods -l app=user-authz-webhook -o wide
  d8 k -n d8-user-authz logs -l app=user-authz-webhook -c kube-rbac-proxy --tail=50
  ```

Module vertical-pod-autoscaler

- VerticalPodAutoscalerDeprecatedUpdateModeAuto CE S9
  ▾ **VerticalPodAutoscaler objects use the deprecated Auto update mode.**

  There are `VALUE` VerticalPodAutoscaler object(s) in the cluster configured with the deprecated

update mode (`spec.updatePolicy.updateMode: Auto`).

The `Auto` update mode is deprecated. It currently behaves like `Recreate` (the VPA updater evicts pods to apply new resource requests) and its semantics are reserved to change in future versions, which makes cluster behavior ambiguous and potentially disruptive.

Set the affected VPA object(s) to one of the supported update modes (`spec.updatePolicy.updateMode`):

- `InPlaceOrRecreate`: Apply recommendations in place when possible, fall back to recreation (recommended).
- `Recreate`: Evict and recreate pods to apply recommendations.
- `Initial`: Apply only when pods are (re)created.
- `Off`: Recommendations only, no changes to running pods.

To list the affected objects, open the **VPA Deprecated Update Mode** Grafana dashboard, or run:

```
kube_verticalpodautoscaler_spec_updatepolicy_updatemode{update_mode="Auto"} == 1
```

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Sysctl parameters managed by the platform

Deckhouse automatically configures and manages a set of the server's kernel parameters using the `sysctl` utility. The configured parameters improve network throughput, prevent resource depletion, and optimize memory management.

If you modify these parameters, Deckhouse will automatically revert them to the values listed below.

Parameter	Value set by Deckhouse	Description
`/sys/block/*/queue/nr_requests`	`256`	Number of queued requests for block devices.
`/sys/block/*/queue/read_ahead_kb`	`256`	Amount of extra data that kernel reads from the disk to improve future read performance.
`/sys/kernel/mm/transparent_hugepage/enabled`	`never`	Disables Transparent HugePage.
`/sys/kernel/mm/transparent_hugepage/defrag`	`never`	Disables the Transparent HugePage defragmentation.
`/sys/kernel/mm/transparent_hugepage/use_zero_page`	`0`	Disables usage of huge zero pages.
`/sys/kernel/mm/transparent_hugepage/khugepaged/defrag`	`0`	Disables `khugepaged` defragmentation.
`/proc/sys/net/ipv4/conf/*/rp_filter`	`0`	Disables reverse path filtering for all interfaces.
`fs.file-max`	`1000000`	Maximum number of open files.
`fs.inotify.max_user_instances`	`5120`	Maximum number of inotify instances.
`fs.inotify.max_user_watches`	`524288`	Maximum number of files monitored by a single inotify instance.

Parameter	Value set by Deckhouse	Description
`fs.may_detach_mounts`	`1`	Allows lazy unmounting of a file system.
`kernel.numa_balancing`	`0`	Disables automatic NUMA memory balancing.
`kernel.panic`	`10 (0 if fencing is enabled)`	Time in seconds until the node reboots after it encounters the fatal kernel panic error. By default, it’s set to `10`. If `fencing` mode is enabled for the node, it’s set to `0`, preventing the node from rebooting.
`kernel.panic_on_oops`	`1`	Allows the system to trigger a kernel panic after an unexpected oops error. Required for kubelet to work correctly.
`kernel.pid_max`	`2000000`	Maximum number of process IDs that can be assigned in the system.
`net.bridge.bridge-nf-call-arptables`	`1`	Enables traffic filtering through arptables. Required for kube-proxy to work correctly.
`net.bridge.bridge-nf-call-ip6tables`	`1`	Enables traffic filtering through ip6tables. Required for kube-proxy to work correctly.
`net.bridge.bridge-nf-call-iptables`	`1`	Enables traffic filtering through iptables. Required for kube-proxy to work correctly.
`net.core.netdev_max_backlog`	`5000`	Maximum number of packets allowed in the processing queue.
`net.core.rmem_max`	`16777216`	Maximum receive buffer size in bytes.
`net.core.somaxconn`	`1000`	Maximum number of pending connections.
`net.core.wmem_max`	`16777216`	Maximum send buffer size in bytes.
`net.ipv4.conf.all.forwarding`	`1`	Enables IPv4 packet forwarding between network interfaces. Equivalent to the `net.ipv4.ip_forward` parameter.
`net.ipv4.ip_local_port_range`	`"32768 61000"`	Range of ports available for outgoing TCP and UDP connections.
`net.ipv4.neigh.default.gc_thresh1`	`16384`	Lower threshold for the amount of ARP entries after which the system starts cleaning up old entries.
`net.ipv4.neigh.default.gc_thresh2`	`28672`	Middle threshold for the amount of ARP entries after which the system starts garbage collection.
`net.ipv4.neigh.default.gc_thresh3`	`32768`	Absolute maximum number of ARP entries.

Parameter	Value set by Deckhouse	Description
`net.ipv4.tcp_max_syn_backlog`	`8096`	Maximum number of queued SYN connections.
`net.ipv4.tcp_no_metrics_save`	`1`	Disables saving of TCP metrics of closed connections and reusing them for new connections.
`net.ipv4.tcp_rmem`	`"4096 12582912 16777216"`	Receive buffer sizes for incoming TCP packets in bytes: `"<minimum> <default> <maximum>"`.
`net.ipv4.tcp_slow_start_after_idle`	`0`	Disables using the congestion window (CWND) and slow start algorithm for TCP connections.
`net.ipv4.tcp_tw_reuse`	`1`	Enables reusing the outgoing TCP connections in `TIME-WAIT` state.
`net.ipv4.tcp_wmem`	`"4096 12582912 16777216"`	Send buffer sizes for outgoing TCP packets in bytes: `"<minimum> <default> <maximum>"`.
`net.netfilter.nf_conntrack_max`	`<no-of-cores * 131072> or 524288`	Maximum number of tracked connections in the conntrack table. Calculated as “number of CPU cores” * 131072, but no lower than `524288`.
`net.nf_conntrack_max`	`<no-of-cores * 131072> or 524288`	Maximum number of tracked connections in the conntrack table for older kernels. Calculated as “number of CPU cores” * 131072, but no lower than `524288`.
`vm.dirty_background_ratio`	`5`	Percentage of system memory that can be filled with dirty pages before the kernel starts writing them to disk in the background.
`vm.dirty_expire_centisecs`	`12000`	Duration (in centiseconds) a dirty page can remain in system memory before it must be written to disk.
`vm.dirty_ratio`	`80`	Percentage of system memory that can be filled with dirty pages before all processes must stop and flush data to disk.
`vm.min_free_kbytes`	`131072`	Minimum amount of free memory in kilobytes reserved by the kernel for critical operations.
`vm.overcommit_memory`	`1`	Enables memory overcommitment.
`vm.swappiness`	`0`	Disables swap file usage.

Information about used software

List of third-party software used in the Deckhouse Platform. Includes **only built-in modules** (doesn't include modules from sources).

The list of third-party software used in a specific module can be found on the overview page in the module documentation.

Amazon Web Services Cloud provider

Versions: v1.33.4, v1.34.3, v1.35.2, v1.36.0, v1.37.0

Cloud Controller Manager for Amazon Web Services.

Used in module cloud-provider-aws

Apache License 2.0

Amazon Web Services CSI driver

Versions: v1.54.0, v1.66.0

CSI driver for Amazon EBS.

Used in module cloud-provider-aws

Apache License 2.0

Amazon Web Services Node termination handler

Version: v1.25.6

Gracefully handle instance shutdown within Kubernetes for Amazon EC2.

Used in module cloud-provider-aws

Apache License 2.0

Amazon Web Services Terraform provider

Version: 6.69.1

Terraform provider for Amazon Web Services.

Used in module cloud-provider-aws

Mozilla Public License 2.0

cert-manager

Version: 1.21.2

A Kubernetes add-on to automate the management and issuance of TLS certificates from various issuing sources.

Used in module cert-manager

Apache License 2.0

cert-manager-webhook-yandex

Version: 1a7dd500a97e9206fa5cfebb102decd3889e3544

ACME DNS-01 webhook for Yandex Cloud DNS.

Used in module cert-manager

Apache License 2.0

Chrony
chrony is a versatile implementation of the Network Time Protocol (NTP)

Used in module chrony

GNU General Public License version 2

Cilium

Version: 1.17.17

Cilium is open source software for providing and transparently securing network connectivity and loadbalancing between application workloads such as application containers or processes.

Used in module cni-cilium

Apache License 2.0

Cluster API

Version: 1.12.11

Kubernetes Cluster API for declarative cluster lifecycle management.

Used in module node-manager

Apache License 2.0

Cluster API Provider Metal3

Version: v1.9.5

Infrastructure provider for Kubernetes Cluster API backed by Metal3.

Used in module infra-provider-baremetal

Apache License 2.0

Cluster Autoscaler

Versions: v1.33.1, v1.34.4, v1.35.2, v1.36.1

Kubernetes autoscaler that automatically adjusts the size of the cluster.

Used in module node-manager

Apache License 2.0

CNI plugins

Version: 1.9.1

Some reference and example networking plugins, maintained by the CNI team.

Used in module cni-cilium

Apache License 2.0

CoreDNS
A DNS server/forwarder that chains plugins.

Used in module kube-dns

Apache License 2.0

Descheduler

Version: 0.37.0

A tool to auto-fix scheduling issues Kubernetes does not cover itself.

Used in module descheduler

Apache License 2.0

Dex

Version: 2.46.0

A Federated OpenID Connect Provider with pluggable connectors.

Used in module user-authn

Apache License 2.0

Dynamix Terraform provider

Version: 4.12.2

Terraform provider for Dynamix (DECORT).

Used in module cloud-provider-dynamix

Apache License 2.0

Etcd

Version: 3.6.15

A distributed reliable key-value store for the most critical data of a distributed system.

Used in module control-plane-manager

Apache License 2.0

Flannel

Version: 0.27.4

A simple and easy way to configure a layer 3 network fabric designed for Kubernetes.

Used in module cni-flannel

Apache License 2.0

Gardener Machine Controller Manager

Version: v0.36.0

An operator that manages VMs as a kubernetes custom resource.

Used in module node-manager

Apache License 2.0

Gatekeeper

Version: 3.23.1

Policy-based control for cloud native environments

Used in module admission-policy-engine

Apache License 2.0

Google Cloud Platform Cloud provider

Versions: ccm/v33.4.0, ccm/v34.2.0, ccm/v35.0.5

Cloud Controller Manager for Google Cloud Platform.

Used in module cloud-provider-gcp

Apache License 2.0

Google Cloud Platform CSI driver

Versions: v1.15.4, v1.27.0

CSI driver for Google Compute Engine persistent disks.

Used in module cloud-provider-gcp

Apache License 2.0

Google Cloud Platform Terraform provider

Version: 4.85.0

Terraform provider for Google Cloud Platform.

Used in module cloud-provider-gcp

Mozilla Public License 2.0

Gops

Version: 0.3.27

A tool to list and diagnose Go processes currently running on your system.

Used in module cni-cilium

BSD 3-Clause License

Huawei Cloud provider

Version: v0.26.9

Cloud Controller Manager for Huawei Cloud.

Used in module cloud-provider-huaweicloud

Apache License 2.0

Huawei CSI driver

Version: evs-0.1.11

CSI driver for Huawei Cloud EVS and SFS.

Used in module cloud-provider-huaweicloud

Apache License 2.0

Huawei Terraform provider

Version: 1.69.0

Terraform provider for Huawei Cloud.

Used in module cloud-provider-huaweicloud

Mozilla Public License 2.0

Hubble UI

Version: 0.13.5

Hubble UI is an open-source user interface for Cilium Hubble.

Used in module cilium-hubble

Apache License 2.0

Ironic Python Agent ramdisk

Version: ipa-centos9-stable-2026.1

Default IPA deployment kernel and initramfs.

Used in module infra-provider-baremetal

Apache License 2.0

Ironic Standalone Operator

Version: v0.10.0

Kubernetes operator managing standalone Ironic deployments for Metal3.

Used in module infra-provider-baremetal

Apache License 2.0

Istio

Versions: 1.25.2, 1.27.9, 1.29.6

An open platform to connect, manage, and secure microservices.

Used in module istio

Apache License 2.0

JQ

Version: 1.7.1

A lightweight and flexible command-line JSON processor.

Used in module deckhouse

Mixed (https://github.com/stedolan/jq/blob/master/COPYING)

keepalived

Version: 2.2.7

Provides simple and robust facilities for loadbalancing and high-availability to Linux system and Linux based infrastructures.

Used in module keepalived

GNU General Public License v2.0

Kiali

Versions: 2.12.0, 2.21.0, 2.7.1

Visualisation tool for the istio service mesh topology, and features like circuit breakers or request rates.

Used in module istio

Apache License 2.0

Kube-router

Version: 2.0.1

A turnkey solution for Kubernetes networking with aim to provide operational simplicity and high performance.

Used in module network-policy-engine

Apache License 2.0

Kubernetes

Version: 1.33+

An open source system for managing containerized applications across multiple hosts.

Used in module control-plane-manager

Apache License 2.0

Kubernetes Autoscaler

Version: 1.8.1

A autoscaling-related components for Kubernetes.

Used in module vertical-pod-autoscaler

Apache License 2.0

Libcap-ng

Version: 0.8.5

Libcap-ng is a library for Linux that makes using posix capabilities easy..

Used in module openvpn

GNU General Public License v2.0

Local-path-provisioner
Local Path Provisioner provides a way for the Kubernetes users to utilize the local storage in each node by creating hostPath based persistent volume on the node automatically.

Used in module local-path-provisioner

Apache License 2.0

Metal3 Bare Metal Operator

Version: v0.13.1

Kubernetes operator for provisioning bare metal hosts with Ironic.

Used in module infra-provider-baremetal

Apache License 2.0

Metal3 Ironic Image

Version: v39.0.0

Container image to run OpenStack Ironic as part of Metal3.

Used in module infra-provider-baremetal

Apache License 2.0

MetalLB

Version: 0.15.2

A load-balancer implementation for bare metal Kubernetes clusters, using standard routing protocols.

Used in module metallb

Apache License 2.0

Microsoft Azure Cloud provider

Versions: v1.33.6, v1.34.3, v1.36.1, v1.37.0

Cloud Controller Manager for Microsoft Azure.

Used in module cloud-provider-azure

Apache License 2.0

Microsoft Azure CSI driver

Versions: v1.33.8, v1.34.2, v1.36.0

CSI driver for Microsoft Azure Disks.

Used in module cloud-provider-azure

Apache License 2.0

Microsoft Azure Terraform provider

Version: 3.117.1

Terraform provider for Microsoft Azure Resource Manager.

Used in module cloud-provider-azure

Mozilla Public License 2.0

OAuth2 Proxy

Version: 7.15.5

A reverse proxy and static file server that provides authentication using Providers (Google, GitHub, and others) to validate accounts by email, domain or group.

Used in module user-authn

MIT License

OpenSSL

Version: 3.3.2

TLS/SSL and crypto library.

Used in module openvpn

Apache License 2.0

OpenStack Cloud provider

Versions: v1.33.1, v1.34.1, v1.35.0, v1.36.0

Cloud Controller Manager for OpenStack.

Used in module cloud-provider-openstack

Apache License 2.0

OpenStack Cluster API provider

Version: v0.14.8

Infrastructure provider for Kubernetes Cluster API in OpenStack.

Used in module cloud-provider-openstack

Apache License 2.0

OpenStack CSI driver

Versions: v1.33.1, v1.34.1, v1.35.0, v1.36.0

CSI driver for OpenStack Cinder.

Used in module cloud-provider-openstack

Apache License 2.0

OpenStack Ironic

Version: 752100ac7ff8774510a34963839aaed93bbe8589

Bare metal provisioning service.

> **i** **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Used directors

If Kubernetes cluster nodes are analyzed by security scanners (antivirus tools), you may need to configure them to avoid false positives.

Deckhouse Platform (DP) uses the following directories when running (download in CSV):

- `/mnt/kubernetes-data` (master node) — only exists in clusters deployed in the cloud when a separate disk is used for the etcd database.
- `/var/lib/etcd` (master node) — etcd database.
- `/var/lib/deckhouse/` (master node) — files of Deckhouse modules, which dynamically loads from a registry.
- `/var/lib/upmeter` (master node, the `upmeter` module) — the upmeter module database.
- `/etc/kubernetes` (any node) — manifests of static pods, PKI certificate files.
- `/var/lib/bashible` (any node) — node configuration files.
- `/var/lib/containerd` (any node) — used to store data related to CRI operation (e.g., containerd); contains container image layers, container file system snapshots, meta information, logs, and other container information.
- `/mnt/vector-data` (any node, the `log-shipper` module) — checkpoints of sent logs.
- `/var/log/containers` (any node) — logs of containers (when using `containerd`).
- `/var/lib/kubelet/` (any node) — `kubelet` configuration files.

- `/opt/cni/bin/` (any node) — CNI plugin executables.
- `/opt/deckhouse/bin/` (any node) — executable files required for Deckhouse to work.
- `/var/log/pods/` (any node) — logs of all pod containers that are running on this cluster node.
- `/etc/cni/` (any node) — CNI plugin configuration files.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**
>
> The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

List of reserved Deckhouse Platform DNS names

This page lists the reserved DNS names that Deckhouse Platform (DP) uses. The names are given in the table below.

Use the list if the cluster DNS name template (the `modules.publicDomainTemplate` parameter of the `global` ModuleConfig) is not a wildcard template (for example, `%s-kube.company.my`). In this case, add an A or CNAME record for each name. The record value is the public IP address of the Ingress controller (the HTTP/HTTPS traffic load balancer).

To get the command for adding the DNS names to the local hosts file, use the hosts file data generator.

Hosts file data generator

To access the cluster services without DNS records (for example, from a workstation), add entries for the required names from the table below to the hosts file. Enter your DNS name template (from the `modules.publicDomainTemplate` parameter of the `global` ModuleConfig) and the IP address of the Ingress controller in the generator. The generator returns a ready-to-run command:

DNS name template (publicDomainTemplate) For example, %s.example.i Enter a DNS name template containing `%s`, for example, `%s.domain.my`, `%s-kube.domain.my` or `kube-%s.domain.my`.
IP address of the Ingress controller IP address, for example, 20 Enter a valid IPv4 or IPv6 address.
Generate

List of reserved DNS names

The following table lists the DNS names reserved by DP and the services that use them.

When you add A or CNAME records, use the name from the table in place of `%s` in `publicDomainTemplate`. For example, for the `%s.example.com` template, the `grafana` service gets the name `grafana.example.com`, and for `%s-kube.company.my` — `grafana-kube.company.my`.

Name	Source	Purpose	Note
`api`	The `control-plane-manager` module	Kubernetes API publication. External access to the Kubernetes API via Ingress or Gateway API	To make the name available, enable API publication. The `storage-volume-data-manager` module also uses this name for data export and import (DataExport and DataImport resources). The module obtains the certificate from the Ingress that publishes the Kubernetes API. Therefore, this module also requires API publication

Name	Source	Purpose	Note
`ai-models`	The `ai-models` module	Model downloads and public model catalog (`/v2`, `/api/distribution/...`)	The public catalog is available when `distribution.mode: PublicCatalog` is set
`argocd`	The `operator-argo` module	Argo CD web interface	The name is published only if an Ingress is configured in the ArgoCD resource. The `spec.server.host` parameter sets the name
`code`	Deckhouse Code	Source code management and CI/CD platform	The name is also used to access Code via SSH. You can override the name in the module settings
`code-pages`	Deckhouse Code	GitLab Pages sites	The name is available when Pages are enabled in the CodeInstance resource (`spec.features.pages`). You can override the name with the `spec.features.pages.ingress.hostname` parameter
`code-registry`	Deckhouse Code	Deckhouse Code container image registry	The name is available when the Registry component is enabled in the CodeInstance resource (`spec.features.registry`). You can override the name with the `spec.features.registry.ingress.hostname` parameter
`commander`	The `commander` module	Cluster lifecycle management (creation, updates, inventory)	
`console`	The `console` module	Deckhouse web UI	
`dashboard`	The `dashboard` module	Kubernetes Dashboard web interface for manual cluster management	**Deprecated**. If the `dashboard` module is disabled, the `console` module takes over the `dashboard` name and responds with a `301` redirect to its own address
`ddp`	Deckhouse Development Portal	Deckhouse Development Portal web interface	You can override the name with the `domain.useCustomDomain` and `domain.customDomain` parameters

Name	Source	Purpose	Note
`dex`	The `user-authn` module	OIDC provider: single sign-on (SSO) to web interfaces and the Kubernetes API. The name is also used by dex-authenticators of other modules and by basic-auth-proxy	
`documentation`	The `documentation` module	Web interface with the documentation for the platform version running in the cluster	
`grafana`	The `prometheus` module	Cluster metrics dashboards	If Grafana of the `prometheus` module is not deployed and the `console` module is enabled, the `prometheus` module responds to this name with a redirect to the `console` module
`hubble`	The `cilium-hubble` module	Hubble UI: visualization of network interaction and Cilium network policies	
`istio`	The `istio` module	Kiali web interface: service mesh observability	
`istio-api-proxy`	The `istio` module	Kubernetes API proxy for multicluster: neighboring clusters access the API of this cluster through this proxy	
`istio-metadata`	The `istio` module	Public cluster metadata (root certificate, public keys, API proxy address) for federation and multicluster	
`kubeconfig`	The `user-authn` module	kubeconfig generation web interface for Kubernetes API access	**Deprecated**. Starting from DP version 1.78, the web interface is no longer published
`neuvector`	The `neuvector` module	NeuVector web interface	
`neuvector-api`	The `neuvector` module	NeuVector controller REST API, including the address for connecting other clusters	The name is available when the `controller.apiIngress.enable` parameter is enabled
`observability`	The `observability` module	External read/write access to metrics (`/metrics/main/api/v1/write`)	The name is available when the `externalMetricsAccess.enable` parameter is enabled
`openvpn-admin`	The `openvpn` module	Access to cluster resources via OpenVPN with certificate-based authentication	

Name	Source	Purpose	Note
`payload-registry`	The `payload-registry` module	Access to payload-registry storage	The name is not published when `https.mode: Disabled`
`prometheus`	The `prometheus` module	Prometheus web interface	If Grafana of the `prometheus` module is not deployed and the `console` module is enabled, the `prometheus` module responds to this name with a redirect to the `console` module
`registry`	The `registry` module	External access point to the in-cluster image registry	
`registry-packages-proxy`	The `registry-packages-proxy` module	In-cluster HTTP proxy. Provides access to packages from container image registries	
`status`	The `upmeter` module	Component status page. Shows the availability level over the last 10 minutes	
`stronghold`	Deckhouse Stronghold	Secrets management web interface	
`tools`	The `deckhouse-tools` module	Deckhouse CLI download page	
`upmeter`	The `upmeter` module	Web interface that shows the availability of cluster components	
`virtualization`	DP built-in virtualization	Address for uploading images and disks	

Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.

The platform now offers more features, and editions have changed. We are already updating the documentation, but if you have any questions, please contact your account manager or technical support.

Deckhouse CLI overview and installation

Deckhouse CLI (`d8`) is a command-line interface for working with products in the Deckhouse ecosystem. It combines commands for working with Kubernetes, administering Deckhouse Platform, delivering applications, copying images, creating backups, collecting diagnostic information, virtualization, working with user data, and other tasks.

Starting from release 1.59, `d8` is automatically installed on all DP cluster nodes. The utility can also be installed on a separate administrator machine.

Main command groups

`d8` commands are grouped by purpose:

Commands	Purpose
`d8 k`	Commands for managing a cluster (functionally equivalent to `kubectl`).

Commands	Purpose
`d8 system`	Commands for working with platform system settings, configuration, modules, queues, packages, and system logs.
`d8 status`	Command for obtaining the current platform status.
`d8 backup`	Commands for creating backups of key cluster data and generating diagnostic dumps.
`d8 cr`	Commands for working with the container registry.
`d8 mirror`	Commands for copying the platform component images to the local filesystem or a third-party container registry.
`d8 delivery-kit`	Commands for building, publishing, planning, and deploying applications, as well as for working with Helm, registries, SBOM, and related operations.
`d8 data`	Commands for managing data, as well as exporting and importing it.
`d8 v`	Commands for working with virtual machines created a cluster.
`d8 iam`	Commands for managing Deckhouse users, groups, and access grants.
`d8 stronghold`	Commands for managing the lifecycle of secrets (stronghold module)
`d8 network`	Commands for performing network-related operations in the Deckhouse ecosystem, including CNI migration.
`d8 completion`	Commands for generating shell completion scripts.
`d8 tools`	Auxiliary utilities.
`d8 help`	Built-in help.

How do I install the Deckhouse CLI?

There are two ways to install the Deckhouse CLI:

- Starting with version 0.10, you can install using trdl. This method allows you to get fresh versions of the tool with all improvements and fixes.

  > **i** Note that trdl installation requires Internet access to the tuf repository containing the tool. This method will not work in an air-gapped environment!

- You can manually download the executable file and install it on the system.

trdl-based installation

Starting with the Deckhouse CLI version 0.10, you can install it using trdl.

> ⚠ Versions earlier than 0.10 must be uninstalled before proceeding.
>
> If you need to install one of the versions below 0.10, use the outdated installation method.

1. Install trdl client.
2. Add the Deckhouse CLI repository to trdl:

```
URL=https://deckhouse.ru/downloads/deckhouse-cli-trdl
ROOT_VERSION=1
ROOT_SHA512=343bd5f0d8811254e5f0b6fe292372a7b7eda08d276ff255229200f84e58a8151ab2729df3515cb11372dc3
899c70df172a4e54c8a596a73d67ae790466a0491
REPO=d8

trdl add $REPO $URL $ROOT_VERSION $ROOT_SHA512
```

3. Install the latest stable release of the `d8` utility and check if it works as expected:

```
. $(trdl use d8 0 stable) && d8 --version
```

To avoid having to run `. $(trdl use d8 0 stable)` before every Deckhouse CLI invocation, add the following line to your shell's RC file: `alias d8='trdl exec d8 0 stable -- "$@"'`.

Congratulations, you have installed the Deckhouse CLI.

Installing the executable

- Linux x86-64
- macOS x86-64
- macOS ARM64
- Windows

⚠ The commands below apply to Deckhouse CLI version v0.34.7, which is bundled with the Deckhouse Platform. The latest version of Deckhouse CLI is available on GitHub. You can check your current Deckhouse CLI version using the `d8 --version` command.

1. Download the archive for Linux x86-64 in a convenient way:
   - **From your cluster**:
     1. Turn on the module deckhouse-tools;
     2. Open the web interface with download links. The web interface address is generated according to the publicDomainTemplate template of the Deckhouse global configuration parameter (the `%s` key is replaced with `tools`).

        For example, if `publicDomainTemplate` is set as `%s-kube.company.my`, the web interface will be available at `tools-kube.company.my`;
     3. Click on the button to download Deckhouse CLI for Linux.
   - **From the Deckhouse website**:

     ```
     curl -LO https://deckhouse.io/downloads/deckhouse-cli/v0.34.7/d8-v0.34.7-linux-amd64.tar.gz
     ```
2. Extract the archive:

   ```
   tar -xvf "d8-v0.34.7-linux-amd64.tar.gz" "linux-amd64/bin/d8"
   ```
3. Move the file `d8` to the directory listed in the `PATH` system environment variable (for example, `/usr/local/bin/`):

   ```
   sudo mv "linux-amd64/bin/d8" /usr/local/bin/
   ```

   ℹ `PATH` is a system environment variable containing a list of directories with executable files. This is where the OS will look for the binary when a command is run in the terminal. You can view this list with the `echo $PATH` command.
4. Check that the CLI is working:

   ```
   d8 help
   ```

Congrats, you have successfully installed Deckhouse CLI.

⚠ The commands below apply to Deckhouse CLI version v0.34.7, which is bundled with the Deckhouse Platform. The latest version of Deckhouse CLI is available on GitHub. You can check your current Deckhouse CLI version using the `d8 --version` command.

1. Download the archive for macOS x86-64 in a convenient way:
   - **From your cluster**:
     1. Turn on the module deckhouse-tools;
     2. Open the web interface with download links. The web interface address is generated according to the publicDomainTemplate template of the Deckhouse global configuration parameter (the `%s` key is replaced with `tools`).

        For example, if `publicDomainTemplate` is set as `%s-kube.company.my`, the web interface will be available at `tools-kube.company.my`;
     3. Click on the button to download Deckhouse CLI for macOS.
   - **From the Deckhouse website**:

     ```
     curl -LO https://deckhouse.io/downloads/deckhouse-cli/v0.34.7/d8-v0.34.7-darwin-amd64.tar.gz
     ```
2. Extract the archive:

   ```
   tar -xvf "d8-v0.34.7-darwin-amd64.tar.gz" "darwin-amd64/bin/d8"
   ```
3. Move the file `d8` to the directory listed in the `PATH` system environment variable (for example, `/usr/local/bin/`):

   ```
   sudo mv "darwin-amd64/bin/d8" /usr/local/bin/
   ```

   i `PATH` is a system environment variable containing a list of directories with executable files. This is where the OS will look for the binary when a command is run in the terminal. You can view this list with the `echo $PATH` command.
4. Check that the CLI is working:

   ```
   d8 help
   ```

Congrats, you have successfully installed Deckhouse CLI.

⚠ The commands below apply to Deckhouse CLI version v0.34.7, which is bundled with the Deckhouse Platform. The latest version of Deckhouse CLI is available on GitHub. You can check your current Deckhouse CLI version using the `d8 --version` command.

1. Download the archive for macOS ARM64 in a convenient way:
   - **From your cluster**:
     1. Turn on the module deckhouse-tools;
     2. Open the web interface with download links. The web interface address is generated according to the publicDomainTemplate template of the Deckhouse global configuration parameter (the `%s` key is replaced with `tools`).

        For example, if `publicDomainTemplate` is set as `%s-kube.company.my`, the web interface will be available at `tools-kube.company.my`;
     3. Click on the button to download Deckhouse CLI for macOS.
   - **From the Deckhouse website**:

```
curl -LO https://deckhouse.io/downloads/deckhouse-cli/v0.34.7/d8-v0.34.7-darwin-arm64.tar.gz
```

2. Extract the archive:

   ```
   tar -xvf "d8-v0.34.7-darwin-arm64.tar.gz" "darwin-arm64/bin/d8"
   ```

3. Move the file `d8` to the directory listed in the `PATH` system environment variable (for example, `/usr/local/bin/`):

   ```
   sudo mv "darwin-arm64/bin/d8" /usr/local/bin/
   ```

   > **i** `PATH` is a system environment variable containing a list of directories with executable files. This is where the OS will look for the binary when a command is run in the terminal. You can view this list with the `echo $PATH` command.

4. Check that the CLI is working:

   ```
   d8 help
   ```

Congrats, you have successfully installed Deckhouse CLI.

> **⚠** The commands below apply to Deckhouse CLI version v0.34.7, which is bundled with the Deckhouse Platform. The latest version of Deckhouse CLI is available on GitHub. You can check your current Deckhouse CLI version using the `d8 --version` command.

1. Download the archive for Windows x86-64 in a convenient way.
   - **From your cluster**:
     1. Turn on the module deckhouse-tools;
     2. Open the web interface with download links. The web interface address is generated according to the publicDomainTemplate template of the Deckhouse global configuration parameter (the `%s` key is replaced with `tools`).

        For example, if `publicDomainTemplate` is set as `%s-kube.company.my`, the web interface will be available at `tools-kube.company.my`;
     3. Click on the button to download Deckhouse CLI for Windows.
   - **From the Deckhouse website**, download the archive from this link: Windows x86-64.
2. Extract the archive, move the file `d8.exe` to the directory of your choice, and add the directory to the 'PATH' environment variable of the operating system.
3. Unlock the file `d8.exe`, for example, in the following way:
   - Right-click on the file and select *Properties* from the context menu.
   - In the Properties window, make sure you are on the *General* tab.
   - At the bottom of the General tab, you may see a section that says *Security* with a message like *This file came from another computer and might be blocked to help protect this computer.* If this message is displayed, there will be an *Unblock* button or checkbox next to it.
   - Check the *Unblock* checkbox or click the *Unblock* button, then click *Apply* and *OK* to save the changes.
4. Check that the CLI is working:

   ```
   d8 help
   ```

5. Enable auto-completion in PowerShell by running the following command:

   ```
   d8 completion powershell >> $PROFILE
   ```

Congrats, you have successfully installed Deckhouse CLI.

> **Starting from version 1.76, Deckhouse Kubernetes Platform has been renamed to Deckhouse Platform.**

Deckhouse CLI command reference

> This page is generated automatically.

d8 controls the Deckhouse Kubernetes Platform

Version: v0.34.7

Common options:

- `--help`, `-h`
  help for d8
- `--version`, `-v`
  version for d8

d8 backup

Backup various parts of Deckhouse Kubernetes Platform

Show more...

Backup various parts of Deckhouse Kubernetes Platform

© Flant JSC 2025

Options

- `--context`
  The name of the kubeconfig context to use
- `--kubeconfig`, `-k`
  Path to kubeconfig file. (default is $KUBECONFIG when it is set, otherwise the default kubeconfig path for the current OS user)

d8 backup cluster-config

Usage:

```
d8 backup cluster-config <backup-tarball-path> [options]
```

Take a snapshot of cluster configuration

Show more...

Take a snapshot of cluster configuration.

This command creates a snapshot various kubernetes resources.

© Flant JSC 2025

Options

- `--compress`, `-c`
  Compress result file

Global options

- `--context`
  The name of the kubeconfig context to use
- `--kubeconfig`, `-k`
  Path to kubeconfig file. (default is $KUBECONFIG when it is set, otherwise the default kubeconfig path for the current OS user)

d8 backup etcd

Usage:

```
d8 backup etcd <snapshot-path> [options]
```

Take a snapshot of ETCD state

Show more...

Take a snapshot of ETCD state.

This command creates a snapshot of the Kubernetes underlying key-value database ETCD.

© Flant JSC 2025

Options

- `--etcd-pod`, `-p`
  Name of the etcd pod to snapshot from. (optional)
- `--verbose`
  Verbose log output.

Global options

- `--context`
  The name of the kubeconfig context to use
- `--kubeconfig`, `-k`
  Path to kubeconfig file. (default is $KUBECONFIG when it is set, otherwise the default kubeconfig path for the current OS user)

d8 backup loki

Usage:

```
d8 backup loki [options]
```

Dump logs from Loki api.

Show more...

Dump Loki logs.

This command dump all logs from Loki api or in given range timestamps in DKP.

© Flant JSC 2025

Options

- `--days`
  Limit maximum number of days in range to output per queue from Loki. (Default 5 maximum number of days in range per queue.)
- `--end`
  Set end timestamp range to dump logs from Loki. (Default get max end timestamp from Loki, ex. "2025-01-14 15:04:05".)
- `--limit`
  Limit the number of lines to output per queue from Loki. (Default 5000 max limit strings per queue.)
- `--start`
  Set start timestamp range to dump logs from Loki. (Default get max start timestamp from Loki, ex. "2025-01-12 15:04:05".)

Global options

- `--context`
  The name of the kubeconfig context to use
- `--kubeconfig`, `-k`
  Path to kubeconfig file. (default is $KUBECONFIG when it is set, otherwise the default kubeconfig path for the current OS user)

d8 completion

Generate the autocompletion script for the specified shell

Show more...

Generate the autocompletion script for d8 for the specified shell.
See each sub-command's help for details on how to use the generated script.

d8 completion bash

Usage:

```
d8 completion bash [options]
```

Generate the autocompletion script for bash

Show more...

Generate the autocompletion script for the bash shell.

This script depends on the 'bash-completion' package.
If it is not installed already, you can install it via your OS's package manager.

To load completions in your current shell session:

source <(d8 completion bash)

To load completions for every new session, execute once:

Linux:

d8 completion bash > /etc/bash_completion.d/d8

macOS:

d8 completion bash > $(brew --prefix)/etc/bash_completion.d/d8

You will need to start a new shell for this setup to take effect.

Options

- `--no-descriptions`
  disable completion descriptions

d8 completion fish

Usage:

```
d8 completion fish [options]
```

Generate the autocompletion script for fish

Show more...

Generate the autocompletion script for the fish shell.

To load completions in your current shell session:

d8 completion fish | source

To load completions for every new session, execute once:

d8 completion fish > ~/.config/fish/completions/d8.fish

You will need to start a new shell for this setup to take effect.

Options

- `--no-descriptions`
  disable completion descriptions

d8 completion powershell

Usage:

```
d8 completion powershell [options]
```

Generate the autocompletion script for powershell

Show more...

Generate the autocompletion script for powershell.

To load completions in your current shell session:

```
d8 completion powershell | Out-String | Invoke-Expression
```

To load completions for every new session, add the output of the above command
to your powershell profile.

Options

- `--no-descriptions`

  disable completion descriptions

d8 completion zsh

Usage:

```
d8 completion zsh [options]
```

Generate the autocompletion script for zsh

Show more...

Generate the autocompletion script for the zsh shell.

If shell completion is not already enabled in your environment you will need
to enable it. You can execute the following once:

```
echo "autoload -U compinit; compinit" >> ~/.zshrc
```

To load completions in your current shell session:

```
source <(d8 completion zsh)
```

To load completions for every new session, execute once:

Linux:

```
d8 completion zsh > "${fpath[1]}/_d8"
```

macOS:

```
d8 completion zsh > $(brew --prefix)/share/zsh/site-functions/_d8
```

You will need to start a new shell for this setup to take effect.

Options

- `--no-descriptions`

  disable completion descriptions

d8 cr

Work with container registries

Show more...

Work with container images in OCI/Docker registries: inspect metadata,
transfer (pull/push), and browse contents.

Authentication uses the Docker config (~/.docker/config.json) - run
"d8 cr login" (or "docker login") first if the registry requires
credentials, or pass --username/--password to any command directly.

Options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)

- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr catalog

Usage:

```
d8 cr catalog REGISTRY [options]
```

List the repositories in a registry

Options

- `--full-ref`

  Print the full repository reference (registry/repo)

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr config

Usage:

```
d8 cr config IMAGE [options]
```

Print the config of an image

Show more...

Print the raw config JSON of an image to stdout. Multi-arch indices are
resolved to a single image via --platform.

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr digest

Usage:

```
d8 cr digest [IMAGE] [options]
```

Print the digest of an image

Show more...

By default, fetches the digest of IMAGE from the registry. With --tarball, reads it from a local tarball instead; IMAGE then becomes optional and selects an entry by tag (the first entry is used if omitted).

--full-ref is incompatible with --tarball.

Options

- `--full-ref`

  Print the full image reference with digest (registry/repo@sha256:...); incompatible with --tarball
- `--tarball`

  Read the digest from a local tarball instead of the registry

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr export

Usage:

```
d8 cr export IMAGE [TARBALL] [options]
```

Export the filesystem of an image as a tarball

Show more...

Export writes the merged filesystem of IMAGE as a tar stream to TARBALL (default: "-" = stdout). Output is byte-for-byte equivalent to crane export: linknames are not rewritten, whiteouts are filtered.

For a directory-target extraction with symlink/path-traversal safety checks, use "d8 cr fs extract".

Examples:
  d8 cr export alpine:3.19 -   # stream to stdout
  d8 cr export alpine:3.19 fs.tar   # write to file
  d8 cr export alpine:3.19 - | tar tf -   # list contents

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr fs

Usage:

```
d8 cr fs [options]
```

Inspect or extract files inside a container image

Show more...

Inspect or extract files inside a container image without running it.

Subcommands show the merged filesystem - what a running container would see,
with deleted files hidden.

Path conventions:
- Input PATH is tolerant: "/etc/nginx", "etc/nginx", and "./etc/nginx"
  are all accepted and refer to the same entry.
- Output paths are tar-relative (no leading "/"), matching the convention
  of "crane export IMAGE - | tar tf -" and POSIX tar archives. JSON output
  uses the same tar-relative form.

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr fs cat

Usage:

```
d8 cr fs cat IMAGE PATH [options]
```

Print a file from a container image

Show more...

Print a file from a container image to stdout.

Only regular files are supported. Directories, symlinks, hardlinks and
other non-regular entries return an error. Reads the merged filesystem -
files deleted by upper layers are reported as not-found.

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr fs extract

Usage:

```
d8 cr fs extract IMAGE [options]
```

Extract a container image filesystem to a local directory

Show more...

Extract the merged filesystem of a container image into --output. To
inspect or copy a single file, use "fs cat"; to list a subpath, use
"fs ls IMAGE PATH". An extraction summary is printed when finished.

On interruption (Ctrl+C): partially-written files stay in --output for inspection.
Rerun extract to overwrite them; there is no per-file skip, the full filesystem is
re-materialized from layer 0.

Options

- `--output`, `-o`

  Write the filesystem into this directory

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr fs ls

Usage:

```
d8 cr fs ls IMAGE [PATH] [options]
```

List files inside a container image

Show more...

List files inside a container image.

PATH limits output to that path and its descendants. Leading "./" or "/" is
stripped, so "/etc" and "etc" are equivalent. Output paths are tar-relative
(no leading "/"), matching "crane export | tar tf -".

Options

- `--long`, `-l`

  Long format with mode and size

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr fs tree

Usage:

```
d8 cr fs tree IMAGE [PATH] [options]
```

Show the filesystem of a container image as a tree

Show more...

Render the filesystem of a container image as a tree.

PATH (if given) becomes the tree root and is normalized the same way as in
"fs ls" (leading "./" or "/" stripped, "..", trailing "/" cleaned).

The merged filesystem is rendered.

Options

- `--depth`, `-L`

  Max depth to descend (0 = unlimited)
- `--dirsfirst`

  List directories before files
- `--size`

  Show file sizes (human-readable: B / KB / MB)

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr login

Usage:

```
d8 cr login [REGISTRY] [options]
```

Log in to a container registry

Show more...

Log in to a container registry.

Verifies the credentials against the registry and, on success, writes them to
the Docker config (~/.docker/config.json, honouring $DOCKER_CONFIG). Every
other "d8 cr" command then authenticates from that config automatically, the
same way "docker login" works.

Credentials come from the --username/--password flags; either may be omitted
to be prompted interactively (the password is read without echo). With no
REGISTRY argument the default Docker Hub registry is used.

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

Registry username (overrides the Docker config; use with --password)
- `--verbose, -v`

  Enable debug logs on stderr

d8 cr ls

Usage:

```
d8 cr ls REPO [options]
```

List the tags in a repository

Options

- `--full-ref`

  Print the full image reference (registry/repo:tag)
- `--omit-digest-tags, -O`

  Skip digest-based tags (sha256-*) created by signing tools

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password, -p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username, -u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose, -v`

  Enable debug logs on stderr

d8 cr manifest

Usage:

```
d8 cr manifest IMAGE [options]
```

Print the manifest of an image

Show more...

Print the raw manifest bytes of an image to stdout, exactly as the
registry returned them. Suitable for piping to jq or for signature verification.

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password, -p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username, -u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose, -v`

  Enable debug logs on stderr

d8 cr pull

Usage:

```
d8 cr pull IMAGE... PATH [options]
```

Pull one or more remote images to a local path

Show more...

Pull one or more images and save them to PATH. PATH is a tarball file
for formats "tarball"/"legacy", or a directory for format "oci".

Formats:
  tarball (default) docker-compatible multi-image tarball
  legacy   single-image format compatible with "docker load" (tags only, digests not preserved)
  oci   OCI image-layout directory; keeps all platforms unless --platform is set

When to use:
  tarball - default. Best for shipping one or more images as a single
             file: "docker load" / "podman load" reads it natively.
             Multi-arch indices flatten to one platform - pin it with
             --platform to avoid an ambiguity error.
  oci   - prefer when the destination is OCI-aware tooling (skopeo,
             crane, buildkit, another registry via "cr push --index").
             Preserves the full multi-arch index without --platform.
             Resumable: re-running the same pull skips already-downloaded
             blobs.
  legacy   - last-resort compatibility with very old "docker load" or
             tooling that rejects newer manifests. Lossy: digests are
             not preserved, single-image only. Avoid unless you have a
             specific consumer that fails on tarball.

On interruption (Ctrl+C):
  --format oci   Layer-level resume. Rerun the same pull; existing valid blobs are skipped
                     and in-flight layer temp-files are cleaned up automatically.
  --format tarball| No resume. Rerun replaces the partial archive from scratch.
   legacy
  --cache-path   Layer cache is self-healing: corrupt partial entries are detected on
                     next access and re-downloaded.

Options

- `--cache-path`, `-c`

  Cache image layers under this directory (reused between pulls)
- `--format`

  Output format (one of: tarball, legacy, oci)

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 cr push

Usage:

```
d8 cr push PATH IMAGE [options]
```

Push a local image to a registry

Show more...

A directory PATH is read as an OCI image layout; a file is treated as a
docker-style tarball. Multi-manifest OCI layouts must be pushed with --index.

Prints the pushed reference (with digest) to stdout; use --image-refs to also
write it to a file. --image-refs overwrites the target file if it exists.

Options

- `--image-refs`

  Persist the pushed reference (with digest) to this file
- `--index`

  Push a multi-manifest OCI layout as an index (OCI layout dirs only)

Global options

- `--allow-nondistributable-artifacts`

  Include non-distributable (foreign) layers when pushing
- `--insecure`

  Allow plain HTTP and skip TLS verification (localhost and RFC1918 hosts already auto-allow HTTP)
- `--password`, `-p`

  Registry password or token (overrides the Docker config; use with --username)
- `--platform`

  Resolve images to platform os/arch[/variant][:osversion] (image-level commands only)
- `--username`, `-u`

  Registry username (overrides the Docker config; use with --password)
- `--verbose`, `-v`

  Enable debug logs on stderr

d8 data

Data operations (export/import)

d8 data create

Usage:

```
d8 data create [flags] data_export_name volume_type/volume_name [options]
```

Deprecated: use 'd8 data export create'

Options

- `--namespace`, `-n`

  data volume namespace
- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live

d8 data delete

Usage:

```
d8 data delete [flags] data_export_name [options]
```

Deprecated: use 'd8 data export delete'

Options

- `--namespace`, `-n`

  data volume namespace

d8 data download

Usage:

```
d8 data download [flags] [KIND/]data_export_name [path/file.ext] [options]
```

Deprecated: use 'd8 data export download'

Options

- `--namespace`, `-n`

  data volume namespace
- `--output`, `-o`

  file to save data (default: same as resource)

- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live for auto-created DataExport

d8 data export

Usage:

```
d8 data export [options]
```

Export data (DataExport)

d8 data export create

Usage:

```
d8 data export create [flags] data_export_name volume_type/volume_name [options]
```

Create dataexport kubernetes resource

Options

- `--namespace`, `-n`

  data volume namespace
- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live

d8 data export delete

Usage:

```
d8 data export delete [flags] data_export_name [options]
```

Delete dataexport kubernetes resource

Options

- `--namespace`, `-n`

  data volume namespace

d8 data export download

Usage:

```
d8 data export download [flags] [KIND/]data_export_name [path/file.ext] [options]
```

Download exported data

Options

- `--cleanup`

  Delete auto-created DataExport without prompting (--cleanup=true to delete, --cleanup=false to keep)
- `--namespace`, `-n`

  data volume namespace
- `--output`, `-o`

  file to save data (default: same as resource)
- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live for auto-created DataExport

d8 data export list

Alias: `ls`

Usage:

```
d8 data export list [flags] data_export_name [/path/] [options]
```

List DataExported content information

Options

- `--cleanup`

  Delete auto-created DataExport without prompting (--cleanup=true to delete, --cleanup=false to keep)
- `--namespace`, `-n`

  data volume namespace
- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live for auto-created DataExport

d8 data import

Usage:

```
d8 data import [options]
```

Import data (DataImport)

d8 data import create

Usage:

```
d8 data import create [flags] data_import_name [options]
```

Create DataImport

Options

- `--file`, `-f`

  PVC manifest file path
- `--namespace`, `-n`

  data volume namespace
- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live
- `--wffc`

  Wait for first consumer

d8 data import delete

Usage:

```
d8 data import delete [flags] data_import_name [options]
```

Delete dataimport kubernetes resource

Options

- `--namespace`, `-n`

  data volume namespace

d8 data import upload

Usage:

```
d8 data import upload [flags] data_import_name path/file.ext [options]
```

Upload a file to the provided url

Options

- `--chunks`, `-c`

  number of chunks to upload

- `--dstPath`, `-d`

  destination path of the uploaded file
- `--file`, `-f`

  file to upload
- `--namespace`, `-n`

  data volume namespace
- `--publish`, `-P`

  publish the uploaded file
- `--resume`

  resume upload if process was interrupted

d8 data list

Usage:

```
d8 data list [flags] data_export_name [/path/] [options]
```

Deprecated: use 'd8 data export list'

Options

- `--namespace`, `-n`

  data volume namespace
- `--publish`

  Provide access outside of cluster
- `--ttl`

  Time to live for auto-created DataExport

d8 delivery-kit

Alias: `dk`

A set of tools for building, distributing, and deploying containerized applications

Show more...

A set of tools for building, distributing, and deploying containerized applications.

LICENSE NOTE: The Deckhouse Delivery Kit functionality is exclusively available to users holding a valid license for any commercial version of the Deckhouse Kubernetes Platform.

© Flant JSC 2026

d8 delivery-kit build

Usage:

```
d8 delivery-kit build [IMAGE_NAME...] [options]
```

Build images

Show more...

Build images that are described in werf.yaml.

The result of build command is built images pushed into the specified repo (or locally if repo is not specified).

If one or more IMAGE_NAME parameters specified, werf will build only these images.

Options

- `--add-custom-tag`

  Set tag alias for the content-based tag.
  The alias may contain the following shortcuts:
  - %image%, %image_slug% or %image_safe_slug% to use the image name (necessary if there is more than one image in the werf config);
  - %image_content_based_tag% to use a content-based tag.
  For cleaning custom tags and associated content-based tag are treated as one.
  Also can be defined with $WERF_ADD_CUSTOM_TAG_* (e.g. $WERF_ADD_CUSTOM_TAG_1="%image%-tag1", $WERF_ADD_CUSTOM_TAG_2="%image%-tag2")

- `--allow-includes-update`

  Allow use includes latest versions (default $WERF_ALLOW_INCLUDES_UPDATE or false)
- `--allowed-backend-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE)
- `--allowed-backend-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-docker-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE)
- `--allowed-docker-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-local-cache-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of local cache (~/.werf/local_cache by default) volume usage which will cause cleanup of least recently used data from the local cache (default 70% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE)
- `--allowed-local-cache-volume-usage-margin`

  During cleanup of local cache werf would delete local cache data until volume usage becomes below "allowed-local-cache-volume-usage - allowed-local-cache-volume-usage-margin" level (default 5% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE_MARGIN)
- `--annotate-layers-with-dm-verity-root-hash`

  Enable annotation of image layers with dm-verity root hash (default $WERF_ANNOTATE_LAYERS_WITH_DM_VERITY_ROOT_HASH)
- `--backend-network`

  Network mode for the build containers ($WERF_BACKEND_NETWORK or nothing by default)
- `--backend-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_BACKEND_STORAGE_PATH)
- `--bsign-elf-files`

  Enable ELF files signing with bsign (default $WERF_BSIGN_ELF_FILES).
  When enabled, the private elf key must be specified with --elf-pgp-private-key-base64 or --elf-pgp-private-key-fingerprint option
- `--build-report-operations`

  Collect low-level operations statistics: add Operations and StageCache sections to the build report and print operations summary after the build (by default $WERF_BUILD_REPORT_OPERATIONS or false). Also enabled by --log-debug
- `--build-report-path`

  Change build report path and format (by default $WERF_BUILD_REPORT_PATH or ".werf-build-report.json" if not set). Extension must be either .json for JSON format or .env for env-file format. If extension not specified, then .json is used
- `--cache-repo`

  Specify one or multiple cache repos with images that will be used as a cache. Cache will be populated when pushing newly built images into the primary repo and when pulling existing images from the primary repo. Cache repo will be used to pull images and to get manifests before making requests to the primary repo. Also, can be specified with $WERF_CACHE_REPO_* (e.g. $WERF_CACHE_REPO_1=..., $WERF_CACHE_REPO_2=...)
- `--check-built-images`

  Check that all used images are previously built and exist in repo. Exits with error if needed images are not cached and so require to run build instructions (default $WERF_CHECK_BUILT_IMAGES)

- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--dev`

  Enable development mode (default $WERF_DEV).
  The mode allows working with project files without doing redundant commits during debugging and development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project’s werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--disable-auto-host-cleanup`

  Disable auto host cleanup procedure in main werf commands like werf-build, werf-converge and other (default disabled or WERF_DISABLE_AUTO_HOST_CLEANUP)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and push images into the specified repo, to pull base images
- `--docker-server-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_DOCKER_SERVER_STORAGE_PATH)
- `--elf-pgp-private-key-base64`

  Base64-encoded PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_BASE64)
- `--elf-pgp-private-key-fingerprint`

  PGP private key fingerprint (default $WERF_ELF_PGP_PRIVATE_KEY_FINGERPRINT)
- `--elf-pgp-private-key-passphrase`

  Passphrase for the PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_PASSPHRASE)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--final-images-only`

  Process final images only ($WERF_FINAL_IMAGES_ONLY or false by default)
- `--final-repo`

  Container registry storage address (default $WERF_FINAL_REPO)
- `--final-repo-container-registry`

  Choose final-repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_FINAL_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--final-repo-docker-hub-password`

  final-repo Docker Hub password (default $WERF_FINAL_REPO_DOCKER_HUB_PASSWORD)

- `--final-repo-docker-hub-token`

  final-repo Docker Hub token (default $WERF_FINAL_REPO_DOCKER_HUB_TOKEN)
- `--final-repo-docker-hub-username`

  final-repo Docker Hub username (default $WERF_FINAL_REPO_DOCKER_HUB_USERNAME)
- `--final-repo-github-token`

  final-repo GitHub token (default $WERF_FINAL_REPO_GITHUB_TOKEN)
- `--final-repo-harbor-password`

  final-repo Harbor password (default $WERF_FINAL_REPO_HARBOR_PASSWORD)
- `--final-repo-harbor-username`

  final-repo Harbor username (default $WERF_FINAL_REPO_HARBOR_USERNAME)
- `--final-repo-quay-token`

  final-repo quay.io token (default $WERF_FINAL_REPO_QUAY_TOKEN)
- `--follow`

  Enable follow mode (default $WERF_FOLLOW).
  The mode allows restarting the command on a new commit.
  In development mode (--dev), werf restarts the command on any changes (including untracked files) in the git repository worktree
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--insecure-helm-dependencies`

  No-op
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--introspect-before-error`

  Introspect failed stage in the clean state, before running all assembly instructions of the stage
- `--introspect-error`

  Introspect failed stage in the state, right after running failed assembly instruction
- `--introspect-stage`

  Introspect a specific stage. The option can be used multiple times to introspect several stages.

  There are the following formats to use:
  * specify IMAGE_NAME/STAGE_NAME to introspect stage STAGE_NAME of either image or artifact IMAGE_NAME
  * specify STAGE_NAME or */STAGE_NAME for the introspection of all existing stages with name STAGE_NAME

  IMAGE_NAME is the name of an image or artifact described in werf.yaml, the nameless image specified with ~.
  STAGE_NAME should be one of the following: from, beforeInstall, dependenciesBeforeInstall, gitArchive, install, dependenciesAfterInstall, beforeSetup, dependenciesBeforeSetup, setup, dependenciesAfterSetup, gitCache, gitLatestPatch, dockerInstructions, dockerfile, imageSpec
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

Enable debug (default $WERF_LOG_DEBUG).

- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--parallel`, `-p`

  Run in parallel (default $WERF_PARALLEL or true)
- `--parallel-tasks-limit`

  Parallel tasks limit, set -1 to remove the limitation (default $WERF_PARALLEL_TASKS_LIMIT or 5)
- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--project-name`, `-N`

  Set a specific project name (default $WERF_PROJECT_NAME)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--require-built-images`, `-Z`

  Check that all used images are previously built and exist in repo. Exits with error if needed images are not cached and so require to run build instructions
- `--save-build-report`

  Save build report (by default $WERF_SAVE_BUILD_REPORT or false). Its path and format configured with --build-report-path

- `--secondary-repo`

  Specify one or multiple secondary read-only repos with images that will be used as a cache.
  Also, can be specified with $WERF_SECONDARY_REPO_* (e.g. $WERF_SECONDARY_REPO_1=...,
  $WERF_SECONDARY_REPO_2=...)
- `--sign-cert`

  The leaf certificate as path to PEM file or base64-encoded PEM (default $WERF_SIGN_CERT)
- `--sign-elf-files`

  Enable ELF files signing (default $WERF_SIGN_ELF_FILES).
  When enabled, the private signing key must be specified with --sign-key option and the certificate must be specified with --sign-cert option
- `--sign-intermediates`

  The intermediate certificates as path to PEM file or base64-encoded PEM (default $WERF_SIGN_INTERMEDIATES)
- `--sign-key`

  The private signing key as path to PEM file, base64-encoded PEM or hashivault://[KEY] (default $WERF_SIGN_KEY)
- `--sign-manifest`

  Enable image manifest signing (default $WERF_SIGN_MANIFEST).
  When enabled,
  the private signing key must be specified with --sign-key option and
  the certificate must be specified with --sign-cert option
- `--skip-image-spec-stage`

  Force skipping "imageSpec" build stage (default $WERF_SKIP_IMAGE_SPEC_STAGE or false)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--ssh-key`

  Use only specific ssh key(s).
  Can be specified with $WERF_SSH_KEY_* (e.g. $WERF_SSH_KEY_REPO=~/.ssh/repo_rsa,
  $WERF_SSH_KEY_NODEJS=~/.ssh/nodejs_rsa).
  Defaults to $WERF_SSH_KEY_*, system ssh-agent or ~/.ssh/{id_rsa|id_dsa}
- `--synchronization`, `-S`

  Address of synchronizer for multiple werf processes to work with a single repo.

  Default:
  - $WERF_SYNCHRONIZATION, or
  - :local if --repo is not specified, or
  - https://delivery-sync.deckhouse.ru if --repo has been specified.

  The same address should be specified for all werf processes that work with a single repo. :local address allows execution of werf processes from a single host only
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).
- `--virtual-merge`

  Enable virtual/ephemeral merge commit mode when building current application state ($WERF_VIRTUAL_MERGE by default)

d8 delivery-kit bundle

Usage:

```
d8 delivery-kit bundle [options]
```

Work with werf bundles: publish bundles into container registry and deploy bundles into Kubernetes cluster

d8 delivery-kit bundle apply

Usage:

```
d8 delivery-kit bundle apply [options]
```

Apply bundle into Kubernetes

Show more...

Take latest bundle from the specified container registry using specified version tag or version mask and apply it as a helm chart into Kubernetes cluster.

Options

- `--add-annotation`

  Add annotation to deploying resources (can specify multiple).
  Format: annoName=annoValue.
  Also, can be specified with $WERF_ADD_ANNOTATION_* (e.g. $WERF_ADD_ANNOTATION_1=annoName1=annoValue1, $WERF_ADD_ANNOTATION_2=annoName2=annoValue2)
- `--add-label`

  Add label to deploying resources (can specify multiple).
  Format: labelName=labelValue.
  Also, can be specified with $WERF_ADD_LABEL_* (e.g. $WERF_ADD_LABEL_1=labelName1=labelValue1, $WERF_ADD_LABEL_2=labelName2=labelValue2)
- `--atomic`

  Enable auto rollback of the failed release to the previous deployed release version when current deploy process have failed ($WERF_ATOMIC by default)
- `--auto-rollback`, `-R`

  Enable auto rollback of the failed release to the previous deployed release version when current deploy process have failed ($WERF_AUTO_ROLLBACK by default)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--delete-propagation`

  Set default delete propagation strategy (default $WERF_DELETE_PROPAGATION or Foreground).
- `--deno-binary-path`

  Path to the Deno binary to use instead of auto-downloading (default $WERF_DENO_BINARY_PATH)
- `--deploy-graph-path`

  Save deploy graph path to the specified file (by default $WERF_DEPLOY_GRAPH_PATH). Extension must be .dot or not specified. If extension not specified, then .dot is used
- `--deploy-report-path`

  Change deploy report path and format (by default $WERF_DEPLOY_REPORT_PATH or ".werf-deploy-report.json" if not set). Extension must be .json for JSON format. If extension not specified, then .json is used
- `--disable-default-secret-values`

  Do not use secret values from the default .helm/secret-values.yaml file (default $WERF_DISABLE_DEFAULT_SECRET_VALUES or false)
- `--disable-default-values`

  Do not use values from the default .helm/values.yaml file (default $WERF_DISABLE_DEFAULT_VALUES or false)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and push images into the specified repo, to pull base images
- `--env`

  Use specified environment (default $WERF_ENV)
- `--force-adoption`

  Always adopt resources, even if they belong to a different Helm release (default $WERF_FORCE_ADOPTION or false)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--hooks-status-progress-period`

No-op
- `--ignore-bundle-js`

  Do not use the existing bundle.js file. Requires TypeScript source files and Deno to rebuild (default $WERF_IGNORE_BUNDLE_JS)
- `--ignore-secret-key`

  Disable secrets decryption (default $WERF_IGNORE_SECRET_KEY)
- `--insecure-helm-dependencies`

  Allow insecure oci registries to be used in the Chart.yaml dependencies configuration (default $WERF_INSECURE_HELM_DEPENDENCIES)
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--kube-api-server`

  Kubernetes API server address (default $WERF_KUBE_API_SERVER)
- `--kube-auth-password`

  Basic auth password for Kubernetes API (default $WERF_KUBE_AUTH_PASSWORD)
- `--kube-auth-provider`

  Auth provider name for authentication in Kubernetes API (default $WERF_KUBE_AUTH_PROVIDER)
- `--kube-auth-provider-config`

  Auth provider config for authentication in Kubernetes API (default $WERF_KUBE_AUTH_PROVIDER_CONFIG)
- `--kube-auth-username`

  Basic auth username for Kubernetes API (default $WERF_KUBE_AUTH_USERNAME)
- `--kube-burst-limit`

  Kubernetes client burst limit (default $WERF_KUBE_BURST_LIMIT or 100)
- `--kube-ca-data`

  Pass Kubernetes API server TLS CA data (default $WERF_KUBE_CA_DATA)
- `--kube-ca-path`

  Kubernetes API server CA path (default $WERF_KUBE_CA_PATH)
- `--kube-cert`

  Path to PEM-encoded TLS client cert for connecting to Kubernetes API (default $WERF_KUBE_CERT
- `--kube-cert-data`

  Pass PEM-encoded TLS client cert for connecting to Kubernetes API (default $WERF_KUBE_CERT_DATA)
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)
- `--kube-context-cluster`

  Use cluster from Kubeconfig for current context (default $WERF_KUBE_CONTEXT_CLUSTER)
- `--kube-context-user`

  Use user from Kubeconfig for current context (default $WERF_KUBE_CONTEXT_USER)
- `--kube-impersonate-group`

  Sets Impersonate-Group headers when authenticating in Kubernetes. Can be also set with $WERF_KUBE_IMPERSONATE_GROUP_* environment variables
- `--kube-impersonate-uid`

  Sets Impersonate-Uid header when authenticating in Kubernetes (default $WERF_KUBE_IMPERSONATE_UID)
- `--kube-impersonate-user`

  Sets Impersonate-User header when authenticating in Kubernetes (default $WERF_KUBE_IMPERSONATE_USER)
- `--kube-key`

  Path to PEM-encoded TLS client key for connecting to Kubernetes API (default $WERF_KUBE_KEY)
- `--kube-key-data`

  Pass PEM-encoded TLS client key for connecting to Kubernetes API (default $WERF_KUBE_KEY_DATA)
- `--kube-proxy-url`

  Proxy URL to use for proxying all requests to Kubernetes API (default $WERF_KUBE_PROXY_URL)
- `--kube-qps-limit`

  Kubernetes client QPS limit (default $WERF_KUBE_QPS_LIMIT or 30)

- `--kube-request-timeout`

  Timeout for all requests to Kubernetes API (default $WERF_KUBE_REQUEST_TIMEOUT)
- `--kube-tls-server`

  Server name to use for Kubernetes API server certificate validation. If it is not provided, the hostname used to contact the server is used (default $WERF_KUBE_TLS_SERVER)
- `--kube-token`

  Kubernetes bearer token used for authentication (default $WERF_KUBE_TOKEN)
- `--kube-token-path`

  Path to file with bearer token for authentication in Kubernetes (default $WERF_KUBE_TOKEN_PATH)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--namespace`

  Use specified Kubernetes namespace (default $WERF_NAMESPACE)
- `--network-parallelism`

  Parallelize some network operations (default $WERF_NETWORK_PARALLELISM or 30)
- `--no-create-namespace`

  Don't create the release namespace (default $WERF_NO_CREATE_NAMESPACE)
- `--no-final-tracking`

  By default disable tracking operations that have no create/update/delete resource operations after them, which are most tracking operations, to speed up the release (default $WERF_NO_FINAL_TRACKING)
- `--no-install-crds`

  Do not install CRDs from "crds/" directories of installed charts (default $WERF_NO_INSTALL_CRDS)
- `--no-notes`

  Don't show release notes at the end of the release (default $WERF_NO_NOTES)
- `--no-pod-logs`

  Disable Pod logs collection and printing (default $WERF_NO_POD_LOGS or false)
- `--no-remove-manual-changes`

  Don't remove fields added manually to the resource in the cluster if fields aren't present in the manifest (default $WERF_NO_REMOVE_MANUAL_CHANGES)
- `--provenance-keyring`

  Path to keyring containing public keys to verify chart provenance (default $WERF_PROVENANCE_KEYRING)
- `--provenance-strategy`

  Strategy for provenance verifying (default $WERF_PROVENANCE_STRATEGY).
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--release`

  Use specified Helm release name (default $WERF_RELEASE)

- `--release-info-annotations`

  Add annotations to release metadata (default $WERF_RELEASE_INFO_ANNOTATIONS)
- `--release-label`

  Add Helm release labels (can specify multiple). Kind of labels depends or release storage driver. Format: labelName=labelValue.
  Also, can be specified with $WERF_RELEASE_LABEL_* (e.g. $WERF_RELEASE_LABEL_1=labelName1=labelValue1, $WERF_RELEASE_LABEL_2=labelName2=labelValue2)
- `--release-storage`

  How releases should be stored (default $WERF_RELEASE_STORAGE)
- `--release-storage-sql-connection`

  SQL Connection String for Helm SQL Storage (default $WERF_RELEASE_STORAGE_SQL_CONNECTION)
- `--releases-history-max`

  Max releases to keep in release storage ($WERF_RELEASES_HISTORY_MAX or 5 by default)
- `--render-subchart-notes`

  If set, render subchart notes along with the parent (by default $WERF_RENDER_SUBCHART_NOTES or false)
- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--rollback-graph-path`

  Save rollback graph path to the specified file (by default $WERF_ROLLBACK_GRAPH_PATH). Extension must be .dot or not specified. If extension not specified, then .dot is used
- `--runtime-annotations`

  Add annotations which will not trigger resource updates to all resources (default $WERF_RUNTIME_ANNOTATIONS)
- `--runtime-labels`

  Add labels which will not trigger resource updates to all resources (default $WERF_RUNTIME_LABELS)
- `--save-deploy-report`

  Save deploy report (by default $WERF_SAVE_DEPLOY_REPORT or false). Its path and format configured with --deploy-report-path
- `--secret-key`

  Secret key (default $WERF_SECRET_KEY)
- `--secret-values`

  Specify helm secret values in a YAML file (can specify multiple). Also, can be defined with $WERF_SECRET_VALUES_* (e.g. $WERF_SECRET_VALUES_ENV=.helm/secret_values_test.yaml, $WERF_SECRET_VALUES_DB=.helm/secret_values_db.yaml)
- `--set`

  Set helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_* (e.g. $WERF_SET_1=key1=val1, $WERF_SET_2=key2=val2)

- `--set-docker-config-json-value`

  Shortcut to set current docker config into the .Values.global.werf.dockerconfigjson
- `--set-file`

  Set values from respective files specified via the command line (can specify multiple or separate values with commas: key1=path1,key2=path2).
  Also, can be defined with $WERF_SET_FILE_* (e.g. $WERF_SET_FILE_1=key1=path1, $WERF_SET_FILE_2=key2=val2)
- `--set-json`

  Set new values, where the key is the value path and the value is JSON (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_JSON_* (e.g. $WERF_SET_JSON_1=key1=val1, $WERF_SET_JSON_2=key2=val2)
- `--set-literal`

  Set new values, where the key is the value path and the value is the value. The value will always become a literal string (can specify multiple or separate values with commas: key1=val1,key2=val2).)
  Also, can be defined with $WERF_SET_LITERAL_* (e.g. $WERF_SET_LITERAL_1=key1=val1, $WERF_SET_LITERAL_2=key2=val2)
- `--set-root-json`

  Set new keys in arbitrary things in the global root context ("$"), where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you REALLY know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_ROOT_JSON_* (e.g. $WERF_SET_ROOT_JSON_1=key1=val1, $WERF_SET_ROOT_JSON_2=key2=val2)
- `--set-runtime-json`

  Set new keys in $.Runtime, where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_RUNTIME_JSON_* (e.g. $WERF_SET_RUNTIME_JSON_1=key1=val1, $WERF_SET_RUNTIME_JSON_2=key2=val2)
- `--set-string`

  Set STRING helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_STRING_* (e.g. $WERF_SET_STRING_1=key1=val1, $WERF_SET_STRING_2=key2=val2)
- `--skip-dependencies-repo-refresh`, `-L`

  Do not refresh helm chart repositories locally cached index
- `--skip-tls-verify-helm-dependencies`

  Skip TLS certificate validation when accessing a Helm charts repository (default $WERF_SKIP_TLS_VERIFY_HELM_DEPENDENCIES)
- `--skip-tls-verify-kube`

  Skip TLS certificate validation when accessing a Kubernetes cluster (default $WERF_SKIP_TLS_VERIFY_KUBE)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--status-progress-period`

  Status progress period in seconds. Set -1 to stop showing status progress. Defaults to $WERF_STATUS_PROGRESS_PERIOD_SECONDS or 5 seconds
- `--tag`

  Provide exact tag version or semver-based pattern, werf will install or upgrade to the latest version of the specified bundle ($WERF_TAG or latest by default)
- `--templates-allow-dns`

  Allow performing DNS requests in templating (default $WERF_TEMPLATES_ALLOW_DNS)
- `--timeout`, `-t`

  Resources tracking timeout in seconds ($WERF_TIMEOUT by default)
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--values`

  Specify helm values in a YAML file or a URL (can specify multiple). Also, can be defined with

$WERF_VALUES_* (e.g. $WERF_VALUES_1=.helm/values_1.yaml, $WERF_VALUES_2=.helm/values_2.yaml)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit bundle copy

Usage:

```
d8 delivery-kit bundle copy [options]
```

Copy published bundle into another location

Show more...

Take latest bundle from the specified container registry using specified version tag and copy it
either into a different tag within the same container registry or into another container registry.

Options

- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and push images into the specified repos
- `--from`

  Source address of the bundle to copy, specify bundle archive using schema `archive:PATH_TO_ARCHIVE.tar.gz`, specify remote bundle with schema `[docker://]REPO:TAG` or without schema.
- `--helm-compatible-chart`, `-C`

  Set chart name in the Chart.yaml of the published chart to the last path component of container registry repo (for REGISTRY/PATH/TO/REPO address chart name will be REPO, more info https://helm.sh/docs/topics/registries/#oci-feature-deprecation-and-behavior-changes-with-v370). In helm compatibility mode chart is fully conforming with the helm OCI registry requirements. Default true or $WERF_HELM_COMPATIBLE_CHART.
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--insecure-helm-dependencies`

  No-op
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).

- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--rename-chart`

  Force setting of chart name in the Chart.yaml of the published chart to the specified value (can be set by the $WERF_RENAME_CHART, no rename by default, could not be used together with the '--helm-compatible-chart' option).
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--to`

  Destination address of the bundle to copy, specify bundle archive using schema `archive:PATH_TO_ARCHIVE.tar.gz`, specify remote bundle with schema `[docker://]REPO:TAG` or without schema.
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit bundle plan

Usage:

```
d8 delivery-kit bundle plan [options]
```

Plan bundle apply into Kubernetes

Show more...

Take latest bundle from the specified container registry using specified version tag or version mask and plan its deployment as a helm chart into Kubernetes cluster.

Options

- `--add-annotation`

  Add annotation to deploying resources (can specify multiple).
  Format: annoName=annoValue.
  Also, can be specified with $WERF_ADD_ANNOTATION_* (e.g. $WERF_ADD_ANNOTATION_1=annoName1=annoValue1, $WERF_ADD_ANNOTATION_2=annoName2=annoValue2)
- `--add-label`

  Add label to deploying resources (can specify multiple).
  Format: labelName=labelValue.
  Also, can be specified with $WERF_ADD_LABEL_* (e.g. $WERF_ADD_LABEL_1=labelName1=labelValue1, $WERF_ADD_LABEL_2=labelName2=labelValue2)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--delete-propagation`

  Set default delete propagation strategy (default $WERF_DELETE_PROPAGATION or Foreground).
- `--deno-binary-path`

  Path to the Deno binary to use instead of auto-downloading (default $WERF_DENO_BINARY_PATH)
- `--deploy-graph-path`

  Save deploy graph path to the specified file (by default $WERF_DEPLOY_GRAPH_PATH). Extension must be .dot or not specified. If extension not specified, then .dot is used
- `--diff-context-lines`

Show N lines of context around diffs ($WERF_DIFF_CONTEXT_LINES by default)

- `--disable-default-secret-values`

  Do not use secret values from the default .helm/secret-values.yaml file (default $WERF_DISABLE_DEFAULT_SECRET_VALUES or false)
- `--disable-default-values`

  Do not use values from the default .helm/values.yaml file (default $WERF_DISABLE_DEFAULT_VALUES or false)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and push images into the specified repo, to pull base images
- `--env`

  Use specified environment (default $WERF_ENV)
- `--exit-code`

  Return exit code 0 if no changes, 1 if error, 2 if any changes planned (default $WERF_EXIT_CODE or false)
- `--force-adoption`

  Always adopt resources, even if they belong to a different Helm release (default $WERF_FORCE_ADOPTION or false)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--ignore-bundle-js`

  Do not use the existing bundle.js file. Requires TypeScript source files and Deno to rebuild (default $WERF_IGNORE_BUNDLE_JS)
- `--ignore-secret-key`

  Disable secrets decryption (default $WERF_IGNORE_SECRET_KEY)
- `--insecure-helm-dependencies`

  Allow insecure oci registries to be used in the Chart.yaml dependencies configuration (default $WERF_INSECURE_HELM_DEPENDENCIES)
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--kube-api-server`

  Kubernetes API server address (default $WERF_KUBE_API_SERVER)
- `--kube-auth-password`

  Basic auth password for Kubernetes API (default $WERF_KUBE_AUTH_PASSWORD)
- `--kube-auth-provider`

  Auth provider name for authentication in Kubernetes API (default $WERF_KUBE_AUTH_PROVIDER)
- `--kube-auth-provider-config`

  Auth provider config for authentication in Kubernetes API (default $WERF_KUBE_AUTH_PROVIDER_CONFIG)
- `--kube-auth-username`

  Basic auth username for Kubernetes API (default $WERF_KUBE_AUTH_USERNAME)
- `--kube-burst-limit`

  Kubernetes client burst limit (default $WERF_KUBE_BURST_LIMIT or 100)
- `--kube-ca-data`

  Pass Kubernetes API server TLS CA data (default $WERF_KUBE_CA_DATA)
- `--kube-ca-path`

  Kubernetes API server CA path (default $WERF_KUBE_CA_PATH)
- `--kube-cert`

  Path to PEM-encoded TLS client cert for connecting to Kubernetes API (default $WERF_KUBE_CERT
- `--kube-cert-data`

  Pass PEM-encoded TLS client cert for connecting to Kubernetes API (default $WERF_KUBE_CERT_DATA)
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)

- `--kube-context-cluster`

  Use cluster from Kubeconfig for current context (default $WERF_KUBE_CONTEXT_CLUSTER)
- `--kube-context-user`

  Use user from Kubeconfig for current context (default $WERF_KUBE_CONTEXT_USER)
- `--kube-impersonate-group`

  Sets Impersonate-Group headers when authenticating in Kubernetes. Can be also set with $WERF_KUBE_IMPERSONATE_GROUP_* environment variables
- `--kube-impersonate-uid`

  Sets Impersonate-Uid header when authenticating in Kubernetes (default $WERF_KUBE_IMPERSONATE_UID)
- `--kube-impersonate-user`

  Sets Impersonate-User header when authenticating in Kubernetes (default $WERF_KUBE_IMPERSONATE_USER)
- `--kube-key`

  Path to PEM-encoded TLS client key for connecting to Kubernetes API (default $WERF_KUBE_KEY)
- `--kube-key-data`

  Pass PEM-encoded TLS client key for connecting to Kubernetes API (default $WERF_KUBE_KEY_DATA)
- `--kube-proxy-url`

  Proxy URL to use for proxying all requests to Kubernetes API (default $WERF_KUBE_PROXY_URL)
- `--kube-qps-limit`

  Kubernetes client QPS limit (default $WERF_KUBE_QPS_LIMIT or 30)
- `--kube-request-timeout`

  Timeout for all requests to Kubernetes API (default $WERF_KUBE_REQUEST_TIMEOUT)
- `--kube-tls-server`

  Server name to use for Kubernetes API server certificate validation. If it is not provided, the hostname used to contact the server is used (default $WERF_KUBE_TLS_SERVER)
- `--kube-token`

  Kubernetes bearer token used for authentication (default $WERF_KUBE_TOKEN)
- `--kube-token-path`

  Path to file with bearer token for authentication in Kubernetes (default $WERF_KUBE_TOKEN_PATH)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--namespace`

  Use specified Kubernetes namespace (default $WERF_NAMESPACE)
- `--network-parallelism`

  Parallelize some network operations (default $WERF_NETWORK_PARALLELISM or 30)
- `--no-final-tracking`

  By default disable tracking operations that have no create/update/delete resource operations after them,

which are most tracking operations, to speed up the release (default $WERF_NO_FINAL_TRACKING)
- `--no-install-crds`

  Do not install CRDs from "crds/" directories of installed charts (default $WERF_NO_INSTALL_CRDS)
- `--no-remove-manual-changes`

  Don't remove fields added manually to the resource in the cluster if fields aren't present in the manifest (default $WERF_NO_REMOVE_MANUAL_CHANGES)
- `--provenance-keyring`

  Path to keyring containing public keys to verify chart provenance (default $WERF_PROVENANCE_KEYRING)
- `--provenance-strategy`

  Strategy for provenance verifying (default $WERF_PROVENANCE_STRATEGY).
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--release`

  Use specified Helm release name (default $WERF_RELEASE)
- `--release-info-annotations`

  Add annotations to release metadata (default $WERF_RELEASE_INFO_ANNOTATIONS)
- `--release-label`

  Add Helm release labels (can specify multiple). Kind of labels depends or release storage driver.
  Format: labelName=labelValue.
  Also, can be specified with $WERF_RELEASE_LABEL_* (e.g. $WERF_RELEASE_LABEL_1=labelName1=labelValue1, $WERF_RELEASE_LABEL_2=labelName2=labelValue2)
- `--release-storage`

  How releases should be stored (default $WERF_RELEASE_STORAGE)
- `--release-storage-sql-connection`

  SQL Connection String for Helm SQL Storage (default $WERF_RELEASE_STORAGE_SQL_CONNECTION)
- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--runtime-annotations`

  Add annotations which will not trigger resource updates to all resources (default $WERF_RUNTIME_ANNOTATIONS)
- `--runtime-labels`

  Add labels which will not trigger resource updates to all resources (default $WERF_RUNTIME_LABELS)
- `--secret-key`

  Secret key (default $WERF_SECRET_KEY)
- `--secret-values`

  Specify helm secret values in a YAML file (can specify multiple). Also, can be defined with $WERF_SECRET_VALUES_* (e.g. $WERF_SECRET_VALUES_ENV=.helm/secret_values_test.yaml, $WERF_SECRET_VALUES_DB=.helm/secret_values_db.yaml)

- `--set`

  Set helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_* (e.g. $WERF_SET_1=key1=val1, $WERF_SET_2=key2=val2)
- `--set-docker-config-json-value`

  Shortcut to set current docker config into the .Values.global.werf.dockerconfigjson
- `--set-file`

  Set values from respective files specified via the command line (can specify multiple or separate values with commas: key1=path1,key2=path2).
  Also, can be defined with $WERF_SET_FILE_* (e.g. $WERF_SET_FILE_1=key1=path1, $WERF_SET_FILE_2=key2=val2)
- `--set-json`

  Set new values, where the key is the value path and the value is JSON (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_JSON_* (e.g. $WERF_SET_JSON_1=key1=val1, $WERF_SET_JSON_2=key2=val2)
- `--set-literal`

  Set new values, where the key is the value path and the value is the value. The value will always become a literal string (can specify multiple or separate values with commas: key1=val1,key2=val2).)
  Also, can be defined with $WERF_SET_LITERAL_* (e.g. $WERF_SET_LITERAL_1=key1=val1, $WERF_SET_LITERAL_2=key2=val2)
- `--set-root-json`

  Set new keys in arbitrary things in the global root context ("$"), where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you REALLY know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_ROOT_JSON_* (e.g. $WERF_SET_ROOT_JSON_1=key1=val1, $WERF_SET_ROOT_JSON_2=key2=val2)
- `--set-runtime-json`

  Set new keys in $.Runtime, where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_RUNTIME_JSON_* (e.g. $WERF_SET_RUNTIME_JSON_1=key1=val1, $WERF_SET_RUNTIME_JSON_2=key2=val2)
- `--set-string`

  Set STRING helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_STRING_* (e.g. $WERF_SET_STRING_1=key1=val1, $WERF_SET_STRING_2=key2=val2)
- `--show-insignificant-diffs`

  Show insignificant diff lines ($WERF_SHOW_INSIGNIFICANT_DIFFS by default)
- `--show-sensitive-diffs`

  Show sensitive diff lines ($WERF_SHOW_SENSITIVE_DIFFS by default)
- `--show-verbose-crd-diffs`

  Show verbose CRD diff lines ($WERF_SHOW_VERBOSE_CRD_DIFFS by default)
- `--show-verbose-diffs`

  Show verbose diff lines ($WERF_SHOW_VERBOSE_DIFFS by default)
- `--skip-dependencies-repo-refresh`, `-L`

  Do not refresh helm chart repositories locally cached index
- `--skip-tls-verify-helm-dependencies`

  Skip TLS certificate validation when accessing a Helm charts repository (default $WERF_SKIP_TLS_VERIFY_HELM_DEPENDENCIES)
- `--skip-tls-verify-kube`

  Skip TLS certificate validation when accessing a Kubernetes cluster (default $WERF_SKIP_TLS_VERIFY_KUBE)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--tag`

  Provide exact tag version or semver-based pattern, werf will install or upgrade to the latest version of the

specified bundle ($WERF_TAG or latest by default)
- `--templates-allow-dns`

  Allow performing DNS requests in templating (default $WERF_TEMPLATES_ALLOW_DNS)
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--values`

  Specify helm values in a YAML file or a URL (can specify multiple). Also, can be defined with $WERF_VALUES_* (e.g. $WERF_VALUES_1=.helm/values_1.yaml, $WERF_VALUES_2=.helm/values_2.yaml)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit bundle publish

Usage:

```
d8 delivery-kit bundle publish [IMAGE_NAME...] [options]
```

Publish bundle

Show more...

Publish bundle into the container registry. werf bundle contains built images defined in the werf.yaml, Helm chart, Service values which contain built images tags, any custom values and set values params provided during publish invocation, werf addon templates.

Published into container registry bundle can be rolled out by the "werf bundle" command.

Options

- `--add-annotation`

  Add annotation to deploying resources (can specify multiple).
  Format: annoName=annoValue.
  Also, can be specified with $WERF_ADD_ANNOTATION_* (e.g. $WERF_ADD_ANNOTATION_1=annoName1=annoValue1, $WERF_ADD_ANNOTATION_2=annoName2=annoValue2)
- `--add-custom-tag`

  Set tag alias for the content-based tag.
  The alias may contain the following shortcuts:
  - %image%, %image_slug% or %image_safe_slug% to use the image name (necessary if there is more than one image in the werf config);
  - %image_content_based_tag% to use a content-based tag.
  For cleaning custom tags and associated content-based tag are treated as one.
  Also can be defined with $WERF_ADD_CUSTOM_TAG_* (e.g. $WERF_ADD_CUSTOM_TAG_1="%image%-tag1", $WERF_ADD_CUSTOM_TAG_2="%image%-tag2")
- `--add-label`

  Add label to deploying resources (can specify multiple).
  Format: labelName=labelValue.
  Also, can be specified with $WERF_ADD_LABEL_* (e.g. $WERF_ADD_LABEL_1=labelName1=labelValue1, $WERF_ADD_LABEL_2=labelName2=labelValue2)
- `--allow-includes-update`

  Allow use includes latest versions (default $WERF_ALLOW_INCLUDES_UPDATE or false)
- `--allowed-backend-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE)
- `--allowed-backend-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-docker-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE)

- `--allowed-docker-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-local-cache-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of local cache (~/.werf/local_cache by default) volume usage which will cause cleanup of least recently used data from the local cache (default 70% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE)
- `--allowed-local-cache-volume-usage-margin`

  During cleanup of local cache werf would delete local cache data until volume usage becomes below "allowed-local-cache-volume-usage - allowed-local-cache-volume-usage-margin" level (default 5% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE_MARGIN)
- `--annotate-layers-with-dm-verity-root-hash`

  Enable annotation of image layers with dm-verity root hash (default $WERF_ANNOTATE_LAYERS_WITH_DM_VERITY_ROOT_HASH)
- `--backend-network`

  Network mode for the build containers ($WERF_BACKEND_NETWORK or nothing by default)
- `--backend-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_BACKEND_STORAGE_PATH)
- `--bsign-elf-files`

  Enable ELF files signing with bsign (default $WERF_BSIGN_ELF_FILES).
  When enabled, the private elf key must be specified with --elf-pgp-private-key-base64 or --elf-pgp-private-key-fingerprint option
- `--build-report-operations`

  Collect low-level operations statistics: add Operations and StageCache sections to the build report and print operations summary after the build (by default $WERF_BUILD_REPORT_OPERATIONS or false). Also enabled by --log-debug
- `--build-report-path`

  Change build report path and format (by default $WERF_BUILD_REPORT_PATH or ".werf-build-report.json" if not set). Extension must be either .json for JSON format or .env for env-file format. If extension not specified, then .json is used
- `--cache-repo`

  Specify one or multiple cache repos with images that will be used as a cache. Cache will be populated when pushing newly built images into the primary repo and when pulling existing images from the primary repo. Cache repo will be used to pull images and to get manifests before making requests to the primary repo. Also, can be specified with $WERF_CACHE_REPO_* (e.g. $WERF_CACHE_REPO_1=..., $WERF_CACHE_REPO_2=...)
- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--deno-binary-path`

  Path to the Deno binary to use instead of auto-downloading (default $WERF_DENO_BINARY_PATH)
- `--dev`

  Enable development mode (default $WERF_DEV).
  The mode allows working with project files without doing redundant commits during debugging and

development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project's werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--disable-auto-host-cleanup`

  Disable auto host cleanup procedure in main werf commands like werf-build, werf-converge and other (default disabled or WERF_DISABLE_AUTO_HOST_CLEANUP)
- `--disable-default-secret-values`

  Do not use secret values from the default .helm/secret-values.yaml file (default $WERF_DISABLE_DEFAULT_SECRET_VALUES or false)
- `--disable-default-values`

  Do not use values from the default .helm/values.yaml file (default $WERF_DISABLE_DEFAULT_VALUES or false)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and push images into the specified repo and to pull base images
- `--docker-server-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_DOCKER_SERVER_STORAGE_PATH)
- `--elf-pgp-private-key-base64`

  Base64-encoded PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_BASE64)
- `--elf-pgp-private-key-fingerprint`

  PGP private key fingerprint (default $WERF_ELF_PGP_PRIVATE_KEY_FINGERPRINT)
- `--elf-pgp-private-key-passphrase`

  Passphrase for the PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_PASSPHRASE)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--final-images-only`

  Process final images only ($WERF_FINAL_IMAGES_ONLY or true by default)
- `--final-repo`

  Container registry storage address (default $WERF_FINAL_REPO)
- `--final-repo-container-registry`

  Choose final-repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_FINAL_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--final-repo-docker-hub-password`

  final-repo Docker Hub password (default $WERF_FINAL_REPO_DOCKER_HUB_PASSWORD)
- `--final-repo-docker-hub-token`

  final-repo Docker Hub token (default $WERF_FINAL_REPO_DOCKER_HUB_TOKEN)
- `--final-repo-docker-hub-username`

  final-repo Docker Hub username (default $WERF_FINAL_REPO_DOCKER_HUB_USERNAME)
- `--final-repo-github-token`

  final-repo GitHub token (default $WERF_FINAL_REPO_GITHUB_TOKEN)
- `--final-repo-harbor-password`

  final-repo Harbor password (default $WERF_FINAL_REPO_HARBOR_PASSWORD)
- `--final-repo-harbor-username`

  final-repo Harbor username (default $WERF_FINAL_REPO_HARBOR_USERNAME)

- `--final-repo-quay-token`

  final-repo quay.io token (default $WERF_FINAL_REPO_QUAY_TOKEN)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--helm-compatible-chart`, `-C`

  Set chart name in the Chart.yaml of the published chart to the last path component of container registry repo (for REGISTRY/PATH/TO/REPO address chart name will be REPO, more info https://helm.sh/docs/topics/registries/#oci-feature-deprecation-and-behavior-changes-with-v370). In helm compatibility mode chart is fully conforming with the helm OCI registry requirements. Default false or $WERF_HELM_COMPATIBLE_CHART.
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--ignore-secret-key`

  Disable secrets decryption (default $WERF_IGNORE_SECRET_KEY)
- `--insecure-helm-dependencies`

  Allow insecure oci registries to be used in the Chart.yaml dependencies configuration (default $WERF_INSECURE_HELM_DEPENDENCIES)
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--introspect-before-error`

  Introspect failed stage in the clean state, before running all assembly instructions of the stage
- `--introspect-error`

  Introspect failed stage in the state, right after running failed assembly instruction
- `--introspect-stage`

  Introspect a specific stage. The option can be used multiple times to introspect several stages.

  There are the following formats to use:
  * specify IMAGE_NAME/STAGE_NAME to introspect stage STAGE_NAME of either image or artifact IMAGE_NAME
  * specify STAGE_NAME or */STAGE_NAME for the introspection of all existing stages with name STAGE_NAME

  IMAGE_NAME is the name of an image or artifact described in werf.yaml, the nameless image specified with ~.
  STAGE_NAME should be one of the following: from, beforeInstall, dependenciesBeforeInstall, gitArchive, install, dependenciesAfterInstall, beforeSetup, dependenciesBeforeSetup, setup, dependenciesAfterSetup, gitCache, gitLatestPatch, dockerInstructions, dockerfile, imageSpec
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

Disable explanatory output (default $WERF_LOG_QUIET).

- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--parallel`, `-p`

  Run in parallel (default $WERF_PARALLEL or true)
- `--parallel-tasks-limit`

  Parallel tasks limit, set -1 to remove the limitation (default $WERF_PARALLEL_TASKS_LIMIT or 5)
- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--project-name`, `-N`

  Set a specific project name (default $WERF_PROJECT_NAME)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--rename-chart`

  Force setting of chart name in the Chart.yaml of the published chart to the specified value (can be set by the $WERF_RENAME_CHART, no rename by default, could not be used together with the '--helm-compatible-chart' option).
- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--require-built-images`, `-Z`

  Requires all used images to be previously built and exist in repo. Exits with error if needed images are not cached and so require to run build instructions (default $WERF_REQUIRE_BUILT_IMAGES)
- `--save-build-report`

  Save build report (by default $WERF_SAVE_BUILD_REPORT or false). Its path and format configured with --build-report-path
- `--secondary-repo`

  Specify one or multiple secondary read-only repos with images that will be used as a cache.

Also, can be specified with $WERF_SECONDARY_REPO_* (e.g. $WERF_SECONDARY_REPO_1=..., $WERF_SECONDARY_REPO_2=...)

- `--secret-key`

  Secret key (default $WERF_SECRET_KEY)
- `--secret-values`

  Specify helm secret values in a YAML file (can specify multiple). Also, can be defined with $WERF_SECRET_VALUES_* (e.g. $WERF_SECRET_VALUES_ENV=.helm/secret_values_test.yaml, $WERF_SECRET_VALUES_DB=.helm/secret_values_db.yaml)
- `--set`

  Set helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_* (e.g. $WERF_SET_1=key1=val1, $WERF_SET_2=key2=val2)
- `--set-file`

  Set values from respective files specified via the command line (can specify multiple or separate values with commas: key1=path1,key2=path2).
  Also, can be defined with $WERF_SET_FILE_* (e.g. $WERF_SET_FILE_1=key1=path1, $WERF_SET_FILE_2=key2=val2)
- `--set-json`

  Set new values, where the key is the value path and the value is JSON (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_JSON_* (e.g. $WERF_SET_JSON_1=key1=val1, $WERF_SET_JSON_2=key2=val2)
- `--set-literal`

  Set new values, where the key is the value path and the value is the value. The value will always become a literal string (can specify multiple or separate values with commas: key1=val1,key2=val2).)
  Also, can be defined with $WERF_SET_LITERAL_* (e.g. $WERF_SET_LITERAL_1=key1=val1, $WERF_SET_LITERAL_2=key2=val2)
- `--set-root-json`

  Set new keys in arbitrary things in the global root context ("$"), where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you REALLY know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_ROOT_JSON_* (e.g. $WERF_SET_ROOT_JSON_1=key1=val1, $WERF_SET_ROOT_JSON_2=key2=val2)
- `--set-runtime-json`

  Set new keys in $.Runtime, where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_RUNTIME_JSON_* (e.g. $WERF_SET_RUNTIME_JSON_1=key1=val1, $WERF_SET_RUNTIME_JSON_2=key2=val2)
- `--set-string`

  Set STRING helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_STRING_* (e.g. $WERF_SET_STRING_1=key1=val1, $WERF_SET_STRING_2=key2=val2)
- `--sign-cert`

  The leaf certificate as path to PEM file or base64-encoded PEM (default $WERF_SIGN_CERT)
- `--sign-elf-files`

  Enable ELF files signing (default $WERF_SIGN_ELF_FILES).
  When enabled, the private signing key must be specified with --sign-key option and the certificate must be specified with --sign-cert option
- `--sign-intermediates`

  The intermediate certificates as path to PEM file or base64-encoded PEM (default $WERF_SIGN_INTERMEDIATES)
- `--sign-key`

  The private signing key as path to PEM file, base64-encoded PEM or hashivault://[KEY] (default $WERF_SIGN_KEY)
- `--sign-manifest`

  Enable image manifest signing (default $WERF_SIGN_MANIFEST).

When enabled,
the private signing key must be specified with --sign-key option and
the certificate must be specified with --sign-cert option

- `--skip-dependencies-repo-refresh`, `-L`

  Do not refresh helm chart repositories locally cached index
- `--skip-image-spec-stage`

  Force skipping "imageSpec" build stage (default $WERF_SKIP_IMAGE_SPEC_STAGE or false)
- `--skip-tls-verify-helm-dependencies`

  Skip TLS certificate validation when accessing a Helm charts repository (default $WERF_SKIP_TLS_VERIFY_HELM_DEPENDENCIES)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--ssh-key`

  Use only specific ssh key(s).
  Can be specified with $WERF_SSH_KEY_* (e.g. $WERF_SSH_KEY_REPO=~/.ssh/repo_rsa, $WERF_SSH_KEY_NODEJS=~/.ssh/nodejs_rsa).
  Defaults to $WERF_SSH_KEY_*, system ssh-agent or ~/.ssh/{id_rsa|id_dsa}
- `--synchronization`, `-S`

  Address of synchronizer for multiple werf processes to work with a single repo.

  Default:
  - $WERF_SYNCHRONIZATION, or
  - :local if --repo is not specified, or
  - https://delivery-sync.deckhouse.ru if --repo has been specified.

  The same address should be specified for all werf processes that work with a single repo. :local address allows execution of werf processes from a single host only
- `--tag`

  Publish bundle into container registry repo by the provided tag ($WERF_TAG or latest by default)
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--use-build-report`

  Use build report, previously saved with --save-build-report (by default $WERF_USE_BUILD_REPORT or false). Its path and format configured with --build-report-path
- `--use-custom-tag`

  Use a tag alias in helm templates instead of an image content-based tag (NOT RECOMMENDED).
  The alias may contain the following shortcuts:
  - %image%, %image_slug% or %image_safe_slug% to use the image name (necessary if there is more than one image in the werf config);
  - %image_content_based_tag% to use a content-based tag.
  For cleaning custom tags and associated content-based tag are treated as one.
  Also, can be defined with $WERF_USE_CUSTOM_TAG (e.g. $WERF_USE_CUSTOM_TAG="%image%-tag")
- `--values`

  Specify helm values in a YAML file or a URL (can specify multiple). Also, can be defined with $WERF_VALUES_* (e.g. $WERF_VALUES_1=.helm/values_1.yaml, $WERF_VALUES_2=.helm/values_2.yaml)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).
- `--virtual-merge`

  Enable virtual/ephemeral merge commit mode when building current application state ($WERF_VIRTUAL_MERGE by default)
- `--without-images`

  Disable building of images defined in the werf.yaml (if any) and usage of such images in the .helm/templates ($WERF_WITHOUT_IMAGES or false by default — e.g. enable all images defined in the werf.yaml by default)

d8 delivery-kit bundle render

Usage:

```
d8 delivery-kit bundle render [options]
```

Render Kubernetes manifests from bundle

Show more...

Take locally extracted bundle or download bundle from the specified container registry using specified version tag or version mask and render it as Kubernetes manifests.

Options

- `--add-annotation`

  Add annotation to deploying resources (can specify multiple).
  Format: annoName=annoValue.
  Also, can be specified with $WERF_ADD_ANNOTATION_* (e.g. $WERF_ADD_ANNOTATION_1=annoName1=annoValue1, $WERF_ADD_ANNOTATION_2=annoName2=annoValue2)
- `--add-label`

  Add label to deploying resources (can specify multiple).
  Format: labelName=labelValue.
  Also, can be specified with $WERF_ADD_LABEL_* (e.g. $WERF_ADD_LABEL_1=labelName1=labelValue1, $WERF_ADD_LABEL_2=labelName2=labelValue2)
- `--bundle-dir`, `-b`

  Get extracted bundle from directory instead of registry (default $WERF_BUNDLE_DIR)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--deno-binary-path`

  Path to the Deno binary to use instead of auto-downloading (default $WERF_DENO_BINARY_PATH)
- `--disable-default-secret-values`

  Do not use secret values from the default .helm/secret-values.yaml file (default $WERF_DISABLE_DEFAULT_SECRET_VALUES or false)
- `--disable-default-values`

  Do not use values from the default .helm/values.yaml file (default $WERF_DISABLE_DEFAULT_VALUES or false)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and push images into the specified repo, to pull base images
- `--env`

  Use specified environment (default $WERF_ENV)
- `--extra-apiversions`

  Extra Kubernetes API versions passed to $.Capabilities.APIVersions. Can be also set with $WERF_EXTRA_APIVERSIONS_* environment variables, values can be comma-separated
- `--force-adoption`

  Always adopt resources, even if they belong to a different Helm release (default $WERF_FORCE_ADOPTION or false)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--ignore-bundle-js`

  Do not use the existing bundle.js file. Requires TypeScript source files and Deno to rebuild (default $WERF_IGNORE_BUNDLE_JS)
- `--ignore-secret-key`

  Disable secrets decryption (default $WERF_IGNORE_SECRET_KEY)
- `--include-crds`

  Include CRDs in the templated output (default $WERF_INCLUDE_CRDS)
- `--insecure-helm-dependencies`

Allow insecure oci registries to be used in the Chart.yaml dependencies configuration (default $WERF_INSECURE_HELM_DEPENDENCIES)

- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--kube-api-server`

  Kubernetes API server address (default $WERF_KUBE_API_SERVER)
- `--kube-auth-password`

  Basic auth password for Kubernetes API (default $WERF_KUBE_AUTH_PASSWORD)
- `--kube-auth-provider`

  Auth provider name for authentication in Kubernetes API (default $WERF_KUBE_AUTH_PROVIDER)
- `--kube-auth-provider-config`

  Auth provider config for authentication in Kubernetes API (default $WERF_KUBE_AUTH_PROVIDER_CONFIG)
- `--kube-auth-username`

  Basic auth username for Kubernetes API (default $WERF_KUBE_AUTH_USERNAME)
- `--kube-burst-limit`

  Kubernetes client burst limit (default $WERF_KUBE_BURST_LIMIT or 100)
- `--kube-ca-data`

  Pass Kubernetes API server TLS CA data (default $WERF_KUBE_CA_DATA)
- `--kube-ca-path`

  Kubernetes API server CA path (default $WERF_KUBE_CA_PATH)
- `--kube-cert`

  Path to PEM-encoded TLS client cert for connecting to Kubernetes API (default $WERF_KUBE_CERT
- `--kube-cert-data`

  Pass PEM-encoded TLS client cert for connecting to Kubernetes API (default $WERF_KUBE_CERT_DATA)
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)
- `--kube-context-cluster`

  Use cluster from Kubeconfig for current context (default $WERF_KUBE_CONTEXT_CLUSTER)
- `--kube-context-user`

  Use user from Kubeconfig for current context (default $WERF_KUBE_CONTEXT_USER)
- `--kube-impersonate-group`

  Sets Impersonate-Group headers when authenticating in Kubernetes. Can be also set with $WERF_KUBE_IMPERSONATE_GROUP_* environment variables
- `--kube-impersonate-uid`

  Sets Impersonate-Uid header when authenticating in Kubernetes (default $WERF_KUBE_IMPERSONATE_UID)
- `--kube-impersonate-user`

  Sets Impersonate-User header when authenticating in Kubernetes (default $WERF_KUBE_IMPERSONATE_USER)
- `--kube-key`

  Path to PEM-encoded TLS client key for connecting to Kubernetes API (default $WERF_KUBE_KEY)
- `--kube-key-data`

  Pass PEM-encoded TLS client key for connecting to Kubernetes API (default $WERF_KUBE_KEY_DATA)
- `--kube-proxy-url`

  Proxy URL to use for proxying all requests to Kubernetes API (default $WERF_KUBE_PROXY_URL)
- `--kube-qps-limit`

  Kubernetes client QPS limit (default $WERF_KUBE_QPS_LIMIT or 30)
- `--kube-request-timeout`

  Timeout for all requests to Kubernetes API (default $WERF_KUBE_REQUEST_TIMEOUT)
- `--kube-tls-server`

  Server name to use for Kubernetes API server certificate validation. If it is not provided, the hostname used to contact the server is used (default $WERF_KUBE_TLS_SERVER)
- `--kube-token`

  Kubernetes bearer token used for authentication (default $WERF_KUBE_TOKEN)

- `--kube-token-path`

  Path to file with bearer token for authentication in Kubernetes (default $WERF_KUBE_TOKEN_PATH)
- `--kube-version`

  Set specific Capabilities.KubeVersion (default $WERF_KUBE_VERSION)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--namespace`

  Use specified Kubernetes namespace (default $WERF_NAMESPACE)
- `--network-parallelism`

  Parallelize some network operations (default $WERF_NETWORK_PARALLELISM or 30)
- `--output`

  Write render output to the specified file instead of stdout ($WERF_RENDER_OUTPUT by default)
- `--provenance-keyring`

  Path to keyring containing public keys to verify chart provenance (default $WERF_PROVENANCE_KEYRING)
- `--provenance-strategy`

  Strategy for provenance verifying (default $WERF_PROVENANCE_STRATEGY).
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--release`

  Use specified Helm release name (default $WERF_RELEASE)
- `--release-storage`

  How releases should be stored (default $WERF_RELEASE_STORAGE)
- `--release-storage-sql-connection`

  SQL Connection String for Helm SQL Storage (default $WERF_RELEASE_STORAGE_SQL_CONNECTION)
- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)

- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--secret-key`

  Secret key (default $WERF_SECRET_KEY)
- `--secret-values`

  Specify helm secret values in a YAML file (can specify multiple). Also, can be defined with $WERF_SECRET_VALUES_* (e.g. $WERF_SECRET_VALUES_ENV=.helm/secret_values_test.yaml, $WERF_SECRET_VALUES_DB=.helm/secret_values_db.yaml)
- `--set`

  Set helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_* (e.g. $WERF_SET_1=key1=val1, $WERF_SET_2=key2=val2)
- `--set-docker-config-json-value`

  Shortcut to set current docker config into the .Values.global.werf.dockerconfigjson
- `--set-file`

  Set values from respective files specified via the command line (can specify multiple or separate values with commas: key1=path1,key2=path2).
  Also, can be defined with $WERF_SET_FILE_* (e.g. $WERF_SET_FILE_1=key1=path1, $WERF_SET_FILE_2=key2=val2)
- `--set-json`

  Set new values, where the key is the value path and the value is JSON (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_JSON_* (e.g. $WERF_SET_JSON_1=key1=val1, $WERF_SET_JSON_2=key2=val2)
- `--set-literal`

  Set new values, where the key is the value path and the value is the value. The value will always become a literal string (can specify multiple or separate values with commas: key1=val1,key2=val2).)
  Also, can be defined with $WERF_SET_LITERAL_* (e.g. $WERF_SET_LITERAL_1=key1=val1, $WERF_SET_LITERAL_2=key2=val2)
- `--set-root-json`

  Set new keys in arbitrary things in the global root context ("$"), where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you REALLY know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_ROOT_JSON_* (e.g. $WERF_SET_ROOT_JSON_1=key1=val1, $WERF_SET_ROOT_JSON_2=key2=val2)
- `--set-runtime-json`

  Set new keys in $.Runtime, where the key is the value path and the value is JSON. This is meant to be generated inside the program, so use --set-json instead, unless you know what you are doing. Can specify multiple or separate values with commas: key1=val1,key2=val2.
  Also, can be defined with $WERF_SET_RUNTIME_JSON_* (e.g. $WERF_SET_RUNTIME_JSON_1=key1=val1, $WERF_SET_RUNTIME_JSON_2=key2=val2)
- `--set-string`

  Set STRING helm values on the command line (can specify multiple or separate values with commas: key1=val1,key2=val2).
  Also, can be defined with $WERF_SET_STRING_* (e.g. $WERF_SET_STRING_1=key1=val1, $WERF_SET_STRING_2=key2=val2)
- `--show-only`, `-s`

  only show manifests rendered from the given templates
- `--skip-dependencies-repo-refresh`, `-L`

  Do not refresh helm chart repositories locally cached index
- `--skip-tls-verify-helm-dependencies`

Skip TLS certificate validation when accessing a Helm charts repository (default $WERF_SKIP_TLS_VERIFY_HELM_DEPENDENCIES)
- `--skip-tls-verify-kube`

  Skip TLS certificate validation when accessing a Kubernetes cluster (default $WERF_SKIP_TLS_VERIFY_KUBE)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--tag`

  Provide exact tag version or semver-based pattern, werf will render the latest version of the specified bundle ($WERF_TAG or latest by default)
- `--templates-allow-dns`

  Allow performing DNS requests in templating (default $WERF_TEMPLATES_ALLOW_DNS)
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--validate`

  Validate your manifests against the Kubernetes cluster you are currently pointing at (default $WERF_VALIDATE)
- `--values`

  Specify helm values in a YAML file or a URL (can specify multiple). Also, can be defined with $WERF_VALUES_* (e.g. $WERF_VALUES_1=.helm/values_1.yaml, $WERF_VALUES_2=.helm/values_2.yaml)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit chart

Usage:

```
d8 delivery-kit chart [options]
```

Work with charts

d8 delivery-kit chart ts

Usage:

```
d8 delivery-kit chart ts [options]
```

Work with TypeScript charts

d8 delivery-kit chart ts build

Usage:

```
d8 delivery-kit chart ts build [PATH] [options]
```

Build TypeScript chart.

Show more...

Build TypeScript chart in the specified directory. If PATH is not specified, uses the current directory.

Options

- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--deno-binary-path`

  Path to the Deno binary to use instead of auto-downloading (default $WERF_DENO_BINARY_PATH)
- `--dev`

  Enable development mode (default $WERF_DEV).

The mode allows working with project files without doing redundant commits during debugging and development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project's werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout's file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit chart ts init

Usage:

```
d8 delivery-kit chart ts init [PATH] [options]
```

Initialize the files needed to render manifests using TypeScript.

Show more...

Initialize the files needed to render manifests using TypeScript. If PATH is not specified, uses the current directory.

Options

- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--dev`

  Enable development mode (default $WERF_DEV).
  The mode allows working with project files without doing redundant commits during debugging and development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project’s werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions

- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit ci-env

Usage:

```
d8 delivery-kit ci-env CI_SYSTEM [options]
```

Generate werf environment variables for specified CI system

Show more...

Generate werf environment variables for specified CI system.

Currently supported only GitLab (gitlab) and GitHub (github) CI systems

Options

- `--allow-includes-update`

  Allow use includes latest versions (default $WERF_ALLOW_INCLUDES_UPDATE or false)
- `--as-env-file`

  Create the .env file and print the path for sourcing (default $WERF_AS_ENV_FILE).
- `--as-file`

  Create the script and print the path for sourcing (default $WERF_AS_FILE).
- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--dev`

  Enable development mode (default $WERF_DEV).
  The mode allows working with project files without doing redundant commits during debugging and development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project’s werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command will copy specified or default (~/.docker) config to the temporary directory and may perform additional login with new config.
- `--env`

  Use specified environment (default $WERF_ENV)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)

- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--login-to-registry`

  Log in to CI-specific registry automatically if possible (default $WERF_LOGIN_TO_REGISTRY).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--output-file-path`, `-o`

  Write to custom file (default $WERF_OUTPUT_FILE_PATH).
- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--shell`

  Set to cmdexe, powershell or use the default behavior that is compatible with any unix shell (default $WERF_SHELL).
- `--tagging-strategy`

  stub
- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--use-docker-auth-config`

  Generate Docker config from DOCKER_AUTH_CONFIG environment variable instead of copying current Docker config (default $WERF_USE_DOCKER_AUTH_CONFIG).
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).

d8 delivery-kit cleanup

Usage:

```
d8 delivery-kit cleanup [options]
```

Cleanup project images in the container registry

Show more...

Safely cleanup unused project images in the container registry.

The command works according to special rules called cleanup policies, which the user defines in werf.yaml.

It is safe to run this command periodically (daily is enough) by automated cleanup job in parallel with other werf commands such as build, converge and host cleanup.

Options

- `--allow-includes-update`

  Allow use includes latest versions (default $WERF_ALLOW_INCLUDES_UPDATE or false)
- `--allowed-backend-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE)
- `--allowed-backend-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-docker-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE)
- `--allowed-docker-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-local-cache-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of local cache (~/.werf/local_cache by default) volume usage which will cause cleanup of least recently used data from the local cache (default 70% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE)
- `--allowed-local-cache-volume-usage-margin`

  During cleanup of local cache werf would delete local cache data until volume usage becomes below "allowed-local-cache-volume-usage - allowed-local-cache-volume-usage-margin" level (default 5% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE_MARGIN)
- `--backend-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_BACKEND_STORAGE_PATH)
- `--cache-repo`

  Specify one or multiple cache repos with images that will be used as a cache. Cache will be populated when pushing newly built images into the primary repo and when pulling existing images from the primary repo. Cache repo will be used to pull images and to get manifests before making requests to the primary repo. Also, can be specified with $WERF_CACHE_REPO_* (e.g. $WERF_CACHE_REPO_1=..., $WERF_CACHE_REPO_2=...)
- `--cleanup-report-path`

  Change cleanup report path (by default $WERF_CLEANUP_REPORT_PATH or ".werf-cleanup-report.json" if not set). Extension must be .json for JSON format. If extension not specified, then .json is used
- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).

- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--dev`

  Enable development mode (default $WERF_DEV).
  The mode allows working with project files without doing redundant commits during debugging and development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project's werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--disable-auto-host-cleanup`

  Disable auto host cleanup procedure in main werf commands like werf-build, werf-converge and other (default disabled or WERF_DISABLE_AUTO_HOST_CLEANUP)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read, pull and delete images from the specified repo
- `--docker-server-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_DOCKER_SERVER_STORAGE_PATH)
- `--dry-run`

  Indicate what the command would do without actually doing that (default $WERF_DRY_RUN)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--final-repo`

  Container registry storage address (default $WERF_FINAL_REPO)
- `--final-repo-container-registry`

  Choose final-repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_FINAL_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--final-repo-docker-hub-password`

  final-repo Docker Hub password (default $WERF_FINAL_REPO_DOCKER_HUB_PASSWORD)
- `--final-repo-docker-hub-token`

  final-repo Docker Hub token (default $WERF_FINAL_REPO_DOCKER_HUB_TOKEN)
- `--final-repo-docker-hub-username`

  final-repo Docker Hub username (default $WERF_FINAL_REPO_DOCKER_HUB_USERNAME)
- `--final-repo-github-token`

  final-repo GitHub token (default $WERF_FINAL_REPO_GITHUB_TOKEN)
- `--final-repo-harbor-password`

  final-repo Harbor password (default $WERF_FINAL_REPO_HARBOR_PASSWORD)
- `--final-repo-harbor-username`

  final-repo Harbor username (default $WERF_FINAL_REPO_HARBOR_USERNAME)
- `--final-repo-quay-token`

  final-repo quay.io token (default $WERF_FINAL_REPO_QUAY_TOKEN)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)

- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--insecure-helm-dependencies`

  No-op
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--keep-list`

  Set path to keep list file (default $WERF_KEEP_LIST)
- `--keep-stages-built-within-last-n-hours`

  Keep stages that were built within last hours (default $WERF_KEEP_STAGES_BUILT_WITHIN_LAST_N_HOURS or 2)
- `--kube-api-server`

  Kubernetes API server address (default $WERF_KUBE_API_SERVER)
- `--kube-ca-data`

  Pass Kubernetes API server TLS CA data (default $WERF_KUBE_CA_DATA)
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Scan for used images only in the specified kube context, scan all contexts from kube config otherwise (default false or $WERF_SCAN_CONTEXT_ONLY)
- `--kube-scan-namespaces`

  Kubernetes namespaces to scan for each selected context (can specify multiple). Takes precedence over --scan-context-namespace-only when set.
- `--kube-token`

  Kubernetes bearer token used for authentication (default $WERF_KUBE_TOKEN)
- `--kube-token-path`

  Path to file with bearer token for authentication in Kubernetes (default $WERF_KUBE_TOKEN_PATH)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--parallel`, `-p`

  Run in parallel (default $WERF_PARALLEL or true)
- `--parallel-tasks-limit`

Parallel tasks limit, set -1 to remove the limitation (default $WERF_PARALLEL_TASKS_LIMIT or 5)

- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--project-name`, `-N`

  Set a specific project name (default $WERF_PROJECT_NAME)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--save-cleanup-report`

  Save cleanup report (by default $WERF_SAVE_CLEANUP_REPORT or false). Its path configured with --cleanup-report-path
- `--scan-context-namespace-only`

  Scan for used images only in namespace linked with context for each available context in kube-config (or only for the context specified with option --kube-context). When disabled will scan all namespaces in all contexts (or only for the context specified with option --kube-context), unless --kube-scan-namespaces is set. (Default $WERF_SCAN_CONTEXT_NAMESPACE_ONLY)
- `--scan-context-only`

  Scan for used images only in the specified kube context, scan all contexts from kube config otherwise (default false or $WERF_SCAN_CONTEXT_ONLY)
- `--secondary-repo`

  Specify one or multiple secondary read-only repos with images that will be used as a cache.
  Also, can be specified with $WERF_SECONDARY_REPO_* (e.g. $WERF_SECONDARY_REPO_1=..., $WERF_SECONDARY_REPO_2=...)
- `--skip-tls-verify-kube`

  Skip TLS certificate validation when accessing a Kubernetes cluster (default $WERF_SKIP_TLS_VERIFY_KUBE)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--synchronization`, `-S`

  Address of synchronizer for multiple werf processes to work with a single repo.

  Default:
  - $WERF_SYNCHRONIZATION, or
  - :local if --repo is not specified, or
  - https://delivery-sync.deckhouse.ru if --repo has been specified.

  The same address should be specified for all werf processes that work with a single repo. :local address allows execution of werf processes from a single host only

- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).
- `--without-kube`

  Do not skip deployed Kubernetes images (default $WERF_WITHOUT_KUBE)

d8 delivery-kit completion

Usage:

```
d8 delivery-kit completion [options]
```

Generate bash completion scripts

Options

- `--shell`

  Set to bash, zsh, fish or powershell (default $WERF_SHELL or bash)

d8 delivery-kit compose

Usage:

```
d8 delivery-kit compose [options]
```

Work with docker-compose

d8 delivery-kit compose config

Usage:

```
d8 delivery-kit compose config [IMAGE_NAME...] [options] [--docker-compose-options="OPTIONS"] [--docker-compose-
command-options="OPTIONS"]
```

Run docker-compose config command with forwarded image names.

Show more...

Run docker-compose config command with forwarded image names.
Image environment name format: $WERF_<FORMATTED_WERF_IMAGE_NAME>_DOCKER_IMAGE_NAME
($WERF_DOCKER_IMAGE_NAME for nameless image).
<FORMATTED_WERF_IMAGE_NAME> is werf image name from werf.yaml modified according to the following
rules:
- all characters are uppercase (app -> APP);
- charset /- is replaced with _ (DEV/APP-FRONTEND -> DEV_APP_FRONTEND).
If one or more IMAGE_NAME parameters specified, werf will build and forward only these images.
Given the following werf configuration:
werf.yaml
project: x
configVersion: 1
---
image: frontend
dockerfile: frontend.Dockerfile
---
image: geodata-backend
dockerfile: backend.Dockerfile
Use described images as follows in your docker compose configuration:
docker-compose.yaml
services:
  frontend:
    image: $WERF_FRONTEND_DOCKER_IMAGE_NAME
  backend:
    image: $WERF_GEODATA_BACKEND_DOCKER_IMAGE_NAME

Options

- `--allow-includes-update`

  Allow use includes latest versions (default $WERF_ALLOW_INCLUDES_UPDATE or false)
- `--allowed-backend-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE)

- `--allowed-backend-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-docker-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE)
- `--allowed-docker-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-local-cache-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of local cache (~/.werf/local_cache by default) volume usage which will cause cleanup of least recently used data from the local cache (default 70% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE)
- `--allowed-local-cache-volume-usage-margin`

  During cleanup of local cache werf would delete local cache data until volume usage becomes below "allowed-local-cache-volume-usage - allowed-local-cache-volume-usage-margin" level (default 5% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE_MARGIN)
- `--annotate-layers-with-dm-verity-root-hash`

  Enable annotation of image layers with dm-verity root hash (default $WERF_ANNOTATE_LAYERS_WITH_DM_VERITY_ROOT_HASH)
- `--backend-network`

  Network mode for the build containers ($WERF_BACKEND_NETWORK or nothing by default)
- `--backend-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_BACKEND_STORAGE_PATH)
- `--bsign-elf-files`

  Enable ELF files signing with bsign (default $WERF_BSIGN_ELF_FILES).
  When enabled, the private elf key must be specified with --elf-pgp-private-key-base64 or --elf-pgp-private-key-fingerprint option
- `--build-report-path`

  Change build report path and format (by default $WERF_BUILD_REPORT_PATH or ".werf-build-report.json" if not set). Extension must be either .json for JSON format or .env for env-file format. If extension not specified, then .json is used
- `--cache-repo`

  Specify one or multiple cache repos with images that will be used as a cache. Cache will be populated when pushing newly built images into the primary repo and when pulling existing images from the primary repo. Cache repo will be used to pull images and to get manifests before making requests to the primary repo. Also, can be specified with $WERF_CACHE_REPO_* (e.g. $WERF_CACHE_REPO_1=..., $WERF_CACHE_REPO_2=...)
- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)

- `--dev`

  Enable development mode (default $WERF_DEV).
  The mode allows working with project files without doing redundant commits during debugging and development
- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project's werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--disable-auto-host-cleanup`

  Disable auto host cleanup procedure in main werf commands like werf-build, werf-converge and other (default disabled or WERF_DISABLE_AUTO_HOST_CLEANUP)
- `--docker-compose-bin-path`

  DEPRECATED: "docker compose" command always used now, this option is ignored. Define docker-compose bin path (default $WERF_DOCKER_COMPOSE_BIN_PATH)
- `--docker-compose-command-options`

  Define docker-compose command options (default $WERF_DOCKER_COMPOSE_COMMAND_OPTIONS)
- `--docker-compose-options`

  Define docker-compose options (default $WERF_DOCKER_COMPOSE_OPTIONS)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read and pull images from the specified repo
- `--docker-server-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_DOCKER_SERVER_STORAGE_PATH)
- `--dry-run`

  Indicate what the command would do without actually doing that (default $WERF_DRY_RUN)
- `--elf-pgp-private-key-base64`

  Base64-encoded PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_BASE64)
- `--elf-pgp-private-key-fingerprint`

  PGP private key fingerprint (default $WERF_ELF_PGP_PRIVATE_KEY_FINGERPRINT)
- `--elf-pgp-private-key-passphrase`

  Passphrase for the PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_PASSPHRASE)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--final-images-only`

  Process final images only ($WERF_FINAL_IMAGES_ONLY or false by default)
- `--final-repo`

  Container registry storage address (default $WERF_FINAL_REPO)
- `--final-repo-container-registry`

  Choose final-repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_FINAL_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--final-repo-docker-hub-password`

  final-repo Docker Hub password (default $WERF_FINAL_REPO_DOCKER_HUB_PASSWORD)
- `--final-repo-docker-hub-token`

  final-repo Docker Hub token (default $WERF_FINAL_REPO_DOCKER_HUB_TOKEN)
- `--final-repo-docker-hub-username`

  final-repo Docker Hub username (default $WERF_FINAL_REPO_DOCKER_HUB_USERNAME)
- `--final-repo-github-token`

final-repo GitHub token (default $WERF_FINAL_REPO_GITHUB_TOKEN)
- `--final-repo-harbor-password`

  final-repo Harbor password (default $WERF_FINAL_REPO_HARBOR_PASSWORD)
- `--final-repo-harbor-username`

  final-repo Harbor username (default $WERF_FINAL_REPO_HARBOR_USERNAME)
- `--final-repo-quay-token`

  final-repo quay.io token (default $WERF_FINAL_REPO_QUAY_TOKEN)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--insecure-helm-dependencies`

  No-op
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--project-name`, `-N`

  Set a specific project name (default $WERF_PROJECT_NAME)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).

- `--repo`

  Container registry storage address (default $WERF_REPO)
- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
- `--repo-github-token`

  repo GitHub token (default $WERF_REPO_GITHUB_TOKEN)
- `--repo-harbor-password`

  repo Harbor password (default $WERF_REPO_HARBOR_PASSWORD)
- `--repo-harbor-username`

  repo Harbor username (default $WERF_REPO_HARBOR_USERNAME)
- `--repo-quay-token`

  repo quay.io token (default $WERF_REPO_QUAY_TOKEN)
- `--require-built-images`, `-Z`

  Requires all used images to be previously built and exist in repo. Exits with error if needed images are not cached and so require to run build instructions (default $WERF_REQUIRE_BUILT_IMAGES)
- `--secondary-repo`

  Specify one or multiple secondary read-only repos with images that will be used as a cache.
  Also, can be specified with $WERF_SECONDARY_REPO_* (e.g. $WERF_SECONDARY_REPO_1=..., $WERF_SECONDARY_REPO_2=...)
- `--sign-cert`

  The leaf certificate as path to PEM file or base64-encoded PEM (default $WERF_SIGN_CERT)
- `--sign-elf-files`

  Enable ELF files signing (default $WERF_SIGN_ELF_FILES).
  When enabled, the private signing key must be specified with --sign-key option and the certificate must be specified with --sign-cert option
- `--sign-intermediates`

  The intermediate certificates as path to PEM file or base64-encoded PEM (default $WERF_SIGN_INTERMEDIATES)
- `--sign-key`

  The private signing key as path to PEM file, base64-encoded PEM or hashivault://[KEY] (default $WERF_SIGN_KEY)
- `--sign-manifest`

  Enable image manifest signing (default $WERF_SIGN_MANIFEST).
  When enabled,
  the private signing key must be specified with --sign-key option and
  the certificate must be specified with --sign-cert option
- `--skip-image-spec-stage`

  Force skipping "imageSpec" build stage (default $WERF_SKIP_IMAGE_SPEC_STAGE or false)
- `--skip-tls-verify-registry`

  Skip TLS certificate validation when accessing a registry (default $WERF_SKIP_TLS_VERIFY_REGISTRY)
- `--ssh-key`

  Use only specific ssh key(s).
  Can be specified with $WERF_SSH_KEY_* (e.g. $WERF_SSH_KEY_REPO=~/.ssh/repo_rsa, $WERF_SSH_KEY_NODEJS=~/.ssh/nodejs_rsa).
  Defaults to $WERF_SSH_KEY_*, system ssh-agent or ~/.ssh/{id_rsa|id_dsa}
- `--stub-tags`

  Use stubs instead of real tags (default $WERF_STUB_TAGS)
- `--synchronization`, `-S`

  Address of synchronizer for multiple werf processes to work with a single repo.

Default:
- $WERF_SYNCHRONIZATION, or
- :local if --repo is not specified, or
- https://delivery-sync.deckhouse.ru if --repo has been specified.

The same address should be specified for all werf processes that work with a single repo. :local address allows execution of werf processes from a single host only

- `--tmp-dir`

  Use specified dir to store tmp files and dirs (default $WERF_TMP_DIR or system tmp dir)
- `--use-build-report`

  Use build report, previously saved with --save-build-report (by default $WERF_USE_BUILD_REPORT or false). Its path and format configured with --build-report-path
- `--verbose`

  Enable verbose output (default $WERF_VERBOSE).
- `--virtual-merge`

  Enable virtual/ephemeral merge commit mode when building current application state ($WERF_VIRTUAL_MERGE by default)
- `--without-images`

  Disable building of images defined in the werf.yaml (if any) and usage of such images in the .helm/templates ($WERF_WITHOUT_IMAGES or false by default — e.g. enable all images defined in the werf.yaml by default)

d8 delivery-kit compose down

Usage:

```
d8 delivery-kit compose down [IMAGE_NAME...] [options] [--docker-compose-options="OPTIONS"] [--docker-compose-command-options="OPTIONS"]
```

Run docker-compose down command with forwarded image names.

Show more...

Run docker-compose down command with forwarded image names.
Image environment name format: $WERF_<FORMATTED_WERF_IMAGE_NAME>_DOCKER_IMAGE_NAME ($WERF_DOCKER_IMAGE_NAME for nameless image).
<FORMATTED_WERF_IMAGE_NAME> is werf image name from werf.yaml modified according to the following rules:
- all characters are uppercase (app -> APP);
- charset /- is replaced with _ (DEV/APP-FRONTEND -> DEV_APP_FRONTEND).
If one or more IMAGE_NAME parameters specified, werf will build and forward only these images.
Given the following werf configuration:
werf.yaml
project: x
configVersion: 1
---
image: frontend
dockerfile: frontend.Dockerfile
---
image: geodata-backend
dockerfile: backend.Dockerfile
Use described images as follows in your docker compose configuration:
docker-compose.yaml
services:
  frontend:
    image: $WERF_FRONTEND_DOCKER_IMAGE_NAME
  backend:
    image: $WERF_GEODATA_BACKEND_DOCKER_IMAGE_NAME

Options

- `--allow-includes-update`

  Allow use includes latest versions (default $WERF_ALLOW_INCLUDES_UPDATE or false)
- `--allowed-backend-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE)
- `--allowed-backend-storage-volume-usage-margin`

During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_BACKEND_STORAGE_VOLUME_USAGE_MARGIN)

- `--allowed-docker-storage-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of backend (Docker or Buildah) storage volume usage which will cause cleanup of least recently used local backend images (default 70% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE)
- `--allowed-docker-storage-volume-usage-margin`

  During cleanup of least recently used local backend (Docker or Buildah) images werf would delete images until volume usage becomes below "allowed-backend-storage-volume-usage - allowed-backend-storage-volume-usage-margin" level (default 5% or $WERF_ALLOWED_DOCKER_STORAGE_VOLUME_USAGE_MARGIN)
- `--allowed-local-cache-volume-usage`

  Set allowed percentage or absolute value (e.g. 10GB) of local cache (~/.werf/local_cache by default) volume usage which will cause cleanup of least recently used data from the local cache (default 70% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE)
- `--allowed-local-cache-volume-usage-margin`

  During cleanup of local cache werf would delete local cache data until volume usage becomes below "allowed-local-cache-volume-usage - allowed-local-cache-volume-usage-margin" level (default 5% or $WERF_ALLOWED_LOCAL_CACHE_VOLUME_USAGE_MARGIN)
- `--annotate-layers-with-dm-verity-root-hash`

  Enable annotation of image layers with dm-verity root hash (default $WERF_ANNOTATE_LAYERS_WITH_DM_VERITY_ROOT_HASH)
- `--backend-network`

  Network mode for the build containers ($WERF_BACKEND_NETWORK or nothing by default)
- `--backend-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_BACKEND_STORAGE_PATH)
- `--bsign-elf-files`

  Enable ELF files signing with bsign (default $WERF_BSIGN_ELF_FILES).
  When enabled, the private elf key must be specified with --elf-pgp-private-key-base64 or --elf-pgp-private-key-fingerprint option
- `--build-report-path`

  Change build report path and format (by default $WERF_BUILD_REPORT_PATH or ".werf-build-report.json" if not set). Extension must be either .json for JSON format or .env for env-file format. If extension not specified, then .json is used
- `--cache-repo`

  Specify one or multiple cache repos with images that will be used as a cache. Cache will be populated when pushing newly built images into the primary repo and when pulling existing images from the primary repo. Cache repo will be used to pull images and to get manifests before making requests to the primary repo. Also, can be specified with $WERF_CACHE_REPO_* (e.g. $WERF_CACHE_REPO_1=..., $WERF_CACHE_REPO_2=...)
- `--config`

  Use custom configuration file (default $WERF_CONFIG or werf.yaml in the project directory)
- `--config-render-path`

  Custom path for storing rendered configuration file
- `--config-templates-dir`

  Custom configuration templates directory (default $WERF_CONFIG_TEMPLATES_DIR or .werf in working directory)
- `--container-registry-mirror`

  (Buildah-only) Use specified mirrors for docker.io
- `--debug`

  Enable debug (default $WERF_DEBUG).
- `--debug-templates`

  Enable debug mode for Go templates (default $WERF_DEBUG_TEMPLATES or false)
- `--dev`

Enable development mode (default $WERF_DEV).
The mode allows working with project files without doing redundant commits during debugging and development

- `--dev-branch`

  Set dev git branch name (default $WERF_DEV_BRANCH or "_werf-dev")
- `--dev-ignore`

  Add rules to ignore tracked and untracked changes in development mode (can specify multiple).
  Also, can be specified with $WERF_DEV_IGNORE_* (e.g. $WERF_DEV_IGNORE_TESTS=*_test.go, $WERF_DEV_IGNORE_DOCS=path/to/docs)
- `--dir`

  Use specified project directory where project’s werf.yaml and other configuration files should reside (default $WERF_DIR or current working directory)
- `--disable-auto-host-cleanup`

  Disable auto host cleanup procedure in main werf commands like werf-build, werf-converge and other (default disabled or WERF_DISABLE_AUTO_HOST_CLEANUP)
- `--docker-compose-bin-path`

  DEPRECATED: "docker compose" command always used now, this option is ignored. Define docker-compose bin path (default $WERF_DOCKER_COMPOSE_BIN_PATH)
- `--docker-compose-command-options`

  Define docker-compose command options (default $WERF_DOCKER_COMPOSE_COMMAND_OPTIONS)
- `--docker-compose-options`

  Define docker-compose options (default $WERF_DOCKER_COMPOSE_OPTIONS)
- `--docker-config`

  Specify docker config directory path. Default $WERF_DOCKER_CONFIG or $DOCKER_CONFIG or ~/.docker (in the order of priority)
  Command needs granted permissions to read and pull images from the specified repo
- `--docker-server-storage-path`

  Use specified path to the local backend (Docker or Buildah) storage to check backend storage volume usage while performing garbage collection of local backend images (detect local backend storage path by default or use $WERF_DOCKER_SERVER_STORAGE_PATH)
- `--dry-run`

  Indicate what the command would do without actually doing that (default $WERF_DRY_RUN)
- `--elf-pgp-private-key-base64`

  Base64-encoded PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_BASE64)
- `--elf-pgp-private-key-fingerprint`

  PGP private key fingerprint (default $WERF_ELF_PGP_PRIVATE_KEY_FINGERPRINT)
- `--elf-pgp-private-key-passphrase`

  Passphrase for the PGP private key (default $WERF_ELF_PGP_PRIVATE_KEY_PASSPHRASE)
- `--env`

  Use specified environment (default $WERF_ENV)
- `--final-images-only`

  Process final images only ($WERF_FINAL_IMAGES_ONLY or false by default)
- `--final-repo`

  Container registry storage address (default $WERF_FINAL_REPO)
- `--final-repo-container-registry`

  Choose final-repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_FINAL_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--final-repo-docker-hub-password`

  final-repo Docker Hub password (default $WERF_FINAL_REPO_DOCKER_HUB_PASSWORD)
- `--final-repo-docker-hub-token`

  final-repo Docker Hub token (default $WERF_FINAL_REPO_DOCKER_HUB_TOKEN)
- `--final-repo-docker-hub-username`

  final-repo Docker Hub username (default $WERF_FINAL_REPO_DOCKER_HUB_USERNAME)
- `--final-repo-github-token`

  final-repo GitHub token (default $WERF_FINAL_REPO_GITHUB_TOKEN)

- `--final-repo-harbor-password`

  final-repo Harbor password (default $WERF_FINAL_REPO_HARBOR_PASSWORD)
- `--final-repo-harbor-username`

  final-repo Harbor username (default $WERF_FINAL_REPO_HARBOR_USERNAME)
- `--final-repo-quay-token`

  final-repo quay.io token (default $WERF_FINAL_REPO_QUAY_TOKEN)
- `--git-work-tree`

  Use specified git work tree dir (default $WERF_WORK_TREE or lookup for directory that contains .git in the current or parent directories)
- `--giterminism-config`

  Custom path to the giterminism configuration file relative to working directory (default $WERF_GITERMINISM_CONFIG or werf-giterminism.yaml in working directory)
- `--home-dir`

  Use specified dir to store werf cache files and dirs (default $WERF_HOME or ~/.werf)
- `--insecure-helm-dependencies`

  No-op
- `--insecure-registry`

  Use plain HTTP requests when accessing a registry (default $WERF_INSECURE_REGISTRY)
- `--kube-config`

  Kubernetes config file path (default $WERF_KUBE_CONFIG, or $WERF_KUBECONFIG, or $KUBECONFIG)
- `--kube-config-base64`

  Kubernetes config data as base64 string (default $WERF_KUBE_CONFIG_BASE64 or $WERF_KUBECONFIG_BASE64 or $KUBECONFIG_BASE64)
- `--kube-context`

  Kubernetes config context (default $WERF_KUBE_CONTEXT)
- `--log-color-mode`

  Set log color mode.
  Supported on, off and auto (based on the stdout’s file descriptor referring to a terminal) modes.
  Default $WERF_LOG_COLOR_MODE or auto mode.
- `--log-debug`

  Enable debug (default $WERF_LOG_DEBUG).
- `--log-pretty`

  Enable emojis, auto line wrapping and log process border (default $WERF_LOG_PRETTY or true).
- `--log-project-dir`

  Print current project directory path (default $WERF_LOG_PROJECT_DIR)
- `--log-quiet`

  Disable explanatory output (default $WERF_LOG_QUIET).
- `--log-terminal-width`

  Set log terminal width.
  Defaults to:
  * $WERF_LOG_TERMINAL_WIDTH
  * interactive terminal width or 140
- `--log-time`

  Add time to log entries for precise event time tracking (default $WERF_LOG_TIME or false).
- `--log-time-format`

  Specify custom log time format (default $WERF_LOG_TIME_FORMAT or RFC3339 format).
- `--log-verbose`

  Enable verbose output (default $WERF_LOG_VERBOSE).
- `--loose-giterminism`

  Loose werf giterminism mode restrictions
- `--platform`

  Enable platform emulation when building images with werf, format: OS/ARCH[/VARIANT] ($WERF_PLATFORM or $DOCKER_DEFAULT_PLATFORM by default)
- `--project-name`, `-N`

  Set a specific project name (default $WERF_PROJECT_NAME)
- `--quiet`

  Disable explanatory output (default $WERF_QUIET).
- `--repo`

Container registry storage address (default $WERF_REPO)

- `--repo-container-registry`

  Choose repo container registry implementation.
  The following container registries are supported: ecr, acr, default, dockerhub, gcr, github, gitlab, harbor, quay.
  Default $WERF_REPO_CONTAINER_REGISTRY or auto mode (detect container registry by repo address).
- `--repo-docker-hub-password`

  repo Docker Hub password (default $WERF_REPO_DOCKER_HUB_PASSWORD)
- `--repo-docker-hub-token`

  repo Docker Hub token (default $WERF_REPO_DOCKER_HUB_TOKEN)
- `--repo-docker-hub-username`

  repo Docker Hub username (default $WERF_REPO_DOCKER_HUB_USERNAME)
